The sintering process consists of preparing a finely ground silicon carbide powder mixed with organic binders and additives and then compacting the powder by isostatically pressing it at high pressure. The resulting compact is then machined to the desired shape and weight and the blank heated to cause agglomeration of the particles. The resulting material is known as reaction-bonded silicon carbide; it can be polished to around 30 angstroms and can be ion figured. If smoother surfaces are required, then a layer of CVD or PVD silicon carbide can be added. A 1.35 m diameter mirror has been fabricated as a demonstration for the European Space Agency's Herschel Space Observatory. The mirror was fabricated in nine segments that were then brazed together to form a unified 26 kg m^{-2} blank. This mirror was not designed to test the limits of lightweight and, consequently, there is no reason to believe that this process could not achieve an areal density comparable to the 7.8 kg m^{-2} of Cesic™ described in the following paragraph. The size of mirrors produced using this technique is currently limited to around 4 m due to the availability of the furnaces required for segment brazing.

The liquid infiltration process is used to create a biphase carbon, silicon carbide material known as Cesic™. This material is manufactured by creating a block of chopped carbon fibers embedded in a phenolic resin. The block is machined to the desired shape and then put into a furnace where the temperature is elevated until the resin is turned to carbon. The temperature is further elevated and liquid silicon infiltrated to produce silicon carbide. Bare Cesic™ can be polished to approximately 100 angstroms. In a subsequent step, a silicon carbide slurry can be applied to the blank that can be polished to around 30 angstroms. It is also possible to add a CVD or PVD silicon carbide layer to the blank that can be polished to obtain angstrom-level surfaces. A 1.04 m diameter Cesic™ mirror has been constructed for the NASA program, Solar Lite. The mirror weighs approximately 60 kg for an areal density of 56 kg m^{-2}. Again, this mirror was not designed to test the limits of lightweighting, but in a separate demonstration, an areal density of 7.8 kg m^{-2} was achieved. The size of mirrors produced using this technique is also currently limited to around 4 m due to the availability of existing furnaces required for infiltration.

The CVD process produces a SiC material that is highly polishable, yielding surface finishes on the order of angstroms. It has been used quite successfully as a coating layer, and has the potential to provide a means of replicating very lightweight mirrors by depositing a thin layer of SiC onto a mandrel. In one approach, the mandrel has the appropriate shape, but not the surface finish. In this case, once the SiC has been deposited, the mandrel is burned away and a SiC mirror blank is left. The blank is then ground and polished to produce the desired figure and finish. If the blank is too thin, this can present a problem in achieving a high-performance mirror. A second approach involves the deposition of SiC onto a figured and polished mandrel. In principle, both the figure and surface finish can be replicated. Success in this approach, however, has been somewhat limited, and although 20-angstrom surface finishes have been

replicated, they have not been repeatable. A 1 m diameter blank was manufactured using the first approach, but it too has not been repeated and the lack of success appears to be due to high stress developed in the deposition process. The residual stress in the blank causes large-scale deformation and frequently fracture.

Beryllium

The extremely high stiffness of beryllium makes it a highly desirable candidate for lightweight mirrors. Unfortunately, it is a highly toxic material and there are only a very few companies involved in the manufacture of beryllium mirrors and even fewer that produce the raw material. Blanks are manufactured by isostatically compressing beryllium powder at high temperature and pressure. The blanks are then machined and subsequently ground and polished. Early beryllium mirrors often exhibited interesting, mysterious changes in figure after seemingly benign handling events. Unpredictable changes in figure also occurred as they were cycled between ambient and cryogenic temperatures. These problems appear to have been resolved with the production of spherical powder. The older powder consisted of irregularly shaped particles and when the powder was compressed, small, irregularly shaped voids were created throughout the material. It is hypothesized that these voids changed in size and shape as the blank was stressed, thereby causing unpredictable dimensional changes in the blank. The spherical powder permits uniform, high-density packing yielding homogeneous blanks that do not appear to exhibit unpredictable dimensional changes.

The lightest-weight beryllium mirror to date ($11.8\ \mathrm{kg\,m^{-2}}$) was made for NASA's James Webb Space Telescope technology program. This technology was selected for the flight mirror. The weight reduction was achieved by machining the blank to create an open back honeycomb structure with an integral face-sheet. The ability to fabricate large beryllium mirrors is limited by the availability of facilities capable of isostatically pressing the material at the requisite pressures and temperatures. Currently, blank sizes are limited by available isostatic presses to around 1.2 m in width and 1.6 m in length. The expense of construction of larger facilities combined with limited need make it highly unlikely that any larger mirrors will be manufactured in the near term. A brazing process, however, has been demonstrated for joining segments to form a large blank. This process could, in principle, permit the fabrication of mirrors several meters in diameter. Bare beryllium can be polished to around 30 angstroms surface finishes. If smoother surfaces are required, beryllium can be vacuum deposited on the blank. Nickel may also be deposited on the blank; this has the added benefit that it can be polished without the special facilities required for the hazardous beryllium polishing operations. The drawback of using nickel is that of the bimetallic effect if the mirror is to be operated over a wide temperature range. The Vavilov Institute in Russia has developed an alternative approach to obtaining good surfaces by creating a glass that matches the coefficient of thermal expansion (CTE) of beryllium over a 50° temperature range. The glass is then fused to the beryllium blank. There have been numerous attempts over the years to produce replicated mirrors using a CVD process to deposit beryllium on a mold. So far these attempts have been unsuccessful, the process producing a material structure that no longer has high stiffness.

Silicon

Silicon as a mirror material has the advantage of being a very homogeneous material that can be polished to very smooth surfaces (angstrom level) very rapidly. A lightweight mirror has been fabricated using a silicon face-sheet brazed to a central core of silicon foam. This mirror 'sandwich' has demonstrated an areal density of $<15\ \mathrm{kg\,m^{-2}}$. Technology has been developed to braze segments together in a manner that has been shown to have no adverse effects on either polishability or cryogenic performance (i.e., no distortion across the braze). Consequently, it should be possible to manufacture lightweight silicon mirrors of 1 m diameter or larger.

Composites

There have been many attempts to manufacture mirrors from composite materials, beginning initially with graphite/epoxy and more recently with graphite/cyanate-ester. These mirror are produced by laying up graphite sheets impregnated with epoxy, or cyanate-ester on a near net shape mold and then curing the material at elevated temperatures. The optical surface is typically created by coating another mold (this time with the desired optical surface) with a passivation layer and then with epoxy and placing the near net shape composite substrate on the epoxy. When the epoxy cures, the completed mirror is separated from the mold and the epoxy surface ion milled to remove residual errors such as fiber print-through. These mirrors can be very lightweight ($\sim 5\ \mathrm{kg\,m^{-2}}$), but typically have problems with large-scale distortion due to inhomogeneities due to

the lay-up process. The epoxy surface replication can also be a problem if the mirror is subjected to temperature extremes. A 3.5 m diameter composite mirror was made as a demonstration for the FIRST program. It has suitable performance for submillimeter and infrared wavelengths, but not for shorter wavelengths. At this time, the accuracy required for large (>1 m) visible imaging systems has not yet been achieved.

Gossamer Mirrors

The term 'gossamer' refers to that category of mirrors that in and of themselves have no structural rigidity beyond spatial scales of fractions of millimeters. Several materials are currently being used for these types of materials including Kapton™ and various other polyimide films. The initial shape of the membrane is formed by a variety of techniques including vacuum forming, pressure forming, spin casting, hot forming, and others. Early mirrors were manufactured by joining together triangular-shaped segments (gores) to form the desired shape. When deployed, these mirrors require some means of applying pressure to achieve the desired shape. Some methods have involved applying force at the edge to put the mirror in tension; some involve using a clear membrane as a face-sheet and then pressurizing the combination to create a 'lens' with a reflecting inner surface. Most recently, techniques have been demonstrated involving various forms of electrostatic deflection to achieve the desired shape after deployment. At present the primary applications are in the area of solar collection, power beaming, and thermal propulsion. The mirrors are approaching the quality required for imaging telescopes, particularly for small sizes. Techniques for correcting these mirrors with 'downstream' active optics have reached the point where it is not unrealistic to imagine that membrane optics could soon reach the accuracy required for imaging. There have been two space-based demonstrations, one by the Russians – a 20 m reflector – and the other by the USA – a 14 m inflatable antenna (Figure 4).

Grazing Incidence Mirrors

Broadband X-ray telescopes make use of the reflection property of materials at angles of grazing incidence. The most common design is based on the X-ray microscope objective designs of Wolter in the early part of the twentieth century. These mirrors are hyperboloids and paraboloids of revolution. This configuration provides a structural rigidity not present in normal incidence mirrors; consequently, X-ray mirrors can be made much lighter. The largest mirror of the Chandra X-ray Observatory is made from Zerodur™ (Figure 5). It is a 1.2 m diameter, 0.9 m long cylindrical mirror with a wall thickness of only 24 mm. Such a thickness in a normal incidence mirror of this size could be easily deformed.

Lightweight approaches in grazing incidence optics are almost all concentrated in various forms of replication. Recent developments in electroformed nickel alloy mirror technology have resulted in a 0.5 m diameter 0.6 m long mirror that weighs only 1.2 kg (Figure 6). A similar-sized mirror in the Chandra telescope weighs over 100 kg. Extremely lightweight cylindrical mirrors have been made from graphite/epoxy and from CVD SiC. Various investigations are underway in producing segments of cylinders that are then mounted to form a complete

cylindrical mirror. These techniques involve a variety of materials including aluminum foil, and beryllium plates. In segment replication, the mandrel is passivated and then coated with the desired reflecting material of the final optic (the passivation process prevents the coating from adhering too strongly to the mandrel.) After the mandrel has been coated with the reflecting material, an epoxy coating is applied and a preformed shell segment is placed on the epoxy. After the epoxy cures, the segment can be removed from the mandrel along with the desired reflective surface (typically gold). In this case, the preformed shell does not have to have as precise a figure, or surface as the mandrel, since the epoxy will accommodate minor differences.

Measurement of Optical Properties of Solids

Introduction

The interaction of light with solids takes place through different mechanisms, depending on the type of material and the range of wavelength investigated. Insulators or dielectrics are typically transparent to visible light while most semiconductors are opaque to visible light yet transparent to infrared radiations; in contrast metallic solids appear shiny because they reflect all wavelength up to the ultraviolet region. The optical properties of a solid depends on its chemical composition and its structural properties and vary for every material, though, one parameter, the complex refractive index **n**, is sufficient to characterize entirely the optical properties of a specific material.

In this article we will briefly review the physics underlining the nature of the refractive index **n**, in order to understand its relationship to the observable quantities such as absorption, reflection, and transmission routinely measured in optics experiments. A description of the experimental techniques, as well as a physical interpretation of the data, will also be presented.

Origin of Light Interaction with Matter

Light is described as a transverse electromagnetic wave consisting of an electric and magnetic field oscillating perpendicular to the direction of propagation at optical frequencies within $10^{13} \rightarrow 10^{17}$ Hz. This range of frequencies comprises the ultraviolet, visible, and infrared domain. On the other hand, solid mediums are composed of charged particles, negative electrons, and positive ions producing electric dipoles, which can be polarized under the action of an electric field. Hence, when electromagnetic radiation impinges upon a material it interacts by polarizing the molecular units, producing oscillating dipole moments. This interaction results in several observable optical phenomena such as reflection, transmission, absorption, or scattering, which will be described in more detail in a following section. The classical model of light propagation assumes that the oscillating electric field can interact with several different types of dipole oscillators within the material. Different dipoles are usually accessed by light wave from different frequency range depending on their mass.

Electronic Oscillators

Lorentz originally proposed that the electrons bound to the nucleus of an atom behave as oscillators. In this representation, electrons behave as if they were held by springs and subjected to a linear restoring force, therefore oscillating up and down (Figure 1a). This representation of an atom might seem to contradict the conventional picture of electrons orbiting around the nucleus; however, it is valid as far as light–matter interactions are concerned. The resonant frequency of such an oscillator is proportional to the inverse of its reduced mass μ defined as

$$\frac{1}{\mu} = \frac{1}{m_e} + \frac{1}{m_N} \qquad [1]$$

where m_N and m_e are the mass of the nucleus and electrons, respectively. The resonant frequency ω_0 is then related to μ according to

$$\omega_0 \propto \sqrt{\frac{1}{\mu}} \qquad [2]$$

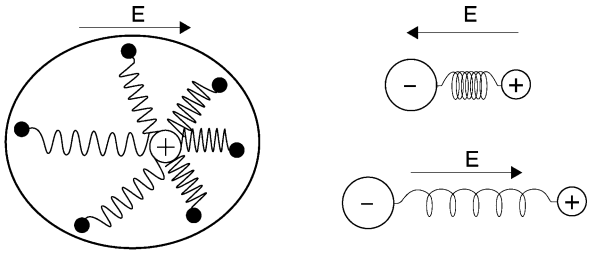

Figure 1 (a) Classical oscillator model of a polyelectronic atom. The electrons depicted as black dots are bound to the positive nucleus by springs, which represent the electrostatic restoring forces between the charged particles. The electronic oscillators are distorted under the effect of an electric field. (b) Classical model of a diatomic vibrational oscillator. The chemical bond is represented as a spring and the charged ions vibrate around their equilibrium position under the effect of an oscillating electric field.

Considering that $m_N \ll m_e$ we can assume that $\mu = m_e$ and show that the smaller mass of the electron determines the resonant frequency of the oscillator. Hence, resonant electronic oscillations are accessed at higher frequencies in the ultraviolet and visible region of the spectrum. In solids, the quantum theory shows that these resonances correspond to excitation of electrons across the gap between a full valence band and an empty conduction band.

Vibrational Oscillators

The second type of dipoles contained in the medium are based on pairs of charged atoms vibrating around their equilibrium position in the solid. Every atom has a different electronegativity, hence the electronic density on atomic pairs is distorted and result in a charge imbalance, which can couple to the electric field of light. This generates oscillating dipoles, which involves the motion of atomic nucleus (Figures 1b). The nuclear mass being several orders of magnitude larger than the electronic mass, we can show by analogy with eqns [1] and [2] that the resonant vibration will occur at lower frequencies in the infrared region. In solids, the quantum theory shows that the lattice atoms vibrate cooperatively and generate quantized lattice waves called phonons.

Free Electron Oscillators

In contrast with the bound electrons from the electronic oscillator model, free electrons can move without being subjected to a restoring force. These correspond to the conduction electrons present in metals and to a smaller extent in doped semiconductors. The free electron oscillator model is therefore

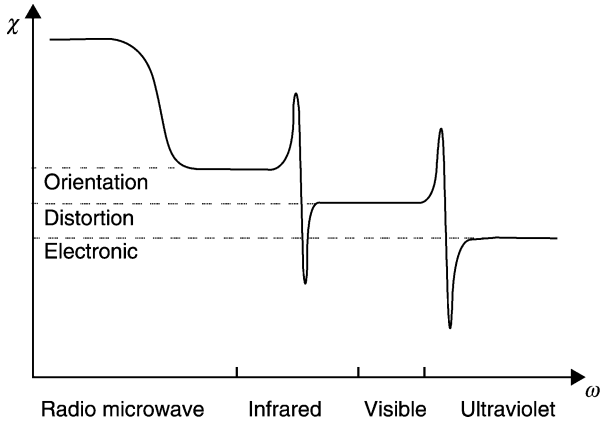

Figure 2 Contributions to the polarizability of a medium as a function of light frequency. At optical frequencies, the molecules cannot re-orient fast enough to follow the reversing electric field and the contribution of dipole orientation is lost.

principally used to describe the optical properties of metals such as reflectivity. The free electrons are well described as conventional oscillator with a natural resonant frequency $\omega_0 = 0$.

The relationship between the applied electric field E and the resulting polarization of the medium P is expressed through the dielectric susceptibility χ as

$$P = \varepsilon_0 \chi E \qquad [3]$$

where ε_0 is the permittivity of vacuum. We can generally recognize three contributions to the dielectric susceptibility or the polarizability of an optical material (Figure 2). Applied fields in the radio or microwave region oscillate slowly enough that polar molecular units can reorient and align in the direction of the field. The characteristic time for orientational motion is fairly long and this contribution is quickly lost when the molecules cannot follow the field oscillating at higher frequency. When the field reaches optical frequency, the two remaining contributions are the vibrational and electronic dipoles mentioned above. The vibrational dipoles involve a distortion of the chemical bond and are the slowest process occurring only in the infrared region. This contribution is lost at visible frequencies and leaves only the fast electronic polarization processes.

If we treat it rigorously, the polarization P is actually expressed as a function of higher order terms according to

$$P = \varepsilon_0\left(\chi E + \chi^{(2)}EE + \chi^{(3)}EEE + \ldots\right) \qquad [4]$$

This gives rise to nonlinear effects such as self-focusing and second or third harmonic generation. However, the higher order susceptibilities $\chi^{(n)}$ are very small and these effects are only significant for very high intensity light source such as lasers. In the following text we will only consider linear optical processes.

The Dipole Oscillator Model (Lorentz Oscillator)

In the Lorentz model, the bound electrons behave as harmonic oscillators and are constrained to vibrate at their natural resonant frequency ω_0. These oscillators are also submitted to a damping force corresponding to a resistance to the motion due to collisional processes. The equation of motion is then

$$m\left(\frac{\mathrm{d}^2x}{\mathrm{d}t^2} + \gamma\frac{\mathrm{d}x}{\mathrm{d}t} + \omega_0^2 x\right) = qE \qquad [5]$$

where x is the displacement along E, γ is the damping factor, m is the mass of the electron and q its charge. The passage of an electromagnetic wave through a medium exerts an oscillating force on the electrons causing them to vibrate up and down. In other words these electronic dipoles are submitted to a forced oscillation induced by an electric field varying periodically with time. The electric field felt by the atomic dipoles is written as

$$E = E_0 e^{i\omega t} \qquad [6]$$

where ω is the frequency of the light.

The electric field of the light wave then drives the dipole oscillations at its own frequency ω and the dipoles displacement oscillates according to

$$x = x_0 e^{i\omega t} \qquad [7]$$

Solving eqn [5] for x in terms of E gives the expression for the displacement of the electrons

$$x = \frac{q/m}{\omega_0^2 - \omega^2 + i\gamma\omega}E \qquad [8]$$

The atomic dipole moment p induced by the electrons displacement is therefore

$$p = qx = \frac{q^2/m}{\omega_0^2 - \omega^2 + i\gamma\omega}E \qquad [9]$$

And for a medium with N atoms per unit volume the total polarization P is

$$P = N\frac{q^2/m}{\omega_0^2 - \omega^2 + i\gamma\omega}E \qquad [10]$$

Our result in eqn [10] only contains one natural frequency ω_0 and therefore only accounts for one

single type of oscillator in the medium. However, normal optical mediums are composed of different kinds of atoms, each with several characteristic resonant frequencies ω_j. In our model, we can simply treat these multiple resonances by considering that each oscillator acts separately and add the contributions of all oscillators.

$$P = \left(\frac{q^2}{m} \sum_j \frac{N_j}{\omega_j^2 - \omega^2 + i\gamma_j\omega} \right) E \qquad [11]$$

Comparing eqns [3] and [11] then gives an expression for the polarizability χ of the medium

$$\chi = \frac{q^2}{\varepsilon_0 m} \sum_j \frac{N_j}{\omega_j^2 - \omega^2 + i\gamma_j\omega} \qquad [12]$$

Additionally, the polarization P is associated with Maxwell's displacement vector, D, through the relationship

$$D = \varepsilon_0 E + P \quad \text{and} \quad D = \varepsilon E \qquad [13]$$

where ε is the permittivity of the medium. The permittivity ε is normally expressed relative to the permittivity of vacuum ε_0 in terms of the dimensionless quantity $\varepsilon_r = \varepsilon/\varepsilon_0$. Where ε_r is the familiar dielectric constant of a material, which is related to the refracted index n as $n = \sqrt{\varepsilon_r}$.

Combining eqns [3] and [13] we obtain an important relationship linking χ to ε_r, and in turn χ to n.

$$\varepsilon_r = 1 + \chi \quad \text{or} \quad n^2 = 1 + \chi \qquad [14]$$

Finally, combining eqns [12] and [14] we obtain the expression for n in terms of the oscillator model.

$$n^2 = 1 + \frac{q^2}{\varepsilon_0 m} \sum_j \frac{N_j}{\omega_j^2 - \omega^2 + i\gamma_j\omega} \qquad [15]$$

The Refractive Index

Two important points should be made concerning the result of eqn [15]. The refractive index is a wavelength-dependent quantity and is a complex quantity. The complex refractive index $\mathbf{n}$ is indeed usually expressed as

$$\mathbf{n} = n + i\kappa \qquad [16]$$

where n is the real refractive index also defined as the ratio of the wave velocity in vacuum to the velocity in the medium $n = c/v$. And κ is the extinction coefficient, which is directly related to the absorption coefficient α as we shall see in the next section.

As we mentioned in the introductory section, the complex refractive index $\mathbf{n}$ is sufficient to characterize the optical properties of the solid. The real part of the index describes the change in velocity or wavelength of a wave propagating from a vacuum into a medium while the imaginary part is a measure of the dissipation rate of the wave in the medium.

By inspection of eqn [15] we can predict the form of the variation of n with wavelength. At frequencies ω below the resonant frequency ω_j, the terms ω^2 and $i\gamma_j\omega$ are much smaller than ω_j^2 and to a first approximation n is constant. When ω reaches a resonant frequency ω_j, the term $(\omega_j^2 - \omega^2)$ goes to zero and since the term $i\gamma_j\omega$ is very small, the value of n increases very sharply and exhibits a resonance line as depicted in Figure 3.

On closer inspection of eqn [15] however, we can see that n is not exactly constant in between resonance lines. As ω rises, the denominator slightly decreases and therefore n rises slowly with frequency. The refractive index is then slightly larger for wave of higher frequency. This is why a glass prism bends blue light more strongly than red light. This phenomenon is called dispersion as waves of different frequencies are 'dispersed' by the prism.

Another important point raised by eqn [15] is that because $(\omega_j^2 - \omega^2)$ goes to zero at a resonant frequency, the damping term $i\gamma_j\omega$ dominates and n becomes almost entirely imaginary. $\mathbf{n}$ is then mostly governed by the extinction coefficient κ. The damping associated with the coefficient γ_j corresponds to a friction force causing a loss of energy, which becomes the dominant effect during resonance. The resonance region is then associated with strong attenuation or

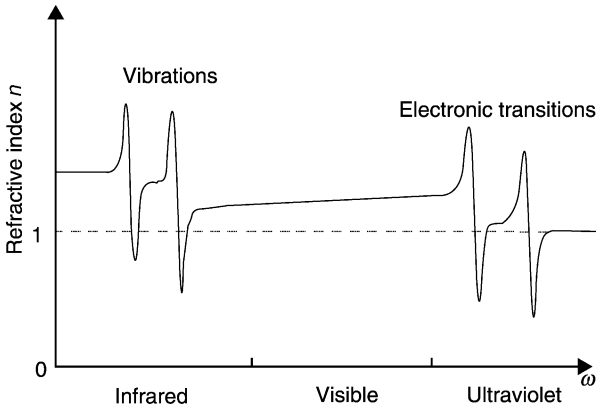

Figure 3 Variation of the refractive index of a hypothetical dielectric solid in the optical frequency range. At high frequency, ω is larger than all resonant frequencies and the refractive index n reaches unity.

absorption of the wave. In contrast, between resonant frequencies, the refractive index is almost entirely real as the imaginary part $i\gamma_j\omega$ is negligible in comparison with $(\omega_j^2 - \omega^2)$. Absorption is then very small and that region corresponds to the transparency domain of the material. In fact, we can assume that $\mathbf{n} = n$ in the transparent region, that is why tables of optical constants of transparent optical materials only list the real part of the refractive index n. However, at resonant frequencies on either side of the transparency domain, absorption becomes significant and the imaginary part of the refractive index must be taken into account so that $\mathbf{n} = n + i\kappa$.

The refractive index $\mathbf{n}$ being a complex quantity it ensues that ε_r must also be complex, since $n = \sqrt{\varepsilon_r}$. Hence we also define the complex dielectric constant as

$$\varepsilon_r = \varepsilon_1 + i\varepsilon_2 \qquad [17]$$

Both parameters describe equivalently the optical properties of a solid so that $\mathbf{n}$ or ε_r are called the optical constants of the material. Note that it is an unfortunate misnomer since they vary distinctly with wavelength (**Figure 3**).

Using equation [17] and $n = \sqrt{\varepsilon_r}$, we can establish the relationships between the real and imaginary parts of $\mathbf{n}$ and ε_r.

$$\varepsilon_1 = n^2 - \kappa^2 \qquad [18]$$

$$\varepsilon_2 = 2n\kappa \qquad [19]$$

We can see that $\mathbf{n}$ and ε_r are not independent variables but that the real and imaginary part of ε_r can be calculated, knowing the real and imaginary part of $\mathbf{n}$ and vice versa.

Moreover, it can be shown that the real and imaginary parts of each individual parameter are not independent either but can be computed from one another with use of the following Kramers–Kronig relations.

$$\varepsilon_1(\omega) = 1 + \frac{2}{\pi}\int_0^\infty \frac{\omega'\varepsilon_2(\omega')}{\omega' 2 + \omega^2}\mathrm{d}\omega' \qquad [20]$$

$$\varepsilon_2(\omega) = -\frac{2\omega}{\pi}\int_0^\infty \frac{\varepsilon_1(\omega')}{\omega' 2 + \omega^2}\mathrm{d}\omega' \qquad [21]$$

In these equations, only the principal value of the integral is calculated so that ε_1 can be computed if ε_2 is known over all frequencies and vice versa. The same equation connect n and κ together.

This analysis shows that it is only necessary to know one real or one imaginary part over a wide frequency range to determine all others. The interaction of light with matter is in fact characterized by a single independent real quantity.

Absorption

All electromagnetic phenomena are governed by Maxwell's equations. The form of an electromagnetic wave propagating through a medium is obtained by solving Maxwell's equation. For a wave propagating along z through a homogeneous, optically isotropic medium the form of the oscillating electric field is given by:

$$E = E_0 e^{i(kz-\omega t)} \qquad [22]$$

where k is the wave vector and ω the angular frequency of the light. For a wave traveling into a transparent medium of refractive index n, the relationship between k and ω is

$$k = \frac{n\omega}{c} \qquad [23]$$

However, for an ordinary optical material there are regions of absorption and the refractive index is therefore complex. We should then rewrite eqn [23] as

$$k = (n + i\kappa)\frac{\omega}{c} \qquad [24]$$

By substituting this value of k in eqn [22] we obtain an expression with two exponential terms

$$E = E_0 e^{-\frac{\omega\kappa z}{c}} e^{i\left(\frac{\omega n z}{c} - \omega t\right)} \qquad [25]$$

The term $e^{i\left(\frac{\omega n z}{c} - \omega t\right)}$ represents a wave traveling at a speed $v = c/n$, while the term $E_0 e^{-(\omega\kappa z/c)}$ represent the amplitude of this wave which decays exponentially with distance z. The intensity I of the wave is proportional to the square of the amplitude so that

$$I \propto e^{-\frac{2\omega\kappa z}{c}} \quad \text{or} \quad I \propto e^{-\alpha z} \qquad [26]$$

where α is the familiar absorption coefficient routinely measured by absorption spectroscopy. Hence we obtain an important relationship relating the observable quantity α to the imaginary part of the refractive index κ according to

$$\alpha = \frac{2\kappa\omega}{c} \qquad [27]$$

Local Field Correction

It should be pointed out that the derivation of our refractive index expression eqn [15] assumes that only the electric field of the light affects the polarization of the dipole oscillators. However, this

assumption is not correct in dense materials because of the contribution from the electric field of neighboring atomic dipoles. The field generated by each dipole will affect all other dipoles in the vicinity. It is possible to approximate this contribution by accounting for the effect of dipoles within a local sphere. The result of this approximation is known as the Clausius–Mossotti equation, which is accurate for isotropic medium such as glasses and cubic crystals

$$\frac{n^2-1}{n^2+2}=\frac{\chi}{3} \qquad [28]$$

Measurable Optical Parameters

Four things can happen to a beam of light propagating through a thick slab of optical material (Figure 4). Some of the light can be reflected at the surface of the solid, some can be absorbed by the sample, some can be scattered in different directions, and some of the light can be transmitted through the sample. The effect on the light beam, resulting from these phenomena, can be quantified by a number of optical coefficients, which characterize the macroscopic properties of the material.

Reflection of light at the surface of a solid is described by the reflectance R defined as the ratio of the reflected intensity I to the incident intensity I_0. For a beam falling perpendicularly on a flat surface, the reflection is called specular and is governed by the complex refractive index according to the Fresnel equation

$$R=\frac{I}{I_0}=\frac{(n-1)^2+\kappa^2}{(n+1)^2+\kappa^2} \qquad [29]$$

This provides us with a second important formula relating a measurable quantity (R) to the optical constant of the material. For measurements performed within the transparency region of a solid, the value of κ is much less than n and eqn [29] reduces to the more familiar form

$$R=\frac{(n-1)^2}{(n+1)^2} \qquad [30]$$

Absorption occurs when the light frequency reaches the natural resonance of some dipole oscillators in the medium. The energy of the electromagnetic wave is partly transferred to the material and generally dissipated in the form of heat. The light intensity is therefore attenuated as it propagates through the material and the attenuation efficiency is quantified by the absorption coefficient α. The intensity decreases exponentially with pathlength z according to Beer's law

$$I(z)=I_0e^{-\alpha z} \qquad [31]$$

where I_0 is the incident intensity. The imaginary part κ of the optical constant can then be directly obtained from measurements of α using eqn [27].

Scattering is the process whereby light is redirected in different directions due to microscopic density fluctuation in the sample produced by defects, impurities, or structural inhomogeneities. The intensity of light propagating in the forward direction is attenuated by the scattering event and it can be quantified in a way equivalent to absorption. The intensity has an exponential dependence on pathlength z analogous to Beer's law

$$I(z)=I_0e^{-Sz} \qquad [32]$$

where S is the scattering coefficient. When the scattering center is smaller than the wavelength of light this phenomenon is called Rayleigh scattering and the scattering coefficient S vary with the inverse fourth power of the wavelength

$$S(\lambda)\propto\frac{1}{\lambda^4} \qquad [33]$$

By measuring light attenuation we cannot tell the difference between absorption and scattering and the total attenuation is $\alpha_{\mathrm{Tot}}=\alpha+S$. However, the scattering contribution is generally much weaker than the absorption and can be neglected so that $\alpha_{\mathrm{Tot}}=\alpha$.

Transmission occurs when the light is neither reflected, absorbed, or scattered. The beam is then transmitted through the sample and the fraction of light exiting the back surface is quantified as the transmittance T. If we disregard scattering in comparison to absorption then conservation of energy

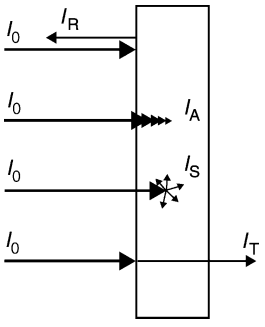

Figure 4 Representation of the four main optical processes happening to a beam as it propagates through a slab of transparent material.

require that

$$R + T + A = 1 \qquad [34]$$

where A is the fraction of light absorbed. The transmittance can then be compiled from R and α for an incident beam I_0 traveling across a sample of thickness l. In this case we must consider the reflection of the light on the front surface as well as on the back surface when it exits the transparent medium. The expression for the transmittance accounting for dual reflection is

$$T = (1 - R)^2 e^{-\alpha l} \qquad [35]$$

It should be noted that a rigorous treatment of eqn [35] should account for multiple reflections between the front and back surface in the interior of the sample. In this case, interference effects complicate the determination of **n** and a modified version of eqn [35] can be computed by summing up the intensities due to the contribution of the multiple reflections.

Transmission and reflection measurement are readily obtained using conventional spectrometers. Two types of spectrometers must be used to cover the entire optical spectral region. FTIR (Fourier Transform Infra Red) spectrometers use a glow bar as the light source, which enable it to cover the infrared and near infrared domain. The UV-VIS (ultraviolet visible) double beam spectrometers use a tungsten and deuterium lamp and cover the spectrum from the ultraviolet down to the near infrared. Using eqns [27], [29] and [35], the reflection and transmission measurements thus obtained are used to calculate the real and imaginary component of the optical constant over the entire optical frequency range.

An example of transmission measurement is shown in Figure 5, for a dielectric and a semiconductor. The two spectra have the same principal features. At short wavelength the edge of the transparency window is due to absorption of energy by the valence electrons. In classical terms this corresponds to the resonance of electronic oscillators, and in quantum mechanical terms to the excitation of electrons from the valence to the conduction band. This edge is due to a sharp increase of κ, which extends over a significant range of frequency corresponding to the domain of opacity or high absorption. The wavelength at the edge determines the minimum energy of the photon necessary to promote an electron across the bandgap E_g. Insulators have a large bandgap and appear transparent to the human eye because visible light is not energetic enough to promote an electron across E_g. In contrast, semiconductors have a smaller bandgap and appear black (opaque) because all the visible light is absorbed to induce electronic transitions. On the low frequency side the transparency window is limited by atomic vibrations in the solid structure. The wavelength of the vibrations increases with the mass of the atomic oscillators. Semiconductor compounds have higher atomic masses and therefore transmit at longer wavelength in the infrared while insulator have lower atomic mass and exhibit their vibrational absorption edge at shorter wavelength.

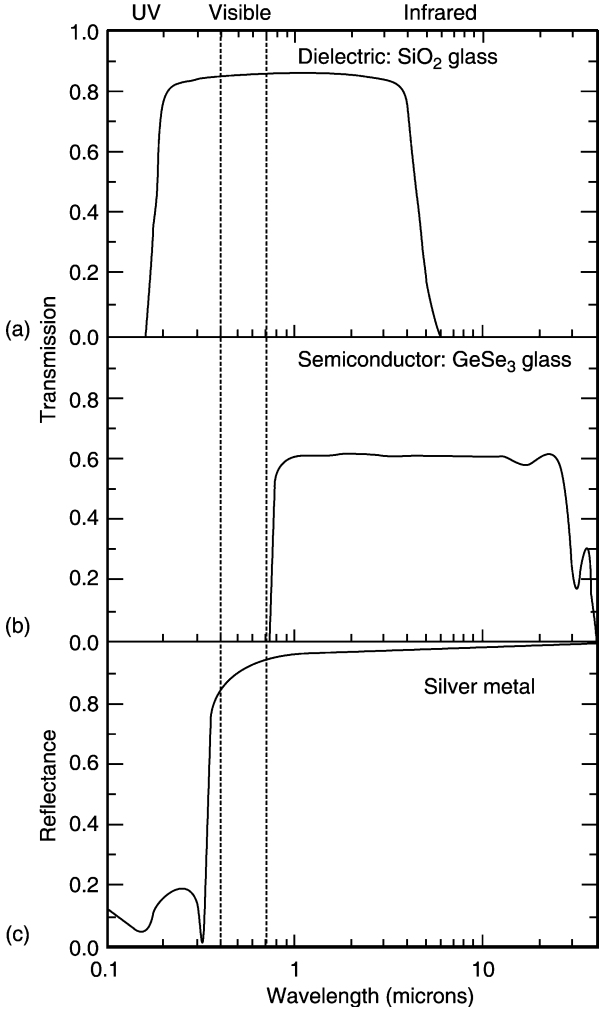

Figure 5 (a) Transmission spectrum of SiO_2 glass, a standard dielectric solid. (b) Transmission spectrum of $GeSe_3$ glass, a semiconductor ($E_g = 1.6$ eV). (c) Reflectance spectrum of silver metal.

In between the two absorption regions, κ is very small and the material is transparent. The refractive index is almost entirely governed by the real part n. Eqn [15] shows that n is proportional to the number N of electronic oscillators. The refractive index will then be higher for heavy atoms with a high electronic

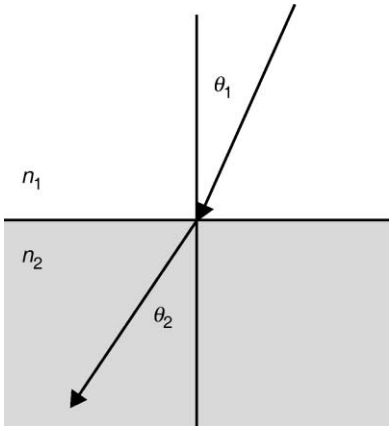

Figure 6 Refraction of a beam propagating across the interface between two mediums of different refractive index. The incident angle and the refraction angle are related to the index of refraction through Snell's Law.

density. Consequently, semiconductors exhibit a maximum transmission of only 60% because of significant surface reflectivity (eqn [35]) resulting from their higher refractive index n (eqn [30]).

Most applications of materials in optics are only concerned with the transparency domain so that the useful optical constant is reduced to the real part n. Hence a number of experimental techniques have been developed to obtain n, often by measuring angles of refraction with the use of Snell's law

$$n_1 \sin\theta_1 = n_2 \sin\theta_2 \qquad [36]$$

where θ_1 is the angle of the beam incident in the medium of index n_1, and θ_2 the angle of the beam refracted at the interface with a medium of index n_2 (Figure 6). The basic principle is to compare the sample with a standard glass of known refractive index and measure the refraction angle at their interface. The sample's index can then be obtained following eqn [36]. Since n varies with wavelength, these techniques are normally performed with monochromatic light and provide n at a single wavelength. Among these methods are: the *Abbe refractometer*, using a glass hemisphere as a standard, the *V-block refractometer*, using a V shaped prism as a standard, and the *prism goniometer* based on the relative deviation between a known glass prism and a prism shaped sample.

Ellipsometry is another technique widely used to measure the index n. This technique is normally used on thin films deposited on substrate, as it allows to simultaneously measure the thickness and the refractive index. However, the method can also be applied to bulk samples. The principle of ellipsometry is based on measuring the change in polarization of a beam reflected off the sample surface as a function of incidence angle. The reflected light is elliptically polarized to an extent depending on n. This technique is especially useful to measure n at frequency range above the absorption edge where the sample is highly absorbing.

Metals

The optical properties of metals are mainly characterized by their very high reflectivity, which causes their shiny appearance. All metals reflect light in the infrared and visible region up to a cutoff frequency in the ultraviolet. This critical frequency is called the plasma frequency ω_p. The physical significance of the plasma frequency can be understood using the Drude–Lorentz model of the free electron oscillator. As mentioned previously, the free electron can be described accurately as dipole oscillators with a resonant frequency $\omega_0 = 0$. If we consider a system with negligible damping, we can introduce $\gamma = 0$ and by assuming all free electrons to be equivalent we can consider only one type of oscillators so that eqn [15] reduces to

$$n^2 = 1 - \frac{\omega_p^2}{\omega^2} \qquad [37]$$

where

$$\omega_p^2 = \frac{Nq^2}{\varepsilon_0 m_e} \qquad [38]$$

Equation [37] means that in the low frequency domain $\omega < \omega_p$, the refractive index n must be imaginary ($n^2 < 0$) and in the high frequency domain $\omega > \omega_p$, n is a real positive number. The low frequency region is therefore dominated by the extinction coefficient κ and the reflectance R, given by eqn [29], is essentially unity. In the high frequency limit, R decreases and n is real. These features are shown in Figure 5c. Metals are opaque and highly reflective below the plasma frequency, while they become transparent in the ultraviolet.

List of Units and Nomenclature

A	absorbance
c	light velocity in vacuum
D	electric displacement
E	electric field
I	intensity of light (power per unit surface)
k	wave vector
m_e	mass of electron
m_N	mass of nucleus
$\mathbf{n}$	complex refractive index
n	real refractive index

p	dipole moment
P	polarization
q	charge of electron
R	reflectance
S	scattering coefficient
T	transmittance
v	phase velocity
α	absorption coefficient
ε_0	permittivity of vacuum
ε_r	relative dielectric constant
κ	extinction coefficient
λ	wavelength
μ	reduced mass
χ	dielectric susceptibility
ω	angular frequency
ω_0	resonant frequency
ω_p	plasma frequency

Introduction

While advances continue in this field, some optical glasses have histories which can be traced to the seventeenth century. These glasses are produced by direct melting of raw materials of relatively high purity. Modern, or nontraditional, optical glasses are more commonly used to transmit light outside the visible region and are often made by nontraditional methods, including many variations on chemical vapor deposition, reactive melt processing, and sol–gel techniques. These glasses are used for ultraviolet and infrared lenses and other optical components, for optical fibers, for glass lasers, and for photonic devices such as optical isolators. Purity requirements and production demands for these glasses are significantly greater than those for traditional optical glasses.

Traditional Optical Glasses

Traditional optical glasses are primarily used as components such as lenses, prisms, or windows for optical systems operating in the visible region. These applications require glasses of high homogeneity, with precisely known refractive indices and dispersions. Glasses, as defined in this article, are nonmetallic, inorganic materials which have no long-range atomic structure and which display a temperature region of time-dependent properties.

Crown and Flint Glasses

Traditional optical glasses are designated as either crown or flint glasses. Crown glasses were originally based on the soda-lime-silica ternary system and were developed for use as window glass. The crown process involved spinning a spherical gob of molten glass to form a flattened disk which was much thicker in the center than at the edges. The edges of these disks were used for window panes, while the 'crown' in the center was often used as a crude lens. Crown glasses have low refractive indices and low to moderate dispersions.

The first flint glasses were potash-lead-silicate glasses prepared using English 'flint' as the source of silica. The presence of lead in these glasses results in

higher refractive indices and dispersions than those of crown glasses.

The designations of crown and flint have since been expanded to include glasses from many other compositional systems. Glasses with lower refractive indices and dispersions are designated as crowns, while those with higher refractive indices and dispersions are designated as flints. Modern crown glasses are based on silicate, phosphate, and borosilicate systems. Additions of fluorine are particularly useful for production of low refractive index, low dispersion glasses, and for adjusting these parameters to meet specific needs. The lowest combinations of refractive index and dispersion are found for glasses based on BeF_2, while the highest combinations of refractive index and dispersion are found in rare earth borate systems. Other common optical glasses contain barium or lanthanum, which can be used to produce either crown or flint glasses, depending on the other components of the glass.

The need for glasses with different combinations of refractive index and dispersion can be traced back to the development of the telescope. Use of lenses made of a single glass made it difficult to obtain sharp images. Newton recognized that this problem was due to divergence of light of different wavelengths while passing through a lens. He felt that this problem was inherent to lenses and could not be eliminated. Others eventually recognized that a compound lens containing a positive crown glass and a negative flint glass would result in cancellation of the divergences and produce a sharper image. While this development did not totally eliminate the colored fringes in telescope images due to the presence of the secondary spectrum, it did lead to major improvements in optical imaging. Binary compound lenses are still fashioned from a combination of crown and flint glasses, with much greater flexibility today due to development of glasses with much more varied combinations of refractive index and dispersion.

Notation for Optical Glasses

Since the refractive index and the dispersion are the two most important characteristics of an optical glass for use as a lens, a notation system has been developed to designate any glass by a six digit number. This notation system requires that the dispersion be expressed by the Abbe number, ν_d, which is defined as

$$\nu_d = (n_d - 1)/(n_F - n_c) \qquad [1]$$

where d, F, and c indicate the value of the refractive index measured at the yellow helium line at 587.6 nm, the blue hydrogen line at 486.1 nm, and the red hydrogen line at 656.3 nm, respectively. Since the Abbe number is a reciprocal dispersion, a large Abbe number indicates a low dispersion, while a small Abbe number indicates a larger dispersion. A glass is then designated by the expression

$$1000(n_d - 1)(10\nu_d) \qquad [2]$$

where each term is rounded to 3 significant digits. A common crown glass known as BK7, for example, which has a n_d of 1.516 800 and ν_d of 64.17 is designated as 517 642. A very high index flint glass, with $n_d = 1.807\,410$ and $\nu_d = 31.61$ would be designated as 807 316. This system can be used for all but the exceptional glasses with $n_d \geq 2.00$. Some tabulations are based on the green mercury line, or e line, at 546.1 nm instead of the yellow helium (d) line. The choice of the d or e line results in a small difference in the reported refractive index and Abbe number for any given glass (Figure 1).

Dispersion Formulae for Optical Glasses

The combination of a refractive index near the middle of the visible region of the spectrum and the Abbe number describe the contribution of an optical glass to the refractive power and chromatic aberration of a lens. This information was sufficient for many early applications of lenses and is still sufficient for the design of optical devices of modest expectations. More sophisticated optical devices require more information for proper design. The simple Abbe number is often insufficient for expressing the dispersion, since it is necessary to provide a

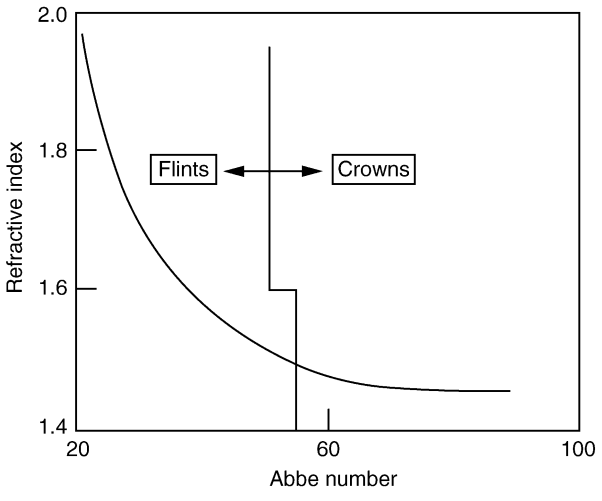

Figure 1 Relation between the refractive index and Abbe number of optical glasses. Commerical optical glasses lie in the regions labeled flint and crown above the curve.

detailed set of values of the refractive index as a function of wavelength across the entire visible region. The refractive index can be listed at a number of wavelengths, or described by an equation covering the entire wavelength range of interest. Although there are a number of expressions for the wavelength dependence of the refractive index, the most commonly used are the Cauchy dispersion formula, or

$$n = a + b\lambda^{-2} + c\lambda^{-4} \quad [3]$$

where a, b, and c are constants derived from a best fit of the data to this expression, and variations of the Sellmeier dispersion formula, which is often simplified to the expression

$$n^2 = A_0 + A_1\lambda^2 + A_2\lambda^{-2} + A_3\lambda^{-4} + A_4\lambda^{-6} + A_5\lambda^{-8} \quad [4]$$

where the six A_n constants are tabulated. The Cauchy dispersion formula is accurate to $\approx 10^{-4}$, while the modified Sellmeier dispersion formula is accurate to $\approx 3 \times 10^{-6}$. The validity of the latter expression can be extended further into the ultraviolet by adding a λ^{-10} term and into the infrared by adding a λ^4 term.

Annealing of Optical Glasses

Much of our knowledge of the behavior of glasses in the glass transformation region is based on studies of the annealing of optical glasses. Glass-forming melts have much higher thermal expansion coefficients than those of solid glasses of the same composition. During cooling of a melt, the density increases rapidly so long as the melt is relatively fluid. As the viscosity increases, the rate of structural rearrangement of the melt slows and eventually becomes fixed at some effective, or fictive, temperature. If the melt is cooled rapidly, the structure of the glass will be representative of a high temperature melt. If the melt is cooled more slowly, the structure will have time to equilibrate at lower temperatures and the glass formed will have the structure of a lower temperature melt and hence will be more dense. Since the refractive index of a solid is related to its density, the refractive index will be less for the glass produced by rapid cooling than for one produced by slower cooling.

There are two ramifications of the cooling effect on refractive index. First, the refractive index will be different for different cooling rates, even though the composition is identical. Statements regarding the refractive index of a glass are only applicable for a known thermal history. Second, but less obvious, the outside of a piece of glass will cool more rapidly than the inside due to the kinetics involved with removing heat from the glass. As a result, a refractive index gradient will exist in the glass, with a lower refractive index at the surface. If the glass is ground and polished to form a lens, the lens will not perform as expected if the shape is based on the assumption that the refractive index is constant through the entire lens. While cooling-induced differences in refractive index between the surface and center of a large block of glass are usually of the order of 0.000 1, they can be ≥ 0.001 for a rapidly cooled block.

Control of the cooling rate is essential for the production of a block of glass of uniform refractive index. The cooling rates used to reduce stresses to acceptable levels in the production of nonoptical glasses are much too fast for the production of optical glasses. Use of a constant cooling rate throughout the glass transformation region will not yield a block of uniform refractive index. Ideally, the cooling rate should be decreased gradually as the temperature decreases throughout the glass transformation region. The production of a fine annealed glass requires a very slow cooling process, with a gradually decreasing cooling rate with decreasing temperature within the temperature region where permanent changes in the structure of the glass can occur.

Athermal Lenses

While the thermal expansion coefficient of many glasses is relatively low, it is not zero. As a result, the dimensions and refractive index of a glass are functions of temperature. Temperature changes in an optical system therefore result in changes in optical path length. While changes in optical path length of this magnitude may be unimportant for optical systems used within a narrow temperature range, those used over ranges exceeding 10 to 20 K must be designed to minimize thermal effects. Production of athermal optical systems, i.e., systems of constant power over a range of temperatures, requires use of glasses where the thermal changes in refractive index are exactly offset by the changes in dimensions, i.e., the optical path length is independent of temperature. This condition is met if the temperature coefficients of the index and the thickness are equal and of opposite sign.

The overall effect of changes in temperature on the optical path length are tabulated in terms of the thermo-optical constant, G, given by

$$G = \alpha(n - 1) + \mathrm{d}n/\mathrm{d}T \quad [5]$$

where α is the linear thermal expansion coefficient, n is the refractive index, and $\mathrm{d}n/\mathrm{d}T$ is the thermal

coefficient of the refractive index. Perfect compensation between changes in index and dimensions are obtained when $G = 0$. Since α is positive for most optical glasses, with values in the range of 3 to 15 ppm/K, this condition requires a negative dn/dT. Negative values of dn/dT are found primarily for glasses containing some fluorine, such as fluoride glasses and those in which oxygen is partially replaced by fluorine, such as fluorosilicates, fluoroborates, etc., or for some phosphate glasses. Silicate glasses rarely, if ever, have a negative value of dn/dT. For the same glassformer, e.g., P_2O_5, use of modifier ions with large diameters and low field strengths favor increasingly negative values of dn/dT.

The value and sign of dn/dT is determined by the competition between the decrease in refractive index induced by an increase in molar volume and the increase in the refractive index induced by an increase in polarizability of the ions in the glass with an increase in temperature. Equation [5] indicates that the absolute value of the refractive index is also important in determining the value of G. If the refractive index is high, then dn/dT must be more negative to yield $G = 0$. As a result, most athermal glasses are crown glasses. The value of dn/dT is also wavelength-dependent, generally decreasing with increasing wavelength. In particular, dn/dT becomes more positive at wavelengths near the UV edge of the glass. An athermal lens is only perfectly athermal at the design wavelength.

A few special glasses and glass-ceramics used for optical applications, e.g., vitreous silica, titanium-doped silica, and some aluminosilicate glass-ceramics, have thermal expansion coefficients which approach zero or are slightly negative. Vitreous silica has a very low refractive index and thermal expansion coefficient and can be used to produce lenses which, while not truly athermal, have relatively low temperature sensitivity. These low thermal expansion materials are often used as substrates for coated reflective optics (mirrors), where dimensional stability is far more important than any change in the refractive index of the substrate.

Production of Traditional Optical Glasses

Quality requirements for optical glasses are much greater than those for other common glasses. A constant refractive index throughout the glass requires an extremely high degree of homogeneity. The glass must be free from defects such as striae (regions of refractive index variation due to density/composition variations) and stones (undissolved material) and the bubble content must be as low as possible. The thermal history of the glass must be such that the refractive index variation, due to differing fictive temperatures, is minimized. Internal stresses must be minimized to yield a low birefringence. The glass must also be free of any species which contribute to absorption in the desired spectral region.

The quality demands of optical glasses require use of much higher quality, and thus more expensive, raw materials. Concentrations of third-row transmission metal ions must be held to rigid specifications, with maximum values usually in the ppm, or even in the ppb range, for the highest quality glasses. Defects are reduced by melting in platinum containers instead of the oxide containers used in the past. Stirring the melt, using platinum wherever possible, is essential for obtaining acceptable homogeneity. Control of the melting atmosphere may be essential for controlling the redox state of the melt. Rigorous annealing schedules must be used to produce glasses with the desired thermal history so that the problems of stress-induced birefringence and refractive index gradients are reduced to acceptable levels.

Non-Traditional Optical Glasses

While most traditional applications of optical glasses involve transmission in the visible, many modern applications require high transmission in the ultraviolet, near-infrared, or infrared regions of the spectrum. Transmission in each of these regions is determined by both the bulk composition of the glass and by the concentration of impurities present. Most nontraditional applications place even more stringent requirements on the purity of the materials used in manufacturing the glass. An extreme example of the demand for purity is found in the glasses used for telecommunication optical fibers, where concentrations of some impurities must be held to the low ppb level.

Ultraviolet-Transmitting Glasses

The ultraviolet transmission of a glass is determined by the intrinsic electronic transitions of the material, by charge transfer absorption bands due to impurities, and by surface and bulk scattering. The first of these is determined by the electronic bandgap of the material, while the other two are controlled by the care taken during production of the glass. These glasses are used in spectroscopy for windows, lenses, UV-lamps, and sample cuvets, for microlithography, and for lenses in excimer laser optical systems.

Vitreous silica is widely used as an ultraviolet transmitting glass for transmission optics at

wavelengths well below 200 nm. The lowest energy absorption band for this glass occurs at 10.2 eV, or 122 nm. Many UV–VIS spectrometers, which normally are capable of measurements extending to 185 to 190 nm, use vitreous silica as optical elements. Additions of alkali or alkaline earth oxides to silica produce nonbridging oxygens in the network. Nonbridging oxygens do not bind the excitable electrons as tightly as bridging oxygens, which shifts the absorption edge to lower energies, i.e., longer wavelenths. These glasses are incapable of high transmission beyond 5 eV, or about 250 nm, and are not used for applications requiring good ultraviolet transmission.

Addition of elements which eliminate nonbridging oxygens favors good ultraviolet transmission. Alumina and/or boric oxide are frequently used in conjunction with alkali or alkaline earth oxides to counter the formation of nonbridging oxygens and preserve the ultraviolet transparency of silicate glasses. This approach can be taken to its logical conclusion by eliminating silica from the composition and producing alkali/alkaline-earth-aluminoborate glasses with good ultraviolet transparency.

In theory, fluoride glasses should provide better ultraviolet transmission than oxide glasses due to the larger bandgaps of fluorides. This assumption is true for single crystals, where fluorides such as CaF_2 are under development for transmission to higher energies than those obtainable with oxide crystals or glasses. In practice, the superiority of fluoride glasses for ultraviolet transmitting glasses has proven difficult to achieve. Vitreous BeF_2 and related glasses have superior ultraviolet transmission when compared to silicate glasses. Unfortunately, BeF_2 is very volatile and quite toxic, which restricts production of glasses based on BeF_2. Some fluoroaluminate and fluorophosphate glasses also have excellent ultraviolet transparency, but difficulties in producing these glasses in large sizes and of optical quality has limited their application.

Impurities are particularly important in production of ultraviolet transmitting glasses. The third-row transition metals, platinum, and cerium are all known to absorb strongly in the region from 200 to 300 nm when dissolved in glasses. Ferric iron has such a strong absorption band at $\approx$230 nm that concentrations of ferric ions must be kept in the low ppm range in glasses used for ultraviolet transmission. Since iron is a very common impurity in the sands used to produce silicate glasses, special care must be taken to minimize the Fe^{3+} content of ultraviolet-transmitting silicate glasses. Since ferrous iron has lower absorption in the ultraviolet, the effect of iron can be reduced by melting under reducing conditions. Platinum can enter melts from the melting unit and can be present as either ions or metallic particles. The ionic form of platinum absorbs ultraviolet light, while the metallic form scatters the same light.

Near-Infrared-Transmitting Glasses

Most glasses have good intrinsic optical transmission in the near-infrared. Absorption in this region is primarily due to impurities. Ferrous iron is especially detrimental to transmission in this region as a result of an extremely broad ligand field absorption band centered at about 1050 nm and extending into the visible and out to over 2000 nm. Reduction of absorption due to ferrous ions is obtained by careful control of raw materials to minimize the amount of iron oxide present and by melting under oxidizing conditions, which converts the ferrous ions to ferric ions. Conversion from ferrous to ferric ions increases the ultraviolet absorption of the glass. If good transmission in both the ultraviolet and near infrared regions is required, the iron content must be held to very low levels.

Although many rare earth ions also have absorption bands in this region, these elements are rarely found as impurities in sufficient levels to impair transmission in the near-infrared region for lenses and other common optical components. A more serious problem occurs for glasses used as optical fibers, where the greater optical path length magnifies the effect of impurities which may be undetectable in the spectra of samples only a few mm thick. The same can be said of absorptions of other ions which have very weak absorption bands in this region. Even higher order overtones/combination bands of infrared vibration absorption bands due to hydroxyl become important in optical fibers. While the hydroxyl absorption in infrared-transmitting glasses used in mm thicknesses is insignificant for concentrations less than 1 ppm, the hydroxyl concentration of optical fibers must be reduced to levels of a few ppb to reduce the effect of the overtone/combination bands to acceptable levels.

Infrared-Transmitting Glasses

Infrared transparency is limited by the intrinsic vibration, or multiphonon, edge of the glass and by the presence of impurities, primarily hydroxyl and carbon dioxide, which absorb in the infrared. The position of the infrared edge is determined by the force constant, which is proportional to the bond strength, and the masses of the ions. The best infrared transmission is found for materials with weak bonds and heavy ions. Infrared transmitting glasses are used in infrared spectrometers, lenses for pyrometers,

infrared transparent domes for aircraft and missiles, and optical components for many systems using infrared lasers.

The fundamental absorptions of B_2O_3, SiO_2, P_2O_5, and GeO_2 lie in the region from 7.5 to 12 μm. These bands have such strong absorptions that the first overtone, at half the wavelength of the fundamental vibration, effectively determines the infrared edge for samples of more than a few hundred micrometers in thickness. The best infrared-transmitting oxide glasses do not contain significant amounts of B_2O_3, SiO_2, or P_2O_5. The lower fundamental vibrational frequency of GeO_2 allows production of some glasses of limited use for infrared transmission to about 5 μm. Comparable transmission is obtained for calcium aluminate glasses. Better transmission has been obtained for glasses combining the oxides of lead, bismuth, or cadmium with gallium oxide. These gallate glasses are termed heavy metal oxide, or HMO, glasses and transmit to ≈7 μm in mm thicknesses. The HMO glasses transmit into the visible, with a cutoff at 400 to 500 nm. Since these glasses are transparent to visible light, they offer advantages over many other infrared-transmitting glasses which are opaque in the visible.

Recently, heavy metal halide (HMH) glasses have been found to exist in a wide range of compositional systems. HMH glasses transmit much further into the infrared than the best oxide glasses, with cutoff wavelengths extending beyond 20 μm. These glasses are much more difficult to prepare than oxide glasses and are highly prone to crystallization, less durable in water, and mechanically weaker than the HMO glasses. Improvements in infrared transmission correlate with degradation in the other properties needed for most applications. Oxide impurities severely degrade the infrared transmission of these glasses. While much greater infrared cutoffs can be obtained in the laboratory, glasses currently produced commercially transmit to ≈8 μm.

Chalcogenide glasses contain either S, Se, or Te as the glassforming anion and are free of oxygen. Commercial compositions transmit to 16 μm, while laboratory samples transmitting beyond 20 μm can be made. These glasses have refractive indices in the infrared in the range of 2 to 3, very low glass transformation temperatures, which limit their temperature range of application, and are, with few exceptions, opaque in the visible. Toxicity is also a problem for Se and Te. Oxygen impurities must be kept below the 1 ppm level to avoid unacceptable absorption bands.

All infrared-transmitting glasses suffer from transmission interference in the region from 2.5 to 6 μm, due to hydroxyl in the glass. Since hydroxyl readily forms in any melt exposed to an atmosphere containing water vapor, great care must be used to reduce the hydroxyl content to acceptable levels. Glasses can be melted in sealed containers, under reactive atmospheres containing fluorine or chlorine, or under vacuum. Some glasses are prepared under dry conditions and then remelted under a vacuum to reduce the hydroxyl content. Similar care must be used to exclude CO_2 from HMH glasses, where a band at 4.25 μm has been assigned to the asymmetric stretching vibration of the dissolved molecules (Figure 2).

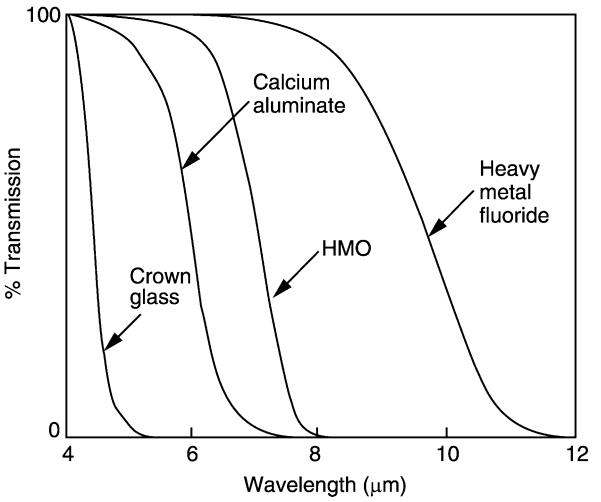

Figure 2 Infrared transmission spectra of several optical glasses showing the effect of glass composition on the infrared cutoff frequency.

Optical Isolators

Optical isolators based on the Faraday effect contain high concentrations of rare earths for paramagnetic devices and lead for diamagnetic devices. The highest concentrations of rare earth ions are obtained in aluminosilicate, aluminoborate, and aluminogermanate systems, where excellent quality glasses can be produced, while the best diamagnetic isolators are obtained using the lead bismuth gallate glasses.

Introduction

Injection molded precision plastic optics in high volumes were first produced during the 1960s. After the development of sophisticated measuring and manufacturing methods in the late 1960s, precise aspheric surfaces were as easy to make as spheric contours in plastics. Today plastic is a widely used low-cost option compared to glass with even more degrees of freedom for optical and component design. Polymer optical systems are used in sensor applications, visual systems, cameras, mobile phones, video-conferencing cameras, scanners, security systems, and so on.

The physical and chemical properties of plastic materials are very different from those of glass. Generally speaking, glass materials are harder, more durable, and more stable against temperature and humidity than plastics. The variety of optical glasses comprises hundreds of different materials. Compared with this the choice for plastic materials is limited only to about 10 different materials (and even less optical parameter variations). However, plastic optics offers other design freedoms that are not achievable with glass optics.

The manufacturing technologies for glass and plastic optics are totally different. Glass lenses are made by a grinding and polishing process whereas precision plastic lenses are usually made by injection molding, compression molding, or casting. Because of the material's characteristics and the manufacturing process, plastic optics have some unique advantages.

High production numbers at low costs

Injection molding is ideal for high-volume production with low-unit costs. Moderate raw material costs and multicavity mold designs (up to 32 cavities) allow large production volumes at a reasonable unit price. In spite of considerable tooling costs, these costs compared to glass design versions, can be relatively low.

Lightweight and hardiness

For a given volume glass is much heavier than plastic (by a factor of 2.3 to 4.9). However, plastic materials are relatively shatter and impact resistant. These features are important for head-mounted systems and other weight-sensitive applications (mobile phones, cameras, etc.).

Design potentials

Injection molding makes it economical to produce sophisticated optical shapes such as aspheres, diffractive optical elements, or even freeform surface structures. From the design point of view, the more sophisticated surface shapes reduce costs or obtain better performance (Fresnel structures, lens arrays, diffractive optical elements, etc.).

Optical systems and component assembly

For typical optical system designs optical components (mirrors, lenses, prisms, etc.) must be fixed in a mounting. With plastic optics it is possible to mold mounting elements, posts, or alignment notches integrally with the optical component. This can reduce part and assembly costs considerably.

Technologies adapted to plastic materials, such as ultrasonic and laser welding, gluing and integrated

snap-in structures, allow fast and cost-efficient automated and manually operated assembling solutions.

History of Transparent Plastic Materials

A Material With No Use

In 1840, the Austrian chemist Redtenbacher (1810–1870), a student of Justus Liebig, discovered during a chemical experiment a malodorous transparent liquidity, the acrylic acid. It was an unwanted byproduct which was not further analyzed at that time. Nevertheless, that discovery can be considered to be the origin of today's plastic optics.

The development of plastics began in the US in 1860 as people were searching for an alternative for ivory in the production of billiard balls.

In 1869 John Wesley Hyatt developed from cellulose nitrate and camphor the first plastic material: celluloid. At first it was used for dental plates and afterwards for shirt collars and as a film base material. Despite its flammability and its lack of light resistance, it was a first economical success.

In the following decades the first synthetical plastics were developed, for example, the material with the trade name Bakelite in 1906.

Otto Röhm's Doctorate

The basis of acrylates was rediscovered in the records of Redtenbacher in 1900. From 1901 onwards, Prof. Pechmann (1850–1902) asked his postgraduates to do more research into the acrylic acid. The acrylic acid is an acetylene compound which can be extracted from carbon, petroleum, or lime.

In 1901 Otto Röhm, a student of Pechmann, wrote his dissertation 'About polymerisation products of the acrylic acid' – the basis of the methacrylate chemistry.

Hermann Staudinger (1881–1965), head of the Institute of Chemistry in Freiburg started theoretical investigations into the structure and natural characteristics of natural and synthetical polymers in 1920. He assumed that the molecules of plastic materials consist of numerous small molecule units. Experiments as proof of the theory led to a rapid development of scientific research and to significant breakthroughs in plastic chemistry. Staudinger won the Nobel Prize for Chemistry for his work in the field of macromolecules in 1953.

In 1928 methyl methacrylate was syntheticized for the first time and patented. Acrylic resin was used as a binder in multi-layer glass.

In the 1920s and 1930s a number of plastic materials were developed, including cellulose acetate CA (photo film, synthetic fiber); polyvinyl chloride PVC (pipes, coatings, isolations); urea formaldehyde resin (dishes, electrical equipment).

Polystyrene resins were commercially produced for the first time in 1937. Polytetrafluoroethene (PTFE) was produced for the first time in 1938, and distributed as 'Teflon' since 1943. Another key development was the synthesis of Nylon, the first technical high-performance plastic material.

Plexiglas Captures the World

The industrial production of methacrylic acid methyl ester began in 1934. With its polymerization to a hard and transparent plastic material, polymethylmethacrylic (PMMA or acrylic) was developed. It was patented in 1936 and caused, under the registered trade name Plexiglas®, a sensation at the world exhibition in Paris in 1936, almost 100 years after the discovery of acrylic acid.

Plates of Plexiglas were manufactured by means of effusion and polymerization between glass plates. At first it was used for watch glass, cockpits, and the construction of street lighting and luminous advertising. People already experimented with Plexiglas injection moulding in 1935. Arthur Kingston, the founder of Combined Optical Industries Limited (COIL) had invented and patented the first plastic lens in 1933.

The First Plastic Lenses in Cameras

The first camera, incorporating plastic optical parts, to be mass produced was the 'Purma Special' introduced by RF Hunter Ltd., in 1937, using 'Perspex' (another brand name for Acrylic), for the direct-vision viewfinder.

Due to the scarcity of natural raw materials at the beginning of World War II, the plastic industry became a source of outstanding substitute materials. This development had a lasting effect far into the post-war period. Results were mainly achieved with technical plastics, such as polycarbonates, acetates, and polyamides. Other plastics were developed as a substitute for metals as well as for hardhats, for high-temperature constructions, and for products which are resistant against acids and bases.

The German chemist Karl Ziegler discovered polyethylene (Polyethen, PE) in 1953 and the Italian chemist Giulio Natta Polypropylene (PP) in 1954.

The Eastman Kodak company is credited with giving birth to the modern-day plastic Fresnel lens. In 1946 Kodak developed a tooling and manufacturing process to mass produce plastic Fresnel lenses.

The circular Fresnel lenses made at that time had spiral grooves like music records.

It took another 10 years of improvement in injection molding techniques to the first plastic lens camera – the Kodak Brownie 44A from 1959.

Between 1953 and 1959 the Polycarbonate polymer was developed by Bayer and General Electrics. Currently acrylics and polycarbonates are still the most important materials for plastic optics.

But not only thermoplastic materials were developed over this time. In May 1940 research work resulted in the monomer allyl diglycol carbonate (ADC). In the following years more than 180 different compounds of this monomer were investigated and examined.

During World War II Columbia Southern Chemical Company (a subsidiary of Pittsburgh Plate Glass) began research into ways of obtaining nonthermoplastic materials. The project was given the name 'Columbia Resins'. The 39th tested (CR 39) turned out to be the most significant due to its unique properties and was used since 1947.

At first, solely the low-refractive CR 39 was available for organic eyeglasses. Only in the mid-1980s did the development begin in the field of high-refractive nonthermoplastic materials.

Properties of Plastics for Optics

As already mentioned, the choice for plastic optical material is limited only to about 10 different types of material. Optical properties (abbe value, refractive index, transparency) as well as mechanical, thermal, and humidity boundary conditions are decisive for the material choice. Different to glass during plastic processing (injection molding, casting, etc.) the process affects not only the geometry but also inner properties like refractive index, transparency, and birefringence.

Optical Properties

Fundamental optical properties are defined by optical transmission, refractive index, and dispersion. For plastic optics birefringence is an important parameter too.

Although the total number of plastic materials has increased in recent years, the range of refractive index and dispersion characteristic is limited to almost two major groups – crown-like materials such as Acrylic (PMMA), Polyolefin (COC, COP) and flint-like materials such as Polystyrene (PS), Polycarbonate (PC) and Styrol-Acrylnitril-Copolymer (SAN).

This strongly limited variety of plastic optical materials significantly restricts the optical design freedom (Figures 1 and 2).

Physical Properties

Important physical properties are weight, impact, and abrasion resistance – and thermal properties like temperature resistance and thermal expansion. Already, during system design, both mechanical and thermal properties have to be taken into consideration. The thermal expansion of optical plastics is approximately ten times higher than that of glass materials. In an optical system this effect has to be compensated for by optical design or mounting.

Typically most optical plastics can withstand temperatures up to 90°C. The maximum service temperature of Polycarbonate and Poly-Olefin materials reaches 120°C.

The specific gravity of plastic optical materials ranges from 1 to 1.3.

Polycarbonate has the highest impact resistance of all optical plastics and so is used for windshields and crash helmets. Acrylic has the best abrasion resistance (Table 1).

Common Materials

Thermoplastics

Thermoplastics are polymers with a linear molecule structure – with or without side chains – which can be deformed reversibly without any modification of their thermoplastic characterization by means of the impact of heat. Optical elements can be manufactured by injection molding or hot embossing.

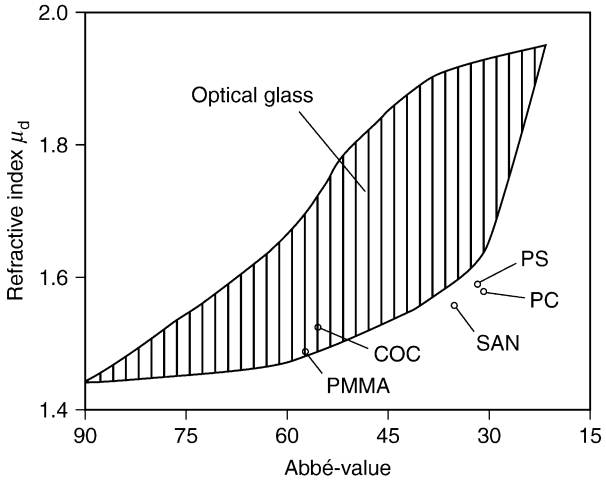

Figure 1 Abbe diagram.

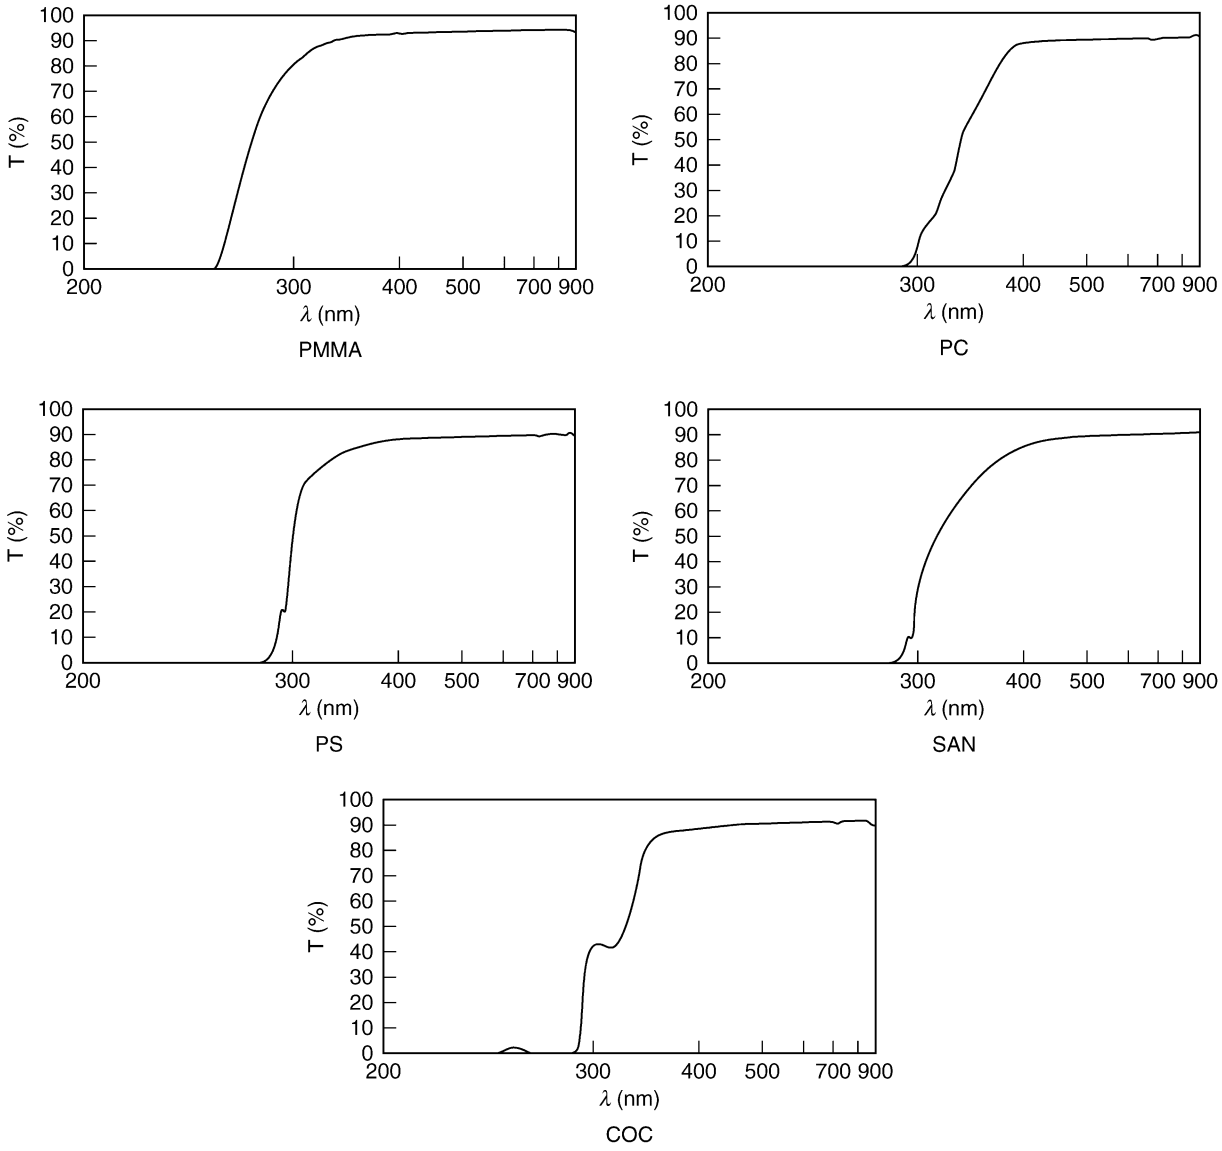

Figure 2 Transmission characteristics.

Typical optical thermoplastic polymers are listed below.

Acrylic or PMMA (Polymethyl methacrylate)
Acrylic is the most commonly used optical plastic. It is moderately priced, easy to mold, scratch resistant, and not very water absorptive. Its transparency is greater than that of most optical glasses throughout the visible range of the spectrum (organic glass). PMMA can replace glass in every application as long as the service temperature is less than 90°C and a low chemical resistance is required. Additives to acrylic (as well as to several other plastics) considerably improve its ultraviolet transmittance and stability.

PC (Polycarbonate)
Polycarbonates are linear polyesters of the carbonic acid which combine many characteristics of metal, glass, and plastics.

Polycarbonate is very similar to styrene in terms of optical properties such as transmission, refractive index, and dispersion. Polycarbonate, however, has a much broader operating temperature band of up to more than 120°C. It is used as the flint material for systems that have to withstand severe thermal conditions.

Another advantage is the high-impact resistance of polycarbonate. Safety glasses and systems requiring durability often consist of polycarbonate. Because of its high ductility polycarbonate is not easily machined.

Table 1 Material properties

Material	*Characteristics*	*Acrylic (PMMA)*	*Polystyrene (PS)*	*Polycarbonate (PC)*	*Styrol-Acrylnitril (SAN)*	*Cyclic Olefin Polymer (COP)*	*Cyclic Olefin Copolymer (COC)*	*Polyether-sulfone (PES)*	*Acrylnitril-Butadien-Styrolco-polymere (ABS)*	*CR39*	*Optical glass (B7)*

PS (Polystyrene)

Polystyrene or Styrene is a low-cost material with excellent molding properties. Styrene has a higher index and a lower numerical dispersion value than other plastics. It is often used as the flint element in color-corrected plastic optical systems.

Compared with acrylic, styrene has lower transmission in the UV range of the spectrum. It has a lower resistance to UV than acrylic but is more easily scratched than acrylic.

Because its surface is less durable, styrene is more typically used in nonexposed areas of a lens system. A styrene lens, when paired with an appropriate acrylic lens, offers an effective achromatic solution.

SAN (Styrol-Acrylnitril-Copolymer)

SAN is a copolymer of certain fractions of Polystyrene and Acrylic (typically 70/30), which allows adjusting refractive indexes. It is a glassy polymer with a low tendency to stress cracks. SAN has slightly more chemical durability than PS and is a low-cost material with excellent molding properties.

ABS/MABS (Acryl-Butadien-Styrol-Copolymer)

ABS is developed from polymerization of styrene and acrylnitrit on polybutadien during the emulsion process. Process variations lead to different material characteristics. Compared to PS, the chemical resistance and temperature stability of ABS is considerably better. ABS has a natural color so it cannot be used for every optical application.

PES (Polyethersulfon)

PES shows a remarkable temperature stability, a low transmission against UV-light, a limited transmission with a natural yellow color, and cannot be used for every optical application. Because of its excellent temperature stability, PES is suitable for assembling, even on electronic motherboards by reflow soldering. This process causes temperature stress up to 220°C (Figure 3).

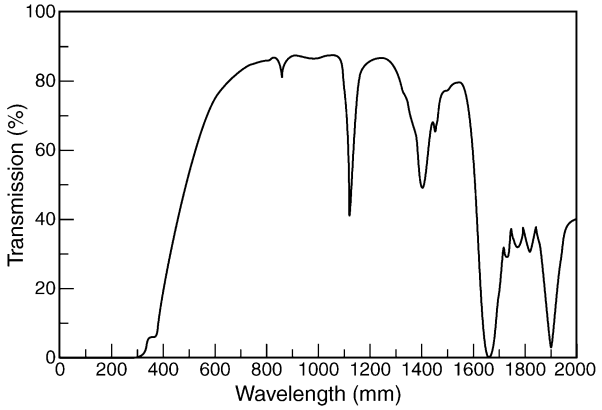

Figure 3 PES.

COP and COC (Cyclic olefin polymer and copolymer)

Cyclic olefin (co-)polymer provides a high-temperature alternative to acrylic. Its refractive index and transmittance are similar but the heat distortion temperature is about 30°C higher than for acrylic. It has a remarkably low water absorption value of less than 0.01% (compared with Polycarbonate 0.2% and PMMA 0.3%).

Cyclic Olefin Polymer (COP) is a family of amorphous plastic resins with low native stress birefringence properties. Zeonex is a resin developed by the Nippon Zeon Company – one grade, E48R, has a heat distortion temperature of about 122°C. Zeon Chemicals has another class of polymers called Zeonor, that can be provided as a lower-cost alternative to Zeonex.

Cyclic Olefin Copolymer (COC), with the trade name of Topas, is another high-temperature alternative to acrylic. Generally, it is a lower-cost alternative to COP. Particularly favorable is the high flowability (good injection moldability) of these thermoplastics.

PMP (Polymethylpenten – TPX®)

PMP has a structure similar to PE, except that only the methyl groups are replaced with isobutyl groups. The chemical resistance can be compared to PP, although it tends to stress crack under the impact of ketones or chlorinated solvents. The main advantages of PMP are its excellent transparency and its good mechanical characteristics, even at high service temperatures of up to 150°C.

PE-HD (high density polyethylene)

If polymerization is controlled catalytically, molecules with a low number of side chains will be received. Compared to PE-LD (low density), the molecules are quite compact with a higher stability and chemical resistance and service temperature can be up to 105°C. PE shows a bad transparency (milky appearance) in the visible spectral range. However, this material is permeable for infrared beams and so is frequently used for motion detectors.

Elastomere

Elastomeres are plastics with loose and networked molecules which are rubber elastic at a normal temperature. The most popular elastomeres are natural rubber and silicone rubber. These materials are optically used as flexible light guides.

Duromeres

Organic glass is a fully synthetic plastic material available in a vitreous state. It consists of macromolecular organic compounds which do not follow any principle of periodic arrangement and are hence amorphous.

Duromeres are plastics with spacial closely networked molecules which are very hard and refractory at a normal temperature. Impact of heat causes an irreversible induration. In most cases, duromers are used to produce plastic lenses made of organic glass. Once they have been thermally treated after production, their shape can no longer be changed.

The well-known plastic CR 39 is one of the organic materials used for plastic lenses.

CR39 plastic is made by polymerization of the allyl diglycol carbonate (ADC). It is a transparent, thermosetting resin which combines an exceptional range of qualities which are not available in other plastic transparent materials. The CR39 plastic is colorless and completely transparent to the visible light and almost completely opaque in the infrared and ultraviolet region of the spectrum. For these reasons, it is largely used for the production of sunglass lenses. They can be colored by surface dyeing or bulk tinting, have high abrasion resistance, and high-quality optical properties. Their weight is about half as much as glass, they keep their excellent optical properties despite long-term exposure to chemicals and resist heat distortion up to 100°C. These qualities, combined with the exceptional optical characteristics, make CR39 the best choice for applications where severe conditions of use exclude all other optical materials.

Additives and Colors

The characteristics of many plastics, particularly of thermoplastic materials, can be changed by adding so-called additives.

UV-filter materials are frequently added to improve the stability of materials in the sunlight. Sometimes nonstabilized plastics tend to yellow (transmittance decreases). Color filters can also be generated by coloring. Infrared coloring permits the production of optical elements which appear black in the visible spectral range. These materials are particularly used for sensors, optical scanners, or remote control front windows. Even characteristics, such as temperature stability, can be influenced by additives.

Manufacturing Methods

The manufacturing processes for glass and plastic optics are totally different. Glass lenses are made by a grinding and polishing process. By contrast, typical manufacturing methods for precise technical plastic optical parts are diamond turning of plastic blocks, injection, and compression molding of granulates. Other methods, such as casting, have their application in special fields like ophthalmics (eyeglasses). In any case, processing transparent plastic materials for optical purposes should take place in a clean environment.

Diamond Point Turning

Diamond point turning is an ultra-precision machining process carried out on special high-performance, ultra-precision diamond CNC-machining systems.

In combination with vibration isolation systems, digital signal processor-based machine control and integrated measuring systems with nanometer programming resolution manufacturing of optical surfaces is possible. This method can be expanded to full 3D-milling systems. With such an arrangement the generation of free-form surface profiles is possible.

Because of the long production time and the high machine costs, this technology is used for prototyping in plastics and nonferrous metals, mold inserts, and series production plastic parts – which cannot be manufactured by injection molding (because of size or precision demands).

Injection Molding

Injection molding produces several parts per shot (molding cycle) in single or multicavity tools. This production method is used for most of the plastic optic parts. Other fabrication techniques are used only when molding is inappropriate.

A plastic injection-molding machine consists of a fixed platen, a moving platen, a clamping unit, and an injection unit. Molding of optical parts requires special machine configurations and auxiliary equipment.

Compression Molding

Compression molding is used in the making of Fresnel lenses or other micro-optical structures. The material is pressed between heated platens with accurately defined temperature cycling during pressing. Mold inserts are formed by electroplated copies, replicated from master structures. These masters can be, for instance, diamond turned structures or diffraction gratings made by holographic methods.

The compression molding process allows realizing small structures with high aspect ratios and tight angular and positioning tolerances.

Manufacturing Process

Optical and System Design

On the one hand, optic design for plastic optics in principle uses the same mathematical algorithms as optic design for glass. On the other hand, designing plastic optics requires a profound understanding of the material properties and the manufacturing processes. Knowledge of production technologies, material characteristics, and assembling methods, together with design expertise, are needed to fully exhaust what precision plastic optics can be. Simply substituting the indices of refraction and re-optimizing, the design will not succeed. Expert design assistance is essential at this stage.

Designing plastic optics with modern design tools allows greater design freedom. The advantage of combining integral mounting structures with the optical surfaces to create mounting flanges, alignment, and snap features, provides the ability to automated assembly. Aspheric, cylindric, or toroidal surfaces are as easy to realize as spherical ones. Microstructures such as diffractive optical elements can be integrated too.

Prototyping

After designing a plastic optical system, lens prototypes can be made by diamond point turning in various plastic materials. The best surface finishes can be obtained with PMMA. Materials such as polycarbonate, pleximid, or Zeonex do not yield smooth surface finishes.

A major problem is the availability of semi-finished plastic blocks in various materials. For PMMA, a wide variety of bars or plates are available. For other materials or colored options, semi-finished items have to be made by injection molding. Because of the high manufacturing costs, diamond point turning is only recommended for making a limited number of prototypes to verify functionality of the optical design and to perform first tests.

In this stage optical systems are normally assembled from single elements. Housing parts often are made from aluminum. The resulting surface quality and system performance cannot be a validation of the manufacturability by injection molding. To get reliable knowledge about this, making a molded prototype from a single-cavity prototype mold is recommended.

The Injection Mold

A high-quality injection mold is obviously essential for precise plastic optic parts. The parts can never be better than the tool – but good tooling, however, does not guarantee good parts. A strong understanding of the whole manufacturing process is the key to producing precision plastic components.

Any injection mold consists of three main parts. The upper half, which is affixed to the injection-side platen, the lower mold half, which is affixed to the ejector-side platen, and the mold-ejection mechanism. Guide pins and taper locks ensure proper alignment of the mold halves.

Production volume and precision required from a tool influences the selection of mold materials and built-in maintenance features.

Single-cavity and multi-cavity molds from two to eight, 16, or even 32 cavitys are used for plastic optic parts.

Thermoplastic materials shrink during cooling in the mold. This geometric effect has to be compensated for in the injection mold. Exact shrink rates can be calculated and the tool can be modified.

For manufacturing optical plastic parts by injection molding, the optical surfaces (plano or aspherical shapes, diffractive, conical, lenticular, and cylindrical surfaces) are generated as separate inserts in the tool.

Aspheric inserts are manufactured by two steps. First a best-fit curve is generated on a stainless steel substrate. The substrate is then subjected to a nickel-plating process (electroless nickel) that deposits a thin layer of nickel (up to 500 μm). In the second step, single-point diamond turning produces the final aspheric or diffractive curve in the nickel. Because the hardness of a nickel-plated insert is less than that of a steel spherical insert, it will be more susceptible to scratch defects (Figure 4).

Pre-Production

A pre-production stage is recommended to check the manufacturing process. Typically this is done by using a single-cavity prototype mold. This mold can be used to find optimal molding conditions.

Optical and mechanical design can be verified with real molded components and design revision is possible to affordable conditions. Often the prototype molds is used to start limited production since production tooling may take much more time.

Series Production

For series production of high volumes, multicavity production molds are required. Depending on quality,

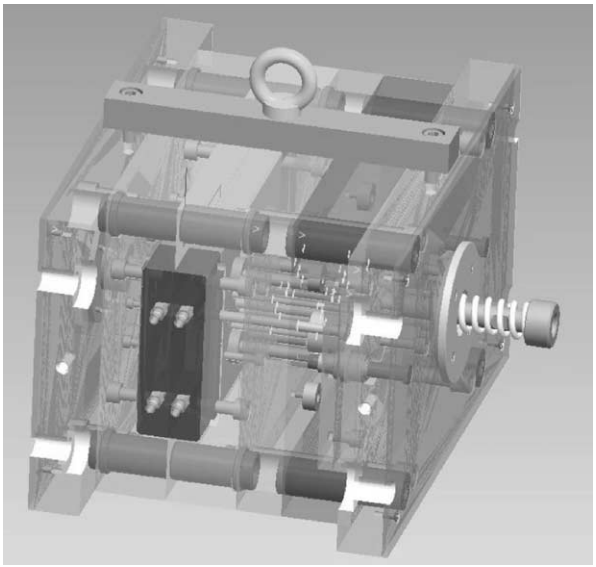

Figure 4 Injection mold.

volume, throughput, and cost, the production tool may have 2, 4, 8 or even up to 32 cavities. The production molds function for at least several hundred of thousands of injection cycles.

Coating and Component Assembly

Coating

Because of their limited temperature and UV resistance, plastic lenses must not be coated in an elevated temperature and radiation environment. During the deposition of thin films onto plastic, the coating chamber temperature is significantly lower than that for glass optics. This requires deposition techniques such as ion-assisted deposition to apply antireflective, conductive, mirror, and beamsplitter coatings.

Today, multi-layer dielectric coatings are routinely deposited on plastic components. Typical broadband antireflection coatings reduce reflection to about 0.5% per surface across the entire visible spectrum. Narrowband, multilayer antireflection coatings can achieve surface reflectances less than 0.2%. Multilayer dielectric coatings can be modified easily to scratch-resistant designs for front lenses and windows.

Several front and back surface reflector coatings are available for plastic substrates. Standard coating metals include aluminum, silver, and gold. Aluminum coatings provide surface reflectances greater than 88% across the visible spectrum and gold coatings greater than 95% for the near-infrared region.

Component Assembly

Many advantages of using plastic optics will come out in manufacturing components. The integration of optical, mechanical, and electronic elements allows building low-cost polymer optical components such as small camera lenses or scanner heads.

Plastic optical assemblies are usually carried out in a clean room environment by manual, semi-, or fully automated processes. The components have to be designed to ensure ease of assembly. Snap-on features, UV-cementing, heat-staking, and ultrasonic and laser welding, can also be employed with plastic materials.

Since most optical tolerances are additive, it is essential to establish quality check points in the manufacturing process to sort out nonconforming sub-assemblies.

Automatic in-line optical performance, monitoring such as MTF testing, can be implemented. SPC techniques should be used here to ensure the process is not drifting out of the controllable range.

Summary

For centuries, glass proved to be the material of choice for all optical applications. During the twentieth century, applications for glass elements and complex optical systems greatly expanded. Early uses of plastic molded elements included toy objectives, gauge windows, and watch crystals. Throughout the 1970s and up to the present day, high-grade polymers were developed specifically for optical applications. These advancements in materials, coupled with improved mold design have enabled plastic optics to replace glass optics in a wide and growing number of applications.

Plastic optic technology permanently expands their traditional limits and fields of application. On the one hand, plastic optic is still limited by material properties but, on the other hand, design and assembling freedoms allow new approaches.

OPTICAL MATERIALS

Sculptured Thin Films

K Robbie, Queen's University, Kingston, ON, Canada

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Optical materials, like all materials, ultimately derive their physical properties from their chemical composition and physical form. Aluminum behaves differently from copper because of a chemical difference, while graphite behaves differently from diamond because of a crystallographic difference. For materials that are not infinite perfect crystals, an important contribution to their electromagnetic (optical) response comes from the morphological form of the material. Morphological form describes the physical structure of the material: a perfect crystal is one type of morphological structure, a porous fibrous bundle is another. An example of a morphological difference is that between snow and ice. Snow and ice are chemically identical, composed of solid water, but they exhibit different optical properties because of a difference in morphology. The polished glasses and large perfect crystals that comprise most optical components have morphologies more like ice than snow; their morphologies are dense and crystalline, with few and small disordered 'defects'. Unlike ice, snow is rich with morphological structure (see Figure 1) arising from the complex growth of each flake in the clouds, and the aggregate growth of snow on the ground. The morphology of snow scatters all colors of visible light, giving it an opaque white appearance, while ice is transparent and nearly colorless.

Sculptured thin films (STFs) are materials with controlled and designed morphology that exhibit a rich behavior unlike that of the constituent materials in bulk; they are the snow to most optical materials' ice. Unlike snow, sculptured thin film morphology is designed to scatter light in a controlled manner to produce a desired optical response. A sculptured thin film could be a coating applied to an optical element where the coating converts polarizations of light, circular or linear, but is composed entirely of an optically isotropic material (which doesn't usually affect the polarization of light). The film morphology is designed to create the desired optical properties. Sculptured thin films are also useful for magnetics, where an example of a sculptured thin film is the metal film coated onto plastic tape for video, audio, and data recording. The film is deposited under conditions that impose an elongated shape onto the magnetic domains, altering the magnetic properties. The morphological form of a sculptured thin film defines the way it responds in electromagnetic, chemical, and biological interaction, and there is hope that these unique materials will someday form the core of technologies that make the world a better place.

Structure in Thin Films

As chemical composition and morphology determine the electromagnetic response of materials, it would be wonderful to have a technique where we could build materials atom by atom, placing each exactly where we wished, and varying the element at will. With this level of control it would be possible to design and fabricate materials for almost any conceivable optical application. In some sense this is what is done now to fabricate lasers and optical switches. Microelectronic and micromachining processes have produced fantastic optical devices by controllably mixing materials (mostly semiconductors) and patterning designed structures. These techniques typically employ a repeated series of thin-film depositions and photolithographic patterning. Examples of thin-film coatings include antireflection coatings on eyeglasses, hard coatings on grocery store barcode scanners,

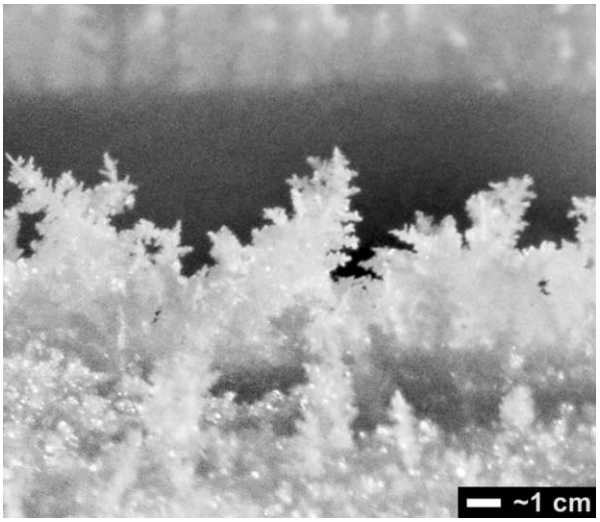

Figure 1 Photograph of snow accumulating at −20 °C. Photo courtesy of Chelsea Elliott.

ultraviolet blocking aluminum inside potato chip bags, and all integrated electronic circuits. Thin films are usually produced by vapor deposition in vacuum, and can be made with most elements and inorganic compounds (and a growing list of organics). Most thin films grow as uniform, dense, two-dimensional (2D) layers, and three-dimensional structure (3D) is produced by removing portions of the film with photolithography and etching. Photolithography is a process where ultraviolet light is projected through a mask and microscope system onto a photosensitive polymer layer atop the thin film. The light hardens areas of the polymer in the pattern of the mask, preventing them from dissolving in a chemical developer solution. Exposed portions of the thin film can then be etched away with chemical or other means. Repeating as desired, many steps can create complex 3D designed structures. Computer chips and other integrated circuits are semiconductor crystals covered with a layered structure of conductors (aluminum, copper, platinum) and insulators (metal and semiconductor oxides) patterned with thin film deposition and lithography. Semiconductor lasers and many other optical devices are made this way as well, usually employing compound semiconductors (GaAs, AlGaAs, GaAsP, InP, etc.). The micrometer-scale patterning made possible with thin-film deposition and etching techniques has produced a wealth of semiconductor optical devices.

Optical lithography, however, is limited in size scale to dimensions comparable to the wavelength of light used to expose the photomask. Modern UV lithography can pattern 100–200 nm structures. Visible light has wavelengths from 400 nm (violet) to 700 nm (red). Shrinking the dimensions of physical structures is a great benefit for optical devices as it allows light to be controlled coherently without strong random scattering. Structures with dimensions comparable to the wavelengths of light strongly scatter light waves; scratches on optical components or imperfections in materials with dimensions comparable to the wavelength are considered defects, and are usually deleterious. However, materials with morphology much smaller than the wavelength (nanometer structure, or nanostructure) are seen by propagating light as homogeneous, with polarization and dispersion effects characteristic of the underlying structure. Sculptured thin films are materials where complex nanostructure has been created by controlling growth parameters dynamically during deposition of a thin film. The simplest sculptured thin film might be one where the temperature is periodically varied during thin-film deposition (although this is a very simple example, lacking the anisotropy central to the sculptured thin-film concept). Variation in the growth process with temperature affects film density, producing a porosity variation (periodic inhomogeneity) as a function of film thickness. Varying porosity produces varying refractive index, and this film would be an optical interference filter. The largest limitation of sculptured thin films is that all attainable structures must be characteristic of the growth process. As all morphological control is accomplished by varying film growth parameters, structure that is not characteristic of thin film growth is not possible. Fortunately, thin film deposition and growth is sufficiently complex to allow the fabrication of a large range of useful structures. As with lithographic patterning, the structural control is two dimensional, but now the third dimension is constructed by continuing the deposition, not by repeating the deposition and lithography cycle. Complex structures can be produced on the scale of tens or hundreds of atoms (approximately tens of nanometers) with controlled 3D morphology. This reduction in size scale compared to lithographic patterning is a huge benefit. Materials can now be designed and created with subwavelength structure to coherently scatter light. Because the morphological structure ($<$100 nm) is much smaller than the wavelength of visible light ($\sim$500 nm), light traveling in a sculptured thin film sees a medium with averaged properties. The material can be designed to control refractive index through a wide range, and birefringence and circular polarization effects are controllable.

The morphological structure of thin films is a vast topic. Thin films are produced with a nonequilibrium growth process, somewhat like the growth of clouds, and the mechanics of the growth determine the structure, which is often very different from that seen in a bulk sample of the same substance. Crystal and morphological structure vary with deposition process conditions, and vary during deposition to record a history of growth much like the rings of a tree, or stratified rock. If chemical composition is varied during the deposition, that change will be reflected in layers in the film. If vapor energy or temperature is varied, variations in density and crystal structure will result. Thin film growth is an aggregation process (the film accumulates over time), and exhibits many of the features of similar processes, sometimes producing materials with structures similar to broccoli or clouds. This self-affine (self-similar) structure is observed over a large range of sizes under some film deposition conditions. Under other deposition conditions, crystallographic effects dominate growth and films become layers of faceted crystals. In sculptured thin films, these growth characteristics are controlled and exploited in a functional manner to

design material properties. For example, magnetic video and audio tapes that have the symbol ME, abbreviating 'metal evaporated', employ a structured magnetic thin film that has superior magnetic response for recording. Similar effects are observed in optical materials, and sculptured thin films appear promising for improving existing optical devices or enabling new ones to be developed.

The most studied form of sculptured thin films is that produced by an asymmetric deposition process. In deposition by vacuum evaporation, a thin film is fabricated by evaporating some source material in vacuum, and condensing a vapor onto a substrate. Eyeglasses, mirrors, television phosphor screens, etc. are coated this way. In most thin films the vapor arrives straight down (perpendicular) to the plane of a flat substrate. The film structure reflects the symmetry of the vapor, and is typically composed of a dense layer with some defects or voids oriented perpendicular to the substrate surface. A thin film exhibiting this morphology is shown in the scanning electron microscope image of Figure 2. When vapor arrives asymmetrically onto a substrate, however, that asymmetry is reflected in the growth, producing structural asymmetry in the resulting film, and altered physical properties. A second scanning electron microscope image is shown in Figure 3, of a sculptured thin film where the orientation of the substrate relative to the vapor is changed twice, producing three layers with different morphologies. The thin uniform gray at the absolute bottom of the image is the edge of the silicon crystal substrate which has been cleaved to reveal an interior section of the film. The bottom and first film layer is inclined to the right, toward the vapor source for the duration of this first part of the deposition. The middle and second film layer has a twisted structure created by slowly rotating the substrate relative to the vapor, while keeping the tilt fixed. The top layer has a vertical structure created by rapidly rotating the substrate. The entire film was produced with the vapor arriving at an angle of 45°, measured from either the plane of the substrate or its perpendicular. Varying the tilt angle has a profound effect on the morphology of thin films. The void structure in these films records the geometry of the deposition. When we cleave a film we are able to observe a 2D slice of this rich morphology. At large tilt angles, glancing angle deposition (GLAD) produces films with highly porous and complex structure. At these angles, the film structure becomes isolated columns of material where growth variations are now reflected in variations in the shape of individual columns. At less oblique vapor angles, growth variations are reflected in the shape of networks of atomic-scale voids within a largely dense film. Indeed, for the best optical devices fabricated to date (with the serial bideposition technique described later) it is difficult to distinguish any variation in structure even using a high-resolution scanning electron microscope. The film deposition process can be designed to control the morphology of the growing film, and to vary the structure as a function of time and thickness. The morphology of these films determines their optical properties; optical birefringence, second harmonic generation, filter bandwidth and attenuation, etc. can all be controlled in sculptured thin films.

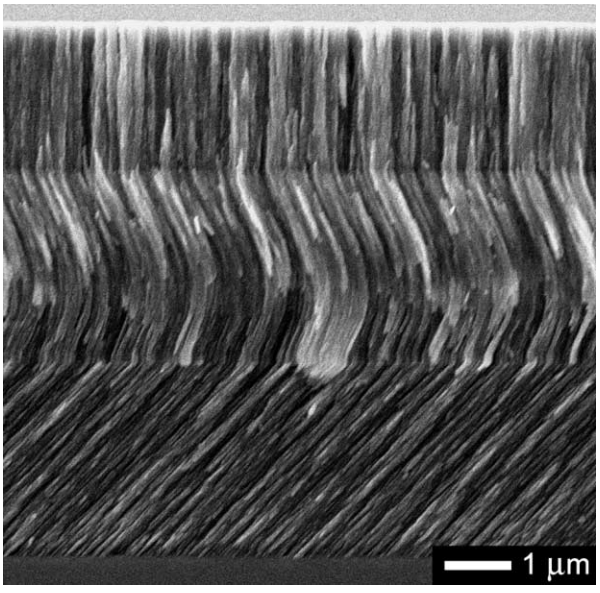

Figure 3 Micrograph of SiO film deposited with a tilt angle of 45° with one layer of no rotation, one layer with one rotation, then one layer with rapid rotation.

Optical Thin Films

Light can be described as a traveling wave with electric and magnetic fields oscillating perpendicular to each other, and to the direction of propagation. If the orientation of the electric field remains constant as the wave propagates, the light is said to be linearly polarized. If the orientation of the electric field rotates through a circular path, the light is circularly polarized, and can be left or right handed. In the most general description, the electric field traces an ellipse during propagation and the light is said to be elliptically polarized. The experimental study of light polarization is called ellipsometry. When light propagates through vacuum or air, the state of polarization remains constant. When light propagates through some types of materials, however, crystallographic or morphological asymmetry (or more correctly, anisotropy) results in different propagation conditions for different polarizations. Upon passage through these materials, the orientation and form of the state of polarization is changed, for example from left circularly polarized (LCP) to right circularly polarized (RCP). When multiple layers of anisotropic materials are combined into an optical circuit, as in the sculptured thin film concept, highly controlled optical response characteristics can be created.

The discussion of the optical properties of thin films begins with definitions of isotropic, uniaxial, and biaxial materials. Isotropic materials have optical properties that are independent of the direction that the light propagates through them. Vacuum and air are isotropic, as is glass. Rotation of the optical material relative to the light propagation direction has no effect on how the light propagates, and the state of polarization remains constant. Uniaxial materials have properties that vary with direction, but with one preferred direction (or axis) where response is independent of rotation. Biaxial materials have properties that are even more dependent on propagation direction, and require two axes to describe their optical properties. For biaxial materials there is no propagation direction where the optical response is independent of rotation. The mineral calcite is an example of a uniaxial material where the refractive index, and therefore the speed of light propagation, varies with direction relative to the crystal structure. This is a direct consequence of the trigonal crystal structure of calcite, and is an example of linear birefringence. Birefringence is the effect caused by anisotropic materials whereby light of different polarizations, even within one ray of light, travel with different speeds. When light propagates in a birefringent material, the orientation of the light's electric field relative to the material's optical axis determines the speed of propagation. Light with different polarization (orientation) propagates at different speeds, and a beam's polarization state is altered on passage through the material. Thin films can be isotropic, uniaxial, or biaxial, depending on the conditions under which the film is deposited. Sculptured thin films are films fabricated in a manner that controllably enhances the anisotropic optical response to produce materials with designed optical properties based on control of their morphological structure. As in calcite where the anisotropic crystal structure yields a uniaxial optical response, anisotropic morphological structure in sculptured thin films yields biaxial optical response. A plan view scanning electron microscope image of an anisotropic thin film is shown in Figure 4. The film was deposited with two vapor sources with the substrate placed between and the vapor arriving from both sides at an angle of 70° from the substrate perpendicular. This film is similar to those produced with the serial bideposition technique, and is optically birefringent. Polarization filters and other optical components can be constructed by designing the morphological structure of the thin film.

As discussed above, when a thin film is deposited from a vapor arriving perpendicular to a flat substrate surface, a structure composed of small (tens of nanometers diameter) columns of film material grows, with the columns oriented perpendicular to the substrate (Figure 2). This film is optically uniaxial, with the preferred axis perpendicular to the substrate, and parallel to the vapor flux. Light propagating along this optical axis (perpendicular to the substrate) travels at one speed regardless of polarization, and independent of rotations of the substrate around this axis. Light propagating along other paths will travel at a speed that depends on the polarization of the light

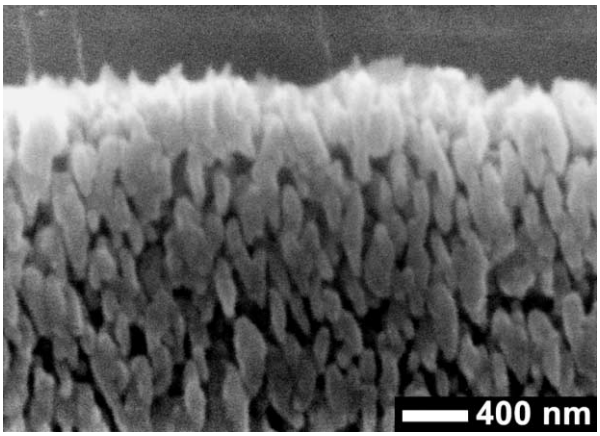

Figure 4 Micrograph of MgF_2 film, viewed from above, deposited with simultaneous growth from two vapor sources.

(orientation of the electric field relative to the propagation direction). The effect is small, and arises from the morphological structure of the film. More pronounced optical response is produced when the vapor arrives onto the substrate at an angle from the substrate perpendicular, producing optically biaxial materials, and enabling exciting polarization and filtering effects. If a thin film of magnesium fluoride is deposited onto a polished piece of glass with the vapor arriving at 45° (relative to an axis perpendicular to the substrate), a slanted columnar film is produced. The morphology of the film is tightly packed columns of polycrystalline magnesium fluoride with diameters between 50 and 200 nanometers (nm), inclined toward the vapor source, and penetrated by a network of atomic-scale voids. Because of the anisotropic nature of the deposition, the voids are anisotropic, and the film is optically biaxial. If the substrate is then held at that tilt angle and is rotated during deposition, the anisotropy in the structure rotates with the deposition, and an important type of sculptured thin film is produced. The electromagnetic description of this type of film is a 'helicoidal bianisotropic medium', describing both the helix shape of the rotation of the structure and the local bianisotropic (biaxial) physical, and optical, structure. Films with helicoidal symmetry are ideally suited for studies involving circular polarizations of light, and many demonstrations of sculptured thin films have involved these films and circularly polarized light. Like many organic molecules and some mineral crystals, these film are chiral, existing in two mirror image forms, called enantiomers. A right-handed structure rotates clockwise traveling away from an observer; a left-handed structure rotates counterclockwise. Also like some organic molecules and mineral crystals, helicoidal films are optically active – they affect the polarization of light. The observed effect depends on the wavelength of light relative to the physical helicoidal structure. If these two lengths match, a strong resonance effect is observed where the light wave coherently scatters from the anisotropic structure. Filters to produce and convert circular polarized light have been constructed with sculptured thin films of this type.

The range of structural control over the morphology of thin optical films limits the ability to tailor optical response for desired applications. While optical systems must always be treated as a whole to determine response properties, the description of some basic elements is useful. A film deposited at normal incidence will be uniaxial with the axis perpendicular to the substrate. For light propagation along this axis (common for optical systems), the material exhibits no birefringence. This structure is often called an isotropic element even though the columnar structure is slightly optically anisotropic. A truly isotropic layer could be produced by ion bombardment or elevated temperature during deposition, either of which would have the effect of eliminating the columnar structure and reducing anisotropy in the film. The second elemental structure is a slanted columnar film that is commonly described as a matchstick morphology. It is produced by changing the vapor incidence away from the substrate normal, leading to an inclination of the column structure toward the vapor source, as described above. Further structures can include: helicoidal structure where the anisotropy rotates through the thickness of the film, and periodically bent nematic structure where the anisotropy tilts in an s-shaped pattern through the film (fabricated with a complex pattern of rotations and depositions). These four elementary microstructures are shown in **Figure 5**. Electrical, optical, and magnetic anisotropy can also be increased by depositing obliquely from two sides instead of one, and this technique (called serial bideposition) can be used to increase the anisotropy in sculptured thin films. At extremely oblique deposition angles, a regime called glancing angle

deposition, a rapid increase in porosity with approximately constant column tilt results from a competition between deposition processes. Films deposited here are highly porous and strongly scatter light, limiting their usefulness for conventional optical devices, though some application has been seen in these highly porous films when impregnated with liquid crystals, and switched similarly to liquid crystal displays. An example of a highly porous optical filter with circular polarization effects is shown in Figure 6, where two layers of helicoidal porous films are deposited with different handedness and pitch. Sculptured thin films for most optical devices are deposited at less oblique angles to reduce porosity and therefore diffuse light scatter (haze) as well as sensitivity to humidity and other environmental changes.

Combining the concepts of film growth and optical response to morphology leads to the hoped-for vision of sculptured thin films: optical circuits in a chip. Combining the elementary microstructures described above, and employing powerful computer growth modeling and optical design programs, researchers are currently defining and producing sculptured thin films with increasingly complex optical response characteristics. There are substantial steps required to move from the fairly simple optical filters fabricated today to large-scale devices with complex functionality, but continuing success and increasing interest suggest that sculptured thin films could become a dominant optical technology in years to come.

Current Research

While thin films deposited at off-perpendicular incidence angles have been studied for many years, the last decade has produced significant new insights into these materials, leading to the concept of sculptured thin films. Understanding that morphologically rich materials can be used to produce new optical effects has yielded some impressive demonstrations. Research is also underway to explore these materials for chemical, magnetic, biological, and other applications.

Significant research has been conducted in the past few years to develop and extend the concepts of sculptured thin films. Optical studies, both theoretical and experimental, have revealed a range of remarkable properties including circular birefringence and Bragg reflection, liquid crystal alignment and switching, optical interconnection, and even suggestions of photonic bandgaps. Studies of optical sensing of gases and other materials is progressing, and simulation and modeling of the growth processes is ongoing. The following are two examples of optical materials that have been fabricated with sculptured thin-film techniques; one is a polarization discriminatory light-handedness inverter and the second is a liquid crystal switching cell that can be used to electrically modulate the transmission of polarized light. The handedness inverter converts left circularly polarized light to right circularly polarized within a spectral band, and blocks right circular polarized light. It is constructed by combining a layer with vertical columnar, or matchstick, morphology together with a layer with helicoidal morphology. In keeping with the sculptured thin film concept, the films are deposited sequentially during the same deposition, and optical properties are monitored during growth. The transmission spectrum for the devices is shown in Figure 7, where T_{RL} and T_{LR} are the light transmittances of right circularly polarized light when the incident is LCP, and of LCP when the incident is RCP, respectively. LCP light is almost entirely converted to RCP upon transmission, and RCP light is blocked. The bandwidth of the devices is about 50 nm, determined by matching of the circularly polarized light with the layer with helicoidal morphology.

When films are deposited with helicoidal morphology at glancing angles, i.e., glancing angle deposition, highly porous structures are produced where the columns stand alone and are individually shaped by the deposition process. Optical devices can be constructed by filling these porous films with gases or liquids, and there have been demonstrations of display-type switching with liquid crystals, and discussions of chemical sensing possibilities.

Adapted with permission from Hodgkinson IJ, Lakhtakia A and Wu Q-H (2000) Experimental realization of sculptured-thin-film polarization-discriminatory light-handedness inverters, *Optical Engineering*, **39**: 2831–2834.

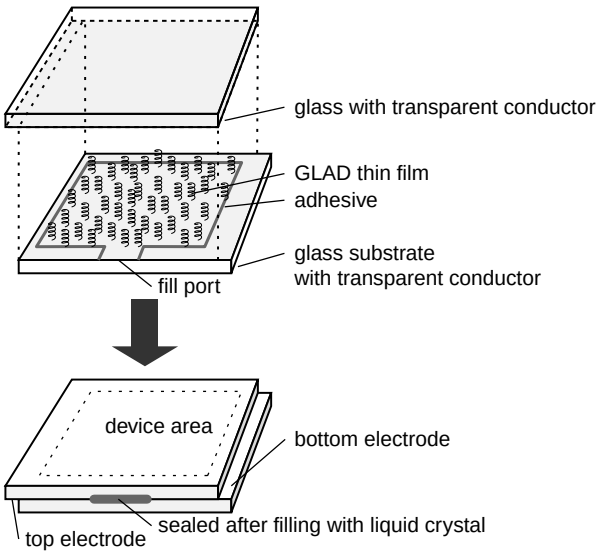

Figure 8 Liquid crystal switching cell schematic with highly porous glancing angle deposited (GLAD) film between glass plates coated with transparent electrodes. Reproduced with permission from Sit JC, Broer DJ and Brett MJ (2000) Alignment and switching of nematic liquid crystals embedded in porous chiral thin films. *Liquid Crystals* 27: 387–391, www.tandf.co.uk/journals.

The device shown in Figure 8 is a liquid crystal switching cell where the space between the electrodes, usually composed solely of liquid crystalline material, is now filled with a highly porous helical structured film. The film structure is somewhat similar to helicoidal film produced for the handedness inverter discussed above, but glancing angle deposition has produced a film of individual formed columns instead of a more dense film with a helicoidal void

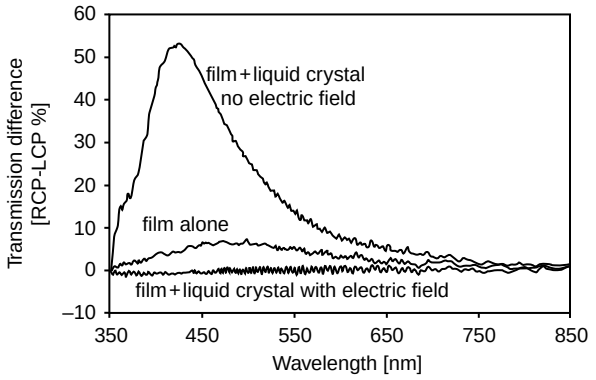

Figure 9 Transmission spectrum for visible light through a liquid crystal cell where the difference between right- and left-circularly polarized light transmission is eliminated with applied electric field. Adapted with permission from Sit JC, Broer DJ and Brett MJ (2000) Alignment and switching of nematic liquid crystals embedded in porous chiral thin films. *Liquid Crystals* 27: 387–391, www.tandf.co.uk/journals.

morphology. When the porous portions of the film are filled with simple nematic liquid crystalline material, the orientation of the rod-like molecules is strongly influenced by the helical columns. An orientational phase occurs in the liquid crystals mirroring the helical structure of the columns in the film, and producing optical properties similar to chiral nematic liquid crystals. The discrimination of left and right circularly polarized light increases relative to the unfilled film. When an electric field is applied across the liquid crystal cell, dipole moments in the liquid crystal molecules force them to align with the field, and chiral optical properties vanish (see Figure 9). Used as an electro-optic filter for circularly polarized light, this cell can switch light transmission on and off. Initial work has not shown clear benefits of this system over conventional liquid crystal display technology, but control of liquid crystal orientation throughout the cell instead of just at the glass plates appears promising. Possibly more complex optical circuits, incorporating layers of porous films filled with liquid crystals, will be useful.

Theoretical and experimental study of sculptured thin films is in its infancy, and many exciting uses for these materials are expected in coming years. Continuing study of thin film growth dynamics will improve and expand the range of structures attainable. Theoretical investigations will aid in the design and understanding of the optical response.

List of Units and Nomenclature

Aluminum (Al)	white metal used in airplanes, mirrors, and microelectronic circuits

Anisotropic	having properties that vary with orientation (rotation)
Biaxial	having anisotropic optical response characteristics that require two axes to describe
Chiral	having a shape that exists in two mirror image forms, called enantiomers
Diamond	carbon crystallographically ordered in a face-centered-cubic lattice, and used in cutting tools and jewelry
Electromagnetic waves	traveling waves of energy that compose light, x-rays, radio-waves, etc.
Epitaxy	growth of a thin film that preserves the crystal structure of the underlying film or substrate
Etching	removing material with chemical or physical atomic scale process
Graphite	carbon crystallographically ordered in hexagonal sheets, and used in pencils and lubricants
Inhomogeneity	varying with translation (position)
Isotropic	having properties that are identical in all directions
Lithography	process where patterns are produced in a sensitive layer by irradiating the layer through a mask with the desired pattern
Magnesium fluoride	ceramic (MgF_2) that is used in thin-film or single-crystal form in many optical systems
Morphology	microstructural shape, or physical arrangement of atoms in a material
Nanometers (nm)	one billionth of a meter, 10^{-9} m
Nematic liquid crystal	optical material composed of rod-shaped organic molecules that usually exhibits uniaxial optical properties
Pitch	physical period for one full rotation of a helical structure
Polarization	orientation and phase of the electric and magnetic fields in a traveling electromagnetic wave; can be linear, circular, or generally, elliptical
Refractive index	the ratio of the speed of light in vacuum to the speed of light in a material
Substrate	object that a thin film is deposited onto, often polished glass or semiconductors
Ultraviolet (UV)	electromagnetic radiation (light) with wavelength shorter than visible light and longer than X-rays
Uniaxial	having optical response characteristics that are anisotropic, but are rotationally symmetric about one axis
Vacuum	absence of matter, typically produced inside sealed glass or steel chambers by removing air with pumps
Vapor flux	moving gas-like collection of material, emitted from a source such as an evaporator or effusion cell, that will condense to form a thin film

Introduction

Smart optical materials are those materials whose optical properties (transmittance, reflectance, absorptance, emittance, fluorescence) can be controlled by external stimuli; either by an applied electric field or voltage, mechanical stress, incident light or electromagnetic field intensity, temperature variation, or time duration. This includes electrochromic, photochromic, thermochromic, nonlinear optical, light emitting, fluorescing, emissive, and piezochromic materials. These materials can be in various states, such as solids, gels, composites, and mesophases. Electrochromic and photochromic materials, however, are used most extensively.

The mechanism for adaptive control of light must be reversible, have a well-defined response time, and have an activation threshold, otherwise, the material is considered passive. The primary mechanisms that can cause variations in optical properties are crystal phase transitions, nonlinear effects in the polarizability, optical energy band transitions and band bending, compositional changes, defect and color center formation, and lattice strain. Crystal phase transitions change the bonding morphology of a material, which affects the energy bandgap. Most optical materials have several possible crystalline phases, depending on temperature. The optical properties of the anatase and rutile phases of TiO_2, for example, are very different, and result from different energy bandstructures (recall that the energy bandstructure depends on lattice spacing and crystalline plane orientation). The crystalline phase of several thermochromic materials changes from the martensite structure to the austenite structure with change in temperature, and an associated change in optical properties. Compositional changes are caused by chemical or physical reactions in the material, such as a metal ion bonding to an atom in the lattice, or loss of an atom in the lattice. The reaction can be caused by an energetic photon or ion driven by an electric field; electrochromic materials fit into this category. If their energy is high enough, incident photons can create defect states in the bandgap of materials, which in turn form color centers that absorb light. Modulated electric and electromagnetic fields can cause changes in the linear and nonlinear polarizability of the atoms in a lattice. Nonlinear optical and piezochromic effects are based on this mechanism.

Photochromic Glass

Photochromic glass is one of the most widely used smart optical materials, and definitely the most widely marketed. It has been around for over 30 years with hundreds of associated patents. The transmission of photochromic materials adjusts to the light level of their environment, but these materials give no output information for data processing or communications. They do, however, require no other external control mechanism other than the intensity of light (characteristics of a true smart material). Photochromic materials darken reversibly when exposed to sunlight or a specific

optical (UV–LWIR) wavelength band. Absorption in specific narrow or broad wavelength bands is due to the formation of color centers, or point defect states in the lattice. The kinetics of darkening has been described by a two-color center model with two rate constants. Energy (usually in the ultraviolet wavelength range) of the incident photons, ionizes atoms in the glass, thus forming 'F' centers. F centers are highly absorptive and the absorption generally occurs in a broad wavelength band. The earliest photochromic glass developed utilized a dispersed and sensitized colloidal silver halide as the darkening agent. Copper oxide was a typical sensitizer and AgCl is also a fairly common impurity used in PC glass. This material darkens by the equation

$$Ag^{I} + Cu^{I} \rightleftharpoons Ag^{0} + Cu^{II} \qquad [1]$$

This type of reaction is fairly typical of these materials. The defect state is created in the silver and copper, creating optical absorption. Photochromic glass can darken down to 22% transmittance in sunlight and become nearly clear indoors, transmitting 85% of visible light. Figure 1 shows the transmittance of the darkened and normal states. Temperature, however, does have an effect on the lenses. The glass will not darken completely at temperatures above 32 °C, and at cold temperatures the lens will get extremely dark in a shorter period of time. Recently, $BaO–R_2O_3–SiO_2$ (R = Al, B, La) nanoparticles have been introduced to enhance photochromicity.

Thermochromic Materials

Thermochromic materials darken and lose transmittance when heated above a critical temperature. They can be as sophisticated as a multilayer thin film optical interference coating or as mundane as a cereal bowl that changes color when heated.

Thermochromic products are used to darken windows of automobiles, for example, when the internal temperature gets above a specific value. The conductivity of these materials also decreases with darkening in many cases because additional electrons are excited into the conduction band due to the increased number of defect states in the bandgap. The most common inorganic thermochromic thin film materials are transition metal oxides, and among these, the vanadium oxide family (V_2O_5, VO_2) shows the best performance. Figure 2 shows the transmittance of a VO_2 thin film before and after heating. Here T_t is the transition temperature. When heated above T_t, the film darkens. Stoichiometric VO_2 darkens at a temperature near $T_t = 68\,°C$ due to a semiconductor to metal transition. The resistivity of VO_2 decreases by three orders of magnitude and the emittance can be increased up to 90% at the transition temperature. This material has promising applications for thermal control of space structures, where surfaces are exposed to intense solar radiation and periods of darkness at very low temperatures. The transition temperature can be engineered (increased or decreased) by doping with metals such as W and Ta.

Loss of transmission can be achieved by absorption or increased reflectance. Reflectance increases with heating are observed in substoichiometric WO_3 films and absorptance increases in stoichiometric films. The reflectance increase is attributed to a decrease in W/O ratio and an associated increase in the refractive index (n) and extinction coefficient (k).

Electrochromic Materials

Electrochromic materials, also called switchable materials, are usually used in the form of thin film devices. Electrochromic windows, or smart windows, have finally reached maturity and promise to be the next major advance in energy-efficient window technology. These devices are used in architectural glazings, automotive mirrors, rear view mirrors, sunroofs, sunglasses, and other high-end applications. Electrochromic devices are well suited for both solar and thermal control. A window can be controllably darkened during periods of bright sunlight and switched back to transparency during the evening or during cloudy periods. Windows with multilayer thin film electrochromic coatings change color and darken with an applied voltage, and bleach with a reverse bias. The magnitude of the applied voltage determines the degree of coloring and bleaching. In addition to a change in visible transmission, the NIR transmission and reflectance, and the associated thermal properties, can also be controlled. The major advantages of electrochromic devices are: (1) power is used only during switching; (2) switching voltages are small (1–5 V); (3) reflectance and transmittance is always specular; (4) gray scale variations are possible; (5) polarization is minimal (reduces birefringence and distortion); and (6) the memory is adjustable in many cases.

The electrochromic effect occurs in inorganic compounds by dual injection (cathodic) or ejection (anodic) of ions (M) and electrons (e^-). A typical reaction for a cathodic coloring material is

$$WO_3(\text{colorless}) + yM^+ + ye^- \rightleftharpoons MyWO_3(\text{blue}) \quad [2]$$

where M is H^+, Li^+, Na^+, Ag^+, etc.

A typical anodic reaction is

$$Ir(OH)_x(\text{colorless}) \rightleftharpoons IrO_x(\text{black}) + XH^+ + xe^- \quad [3]$$

Movement to the right creates color or darkening, and movement to the left results in bleaching. Figure 3 shows the spectral data for the switching of a tungsten oxide film over the solar spectrum; the spectral response of the coating in the bleached and colored (or 'switched') states, and Figure 4 shows the bleached and darkened states of an actual electrochromic window.

Figure 5 shows the design of a simple electrochromic coating. The basic electrochromic coating consists of a transparent top electrode (usually indium tin oxide – ITO), which also injects electrons into the electrochromic layer beneath. By far the most studied and most promising electrochromic material is tungsten oxide (WO_3), which can have either an amorphous or crystalline microstructure. WO_3 has a high coloration efficiency and capacity. Other inorganic materials that are presently being developed for solar control applications are various forms of WO_3, NiO, $WMoO_3$, MoO_3, and IrO_x. Many of these are doped with a conduction ion such as Li^+ or H^+. The ion conductor layer is used to transport protons (H^+), which are supplied by the ion storage or counter-electrode layer, into the electrochromic material. The most promising ion conductors are certain immobile solvent polymer systems, ionic glasses, and open-channel metal oxide structures such as perovskites. Oxides of Ta and Nb also show promise. The bottom layer is another transparent conducting coating. It is possible to inject both electrons and protons into the electrochromic material, thereby inducing a strong absorption band in a given region, e.g., the visible spectrum, that results in a color change. In an

electrochromic device, an externally applied electric field is used to control the injection process (voltage is applied across the two transparent electrodes). The coloration remains for some time, even after the external field is removed. The system returns to the initial state upon reversing the polarity of the external field. It is interesting to note that electrochromic windows being developed by NREL now employ solar cells to facilitate optical switching.

There are two major categories of electrochromic materials: transition metal oxides (including intercalated compounds) and organic compounds (including polymers). Table 1 shows a few of the most common electrochromic materials. Organic electrochromic materials are based on the viologens, anthraquinones, diphthalocyanines, and tetrathiafulvalenues. With organic compounds, coloration is achieved by an oxidation–reduction reaction, which may be coupled to a chemical reaction. The viologens are the most studied of the organic electrochromics. Originally, organic electrochromics tended to suffer from problems with secondary reactions during switching, but recently more stable organic systems have been developed. However, their reliability in harsh environments is questionable, and protective encapsulation may be required.

Electrochromic nickel oxide (NiO) is also being developed. NiO has been combined with manganese oxide, cobalt oxide, and niobium oxide in all alkaline devices.

Nonlinear Optical Materials

Nonlinear optical materials have evolved slowly over the past 20 years. At relatively low light intensities, the properties of most optical materials are independent of intensity of illumination. There is no interaction between the light waves in the medium. However, if the intensity of illumination gets high enough, nonlinear optical effects can occur and the optical properties become intensity dependent. When an electromagnetic field oscillating at optical frequencies ($\sim 10^{13} - \sim 10^{17}$ Hz) is applied to the lattice of a dielectric material, the electrical charges in the lattice become polarized and form electric dipoles. The positive ion cores do not move significantly, but the electrons are displaced in a harmonic motion. The polarization $\mathbf{P}$ is defined as $-Ne\mathbf{X}$, where N is the number of electric dipoles, $\mathbf{X}$ is the displacement of the electrons, and e is the charge on an electron. Here $\mathbf{X}$ is a complex number. Now, $\mathbf{P}$ is related to the electric field E by $\mathbf{P} = \varepsilon_0 \chi E$, where χ is the susceptibility and ε_0 is the permitivity of free space.

The linear dielectric constant is $\mathrm{Re}(1 + \mathbf{X})^{1/2}$, which is just the index of refraction. The imaginary part causes optical absorption.

When the intensity of illumination is high, the elastic limit of the electron's displacement is exceeded and the harmonic restoring force becomes nonlinear in $\mathbf{X}$, which adds quadratic and higher order terms to the expression for $\mathbf{X}$ and $\mathbf{P}$. In addition to the fundamental resonance, the dipoles now also oscillate at twice and thrice their fundamental resonant frequency (second and third harmonics). The polarization then is also nonlinear in displacement and can be expressed by the well-known relation

$$\mathrm{P} = \varepsilon_0(\chi^{(1)}\mathrm{E} + \chi^{(2)}\mathrm{E}^2 + \chi^{(3)}\mathrm{E}^3 + \ldots) \qquad [4]$$

where $\chi^{(2)}$ and $\chi^{(3)}$... are called the nonlinear susceptibilities. The second-order polarization $P^{(2)}$ causes optical mixing phenomena, involving sums and difference frequencies. When mixed with a DC field, the refractive index of the $\chi^{(2)}$ material can be controllably varied by varying the DC field. This is the well-known Pockels effect and is used in optical modulators. Figure 6 shows one method that is used to modulate the refractive index by the photorefractive effect. Here two laser beams (A_1 and A_2) are mixed in the $\chi^{(2)}$ material with the resulting intensity $I = I_o(1 + m\cos(kx))$. The material is polarized in phase with the mixed beams $\rho = \rho_o(1 + m\cos(kx))$, which results in a modulated electric field E_{sc}. The refractive index (Δn in the figure) is modulated in phase with the mixing signal. The $\chi^{(2)}$ materials are also used for frequency doubling.

Barium titanate ($BaTiO_3$), lithium niobate ($LiNbO_3$), KH_2PO_3 (KDP), lithium tantalite ($LiTaO_3$) and potassium niobate ($KNbO_3$) are $\chi^{(2)}$ optical switching and frequency doubling materials that have been studied for decades. Note that because they can be easily polarized, these are also excellent piezoelectric/ferroelectric smart materials.

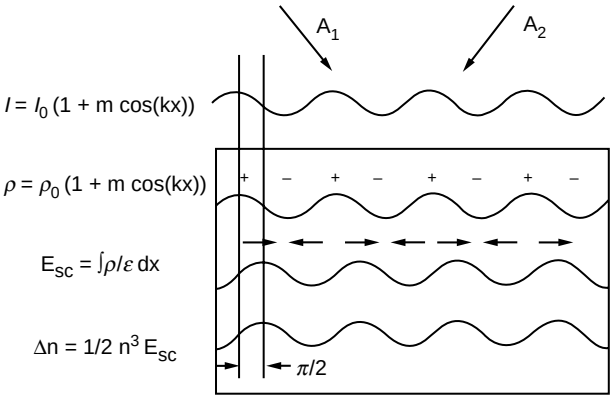

Figure 6 Modulation of the refractive index of a nonlinear optical material with incident laser modulation. From top to bottom: modulated laser intensity I, density ρ, electric field E_{sc}, refractive index Δn, and phase angle $\pi/2$. (Reproduced with permission from Bass M (ed.) (1995) *Handbook of Optics II*. New York: McGraw-Hill.)

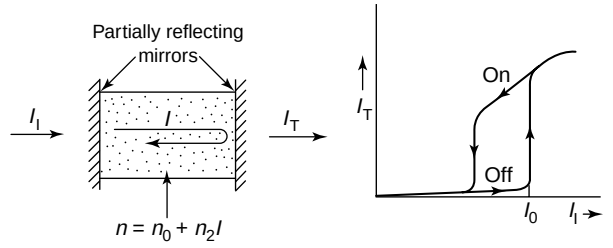

Figure 7 Optical switching behavior of a Fabry–Perot filter. I_i and I_T are the incident and transmitted intensities respectively. (Reproduced with permission from Butcher PN and Cotter D (1990) *The Elements of Nonlinear Optics*. Cambridge, UK: Cambridge University Press.)

The $\chi^{(3)}$ effects are sought after for applications such as laser eye protection, optical sensor protection, optical switching, optical limiting, and signal processing. In this case the refractive index (real and imaginary) depends on the intensity of the incident radiation. Figure 7 shows how this nonlinear effect is used in an optical switching device. It is all based on the change in the optical path length of a Fabry–Perot filter. At normal intensities, the refractive index of the spacer layer is n_0 and the filter is in the 'off' state. The refractive index becomes $n_0 + n_2 I$ and the optical thickness (nt) of the spacer layer changes at high illumination intensities, which in turn shifts the resonant wavelength (frequency) of the Fabry–Perot filter and creates the optical switch ('on' state).

There are a large number of $\chi^{(3)}$ and $\chi^{(2)}$ organic materials, including dyes, dimethylamino nitrostilbene, methyl nitroanaline, poly-BCMU, polydiacetylenes, and urea. Because they are essentially chains, many organic molecules can be easily polarized and possess higher order susceptibilities. The polarizability of organic materials is often enhanced by the mobility of delocalized π electrons in C–C bonds in aromatic rings. Hybrid nonlinear materials have even been formed by combining organic and inorganic components such as metallophthalocyanines which display very strong excited state absorptions. Most of these materials are deposited by spin casting.

Emissive Materials

Two of the newest applications of smart optical materials are emissive displays and electronic ink. This encompasses light-emitting polymers and small molecules, light-emitting diodes, and quantum cascade lasers. Organic light-emitting device (OLED) technology is leading the revolution in the flat panel display industry. This device was first invented by Tang and Van Slike and first reported in *Applied Physics Letters* in 1987. Figure 8a shows the layer structure of the OLED and Figure 8b shows a blue OLED pixel. The device is deposited onto an indium tin oxide (ITO)-coated glass or plastic substrate, with the ITO acting as the anode. The active layers can be either light-emitting polymers or small molecules. About 500 Å of a hole transport material (hole transport layer, HTL), here a tertiary amine, is deposited over the ITO. An aluminum trisquinalate (Alq), which transports electrons (electron transport layer, ETL) is deposited next. The device is topped off with

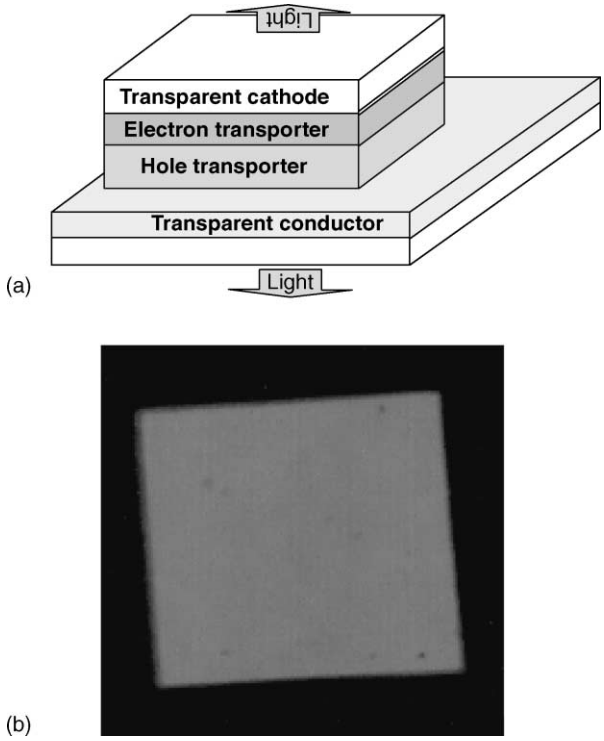

Figure 8 (a) Layer diagram of an OLED. (b) Blue OLED pixel.

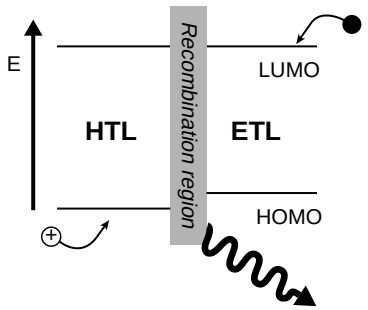

Figure 9 Simple energy level diagram of an OLED showing the relationship between the ETL and LUMO, and HTL and HOMO.

a low work function cathode, usually Ag:Mg or Ca. The entire device thickness is about 1000 Å. Even a dust particle can ruin the operation of an OLED by creating inactive regions or shorting out the electrodes.

The OLED emits light in a blue, green, or red wavelength band when activated by an electric current, i.e., electron and hole injection. The device functions by injecting holes from the ITO into the HTL. As shown in the simplified energy band diagram (Figure 9) for an OLED, the hole moves into the HOMO (highest occupied molecular orbital), which loosely corresponds to the valence band of a semiconductor. Electrons are injected from the cathode into the ETL, where it is transported into the LUMO (lowest unoccupied molecular orbital), which loosely corresponds to the conduction band of a semiconductor. When a voltage is applied between the anode and cathode, an electron flows and the holes and electrons combine in the ALQ layer and form excitons. Light is emitted when the excitons decay back a lower energy state. The color of the emitted light (green, red, or blue) can be changed by changing the HTL and ETL material composition. Light is emitted by fluorescence processes, from both singlet and triplet states if the material chemistry is correct, which results in 100% internal quantum efficiency. Twenty percent external quantum efficiency results from using all available exciton states. Photons can be lost through absorption in the layers, scattering, reflection between layers, and waveguide modes. These factors must be minimized to maximize the external quantum efficiency.

OLED video displays now have outputs near 100 cd/m (20 lm/W), which is about twice the normal video brightness. Red, green, and blue OLEDs now emit with very high efficiencies. For comparison, a 100 W light bulb emits at 17 lm/W and the best fluorescent light emits at 80 lm/W. Today, OLEDs are already sitting at intensities of 50–60 lm/W, and could easily push 150 lm/W in the near future. Another advantage of OLED displays is their wide viewing angle, up to 160°.

There are several types of OLED display configurations. Figure 10 shows a passive matrix display geometry and placement of the OLED layers. Here the OLED is sandwiched between crossed cathode and anode contacts. By injecting current between sets of crossed anode and cathode rows, the OLED will light up, each contact point forming a pixel. Displays can typically have as many as 3 million pixels. OLED displays seem brighter and livelier to the eye because the colors are additive, rather than subtractive as with LCD displays. For a full-color passive matrix display green, red, and blue pixels must be located very close together. Sony has developed an active matrix 13-inch diagonal display with 800×600 pixels (~150 000 functioning OLEDs).

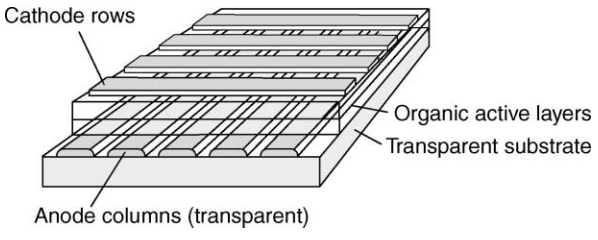

Figure 10 Geometry of a passive matrix display.

Among the more promising pixel geometries is the SOLED, the stacked OLED, where, red, green, and blue pixels are stacked on top of each other. It is mandatory that the pixels and the electrical contacts be transparent for this design, or light will not be transmitted through each layer. Very thin Mg contacts are used with a top sputtered ITO cathode. The emitted color is simply changed by applying current across the pixels, with white being obtained when all pixels are activated.

The future of OLED displays is plastics, or the flexible OLED (FOLED). Plastic substrates are lightweight, low cost, and rugged. However, they have an inherent problem of being very permeable to oxygen and water vapor, both of which severely degrade performance of the OLED by reacting with the anode layer. For displays to be practical, they must have lifetimes in excess of 10 000 hr and preferably 20 000 hr. Barrier coatings are now being developed for plastics to prevent oxygen and water ingress and extend the life of the OLED to this goal.

Electronic ink is a display medium that can be formatted using a passive matrix. It consists of millions of tiny negatively charged microcapsules, about 100 microns in diameter, floating inside a liquid medium. Each microcapsule is filled with hundreds of pigmented chips. One half of each microcapsule is white and the other half is dyed blue. When an electric charge is applied to the microcapsules, the chips are drawn either to the bottom or top of the microsphere. The viewer sees dark areas when they are drawn to the top. In another version being developed by Xerox Corp., half the chip is white and half the chip is dark. When an electric charge is placed on the chip, the dark side is oriented up and the white side down, creating dark regions where charge is placed. This can be easily erased and reformatted into text, symbols, signs, and pictures.

Future smart optical materials will simulate biological systems such as an insect's eye and will employ quantum structures to achieve optical switching, emission, and control of optical properties.

List of Units and Nomenclature

Absorptance (A)	The amount of light absorbed by an optical element divided by the incident intensity. $A = 1 - T - R$.
Active matrix display	A display geometry in which the voltage to the pixel is controlled individually by a transistor.
Candela (cd)	Formerly known as a candle. The luminous intensity equal to 1/60 of the luminous intensity per square meter of a black body radiator operating at the temperature of freezing platinum.
Exciton	An electron–hole pair, usually generated by a photon.
FOLED	Organic light emitting device on a flexible plastic substrate.
LCD	Liquid crystal diode.
Lumen (lm)	A unit of luminous flux equal to the luminous flux emitted in a solid angle of one steradian for a point source having an intensity of one candela.
NIR	The near-infrared spectral region, consisting of wavelengths between 700 and 2500 nm.
Passive matrix display	A display geometry consisting of a grid of horizontal and vertical wires. At the intersection of each grid is an active element (LCD or OLED) which constitutes a single pixel, either letting light through or blocking it.
Piezoelectric	Capable of generating a voltage when a force or stress is applied.
Polarization (coulomb/m^3)	A vector quantity equal to the electric dipole moment per unit volume.
Quantum efficiency	The number of electrons, holes, or electron–hole pairs generated per incident photon at a given optical wavelength.
Reflectance (R)	The intensity of light reflected from an optical element divided by the incident intensity. $R = 1 - T - A$.
Susceptibility (no units)	A scalar quantity equal to the ratio of the electric polarization of a material to the electric field strength.
Transmission (T)	The intensity of light transmitted through an optical element divided by the incident intensity. Note that transmission + reflection + absorption = 1 ($T + R + A = 1$).
UV	The ultraviolet spectral region consisting of wavelengths between 200 and 400 nm.
Visible	The spectral region consisting of wavelengths between 400 and 700 nm.
Wavelength (μm or nm)	The length of one oscillation of a light wave.

Sol-Gel Materials

Lisa C Klein, Rutgers the State University of New Jersey, Piscataway, NJ, USA

Introduction

Sol-gel optics represents a methodology for fabricating optical materials in fiber, thin film, and bulk geometries. Defined broadly, sol-gel optics encompasses a variety of optical devices that contain sol-gel processed components. The optical device may be based wholly on sol-gel processing or incorporate a sol-gel material, along with conventional optical materials. Principally, the optical devices prepared by sol-gel processing or assembled with sol-gel materials are traditional optics or, in some cases, opto-electronics. Among the current sol-gel optical materials, by far the most common are oxides. Further, the majority of sol-gel optics is for transparent components, which typically means glasses, and, consequently, silicates.

In fact, most sol-gel materials have been developed to duplicate conventional silica optical materials. While glass melting technology is highly advanced for making quality lenses, an equivalent material can be made using a sol-gel route. Similarly, ultralow-loss optical fiber can be made by chemical vapor deposition (CVD). Now sol-gel processing can be used to prepare comparable fibers for telecommunications. In cases where sol-gel processing produces an exact duplicate of optical materials produced other ways, the perceived advantage is that sol-gel precursors have a higher purity and better level of mixing than powder raw materials. Perhaps, a more significant advantage is that sol-gel formulations can be designed to promote a particular geometry in the final material, essentially making near-net shape materials.

While sol-gel processing is not designed to produce new optical phenomena, it does offer new ways to assemble materials to produce new optical designs, such as filters, Bragg gratings, amplifiers, and beam splitters. One noted case of sol-gel materials in nonlinear optics is the case where semiconductor particles are trapped in nanometer-sized pores. This leads to so-called quantum dots. The microporosity of the gel, no doubt, assists in this effect, but it is not the gel itself that has produced the optical effect. The optical effect is derived from the nanometer size of the particles. The gel serves as a transparent host that restricts the size of the particles and provides for their uniform distribution.

Sol-Gel Chemistry of Oxide Optical Materials

The sol-gel process for oxides is the name given to any one of a number of processes involving a solution or

sol that undergoes a sol-gel transition. Solution refers to a single-phase liquid, while a sol is a kinetically stabilized suspension of colloidal particles. At the transition, the solution or sol becomes a rigid, porous mass by destabilization, precipitation, or supersaturation. Once the solution or sol goes through a sol-gel transition, it is a rigid two-phase system of solid and solvent filled pores. The sol-gel transition is not reversible.

In using a sol-gel process, it is important to be familiar with the reagents, the intermediates and the products. The most important reagent in this case is a hydrolyzable organometallic which is called a metal alkoxide, $M(OR)_x$ where (OR) is an alkoxy group. Alkoxides are the precursors for SiO_2, GeO_2 or B_2O_3, among others. Hydrolysis occurs when the metal alkoxide and water are mixed in a mutual solvent.

The first step is choosing the right reagents. Since most of the glasses are silicates, we start with the silica precursor. Of the available silicon alkoxides, tetraethylorthosilicate (TEOS) is used most often, because it reacts slowly with water and comes to equilibrium as a complex silanol. The colorless liquid $Si(OC_2H_5)_4$ has a density of about 0.9 g/cm^3, is easy to handle safely and is extremely pure when distilled. Most metal alkoxides are prepared by the reaction of halogenated species or pure metals with alcohol.

The two other ingredients in a typical formulation are alcohol and distilled water. In the case of TEOS, ethanol serves as the mutual solvent for TEOS and water. Once TEOS is dissolved in ethanol to make it soluble in water, the chemical reactions hydrolyzation and polymerization begin. The chemical reactions are approximately:

Hydrolyzation

$$-\overset{|}{\underset{|}{Si}}-O-C_2H_5 + H_2O \rightarrow -\overset{|}{\underset{|}{Si}}-OH + C_2H_5OH \qquad [1]$$

Polymerization

$$-\overset{|}{\underset{|}{Si}}-O-C_2H_5 + Si-OH \rightarrow -\overset{|}{\underset{|}{Si}}-O-\overset{|}{\underset{|}{Si}} + C_2H_5OH \qquad [2]$$

An acid is usually added to control the rates of these reactions. The temperature is often ambient, and mixing is continued for between 1 and 3 hours. Complete hydrolysis does not occur. Instead, condensation occurs between silanol and ethoxy groups to give bridging oxygens or siloxane groups. The intermediates that remain soluble in the alcohol–water medium are silanols, ethoxysilanols, and polysiloxanes.

The equipment needed for laboratory-scale production consists of a narrow-necked glass flask with magnetic stir bar on a stirring hot plate. The reactants are added volumetrically to the flask in the order: solvent, TEOS, water, and acid. When everything is dissolved and the solution is clear, the hot plate may be turned on to accelerate reactions or a reflux condenser may be attached.

The parameters that influence the chemical reactions are temperature, pH, amount of water, solvent, and precursor. More complex compositions are easier to mix in longer chain alcohols, and longer chain organic groups give slower reaction rates. Low pH favors a polymerization scheme that gives linear molecules and the solution remains clear. High pH favors cluster growth and the solution may become cloudy. At high pH or high water, solutions produce cross-linked polymers or branched clusters. A small volume fraction of branched clusters restricts flow, when the same volume fraction of linear polymers does not. At a higher volume fraction, the linear polymers become tangled, and then low water solutions will gel. The result of these reactions under all conditions is an increase in the molecular weight of the oxide polymer. Eventually, the solution reacts to a point where the molecular structure is no longer reversible, and the sol-gel transition has been reached.

Shapes, Compositions and Precursor Concentrations

A sampling of compositions and precursors is given in Table 1. Some compositions such as SiO_2 and TiO_2–SiO_2 have been prepared in bulk, to duplicate materials made by melting for lenses and mirror blanks. Other compositions such as B_2O_3–SiO_2 have been prepared for thin-film applications. The distinguishing aspect between the solutions formulated for bulk objects and those formulated for thin films is the oxide concentration in the solution. An indication of the solution concentration is the molar ratio of water to alkoxide. The higher ratios are used when bulk objects are desired.

Table 2 gives a sampling of the geometries for sol-gel silica. For each geometry, an example of a shape is given, with an application for each shape and the approximate dimensions of the sol-gel material.

In terms of near-net shape processing, when the material goes through its sol-gel transition, it proceeds to dry and shrink. This phase is characterized either by isotropic shrinkage or anisotropic shrinkage. Monoliths fall into the first category with isotropic shrinkage following molding. Thin films on substrates fall into the second category with anisotropic shrinkage following dipping. Fibers also show

Table 1 Typical compositions of sol-gel optical materials

Oxides	*Precursors*	*Compositions in mol %*	R^*
Single oxide

Table 2 Geometries and approximate dimensions for selected applications of sol-gel silica

Geometry	*Shape*	*Dimensions*	*Application*
Monolith	Flat disk	10 cm diameter 1 cm thick	Lens
	Cylinder	0.5 cm diameter 2 cm long	Rigid host for chromophores
Thin film	Film on Si wafer	500 nm thick	Antireflection
	Film on Hollow tube	~10 000 nm thick	Solar collector panel
Fiber	Rod	0.8 cm diameter 25 cm long	Preform for drawing
	Filament	150 micron diameter/100 m length	Lightguide

anisotropic shrinkage, though it depends on whether or not the fiber is drawn from a preform many times its diameter or produced from a filament that is closer to its diameter.

Sol-Gel Monolith Processing

Monoliths formed from an alkoxide solution are achieved only in dilute solutions. Therefore, alkoxide gels are somewhat difficult to dry because of their small pores (<10 nm). To avoid cracking in alkoxide gels, different treatments have been tried. Aerogels are dried in an autoclave by hypercritical techniques. That is, the solvent is removed above its critical point. The resulting gel is about 10% dense and shows no shrinkage. Xerogels are dried by natural evaporation. Xerogels are 60% dense and have reductions 40–60% in volume.

Alternatively, monoliths can be formed from colloidal solutions. These particles coalesce at gelling. Colloidal gels are easily dried, and they are less likely to crack than alkoxide xerogels. While alkoxide gels have small pores, colloidal gels have larger pores or voids between particles. For the same reason, colloidal gels densify at higher temperatures than alkoxide xerogels. The higher temperature for colloidal gels may lead to undesirable crystallization.

By either route, a serious problem for sol-gel processing is the presence of water. Especially when monoliths are used for fiber drawing, residual OH ions have a deleterious effect on optical properties. That is why non-aqueous solvents, as well as fluorination or chlorination treatments, have been investigated to reduce the OH content.

Sol-Gel Fiber Processing

While monolithic pieces need high water content, fibers can be drawn out of low water content

solutions. The sol-gel process allows one to bait and draw a string of gel about the same diameter as the desired fiber directly from the solution. This has been shown where the water to alkoxide ratio was controlled to give the property of spinnability. The time and manner in which the system loses fluidity depend on composition and catalyst. Low water solutions show a gradual increase in viscosity before losing fluidity, while high water solutions lose fluidity more abruptly from a lower viscosity. A problem with this method is the shape of the fiber, which tends not to be cylindrical.

Another approach to making near-net shape fibers from a sol-gel process involves coating a shell or concentric shells of sol-gel glass on a filament of textile fiber. This approach is referred to as the volatile host method, where a plastic filament is used as a template. Multiple dipping or adjustment of the viscosity can lead to different thicknesses. Upon exposure to atmospheric moisture, the films gel. After gelling, a rigid, continuous shell runs the length of the filament.

Once the shell has hardened, solvent and water can escape through interconnected pores. The shell shrinks in the radial dimension, but remains continuous along its axis. During heat treatment and desiccation, little if any densification occurs at temperatures well below the glass transition. The interconnected pore structure remains open until the volatile host is eliminated and undesirable gases are removed. This method is capable of producing optical fibers, but is more suitable for hollow fibers or ion exchange media.

Sol-Gel Thin Film Processing

Like sol-gel fibers, sol-gel thin films are prepared from low water content solutions. The process is exceedingly simple. A solution containing the desired oxide precursors is applied to a substrate by dipping or spinning.

At this time, the majority of sol-gel coatings are applied by dipping. This is an approach that allows the properties of the solution to control the deposition. A substrate is lowered into a vessel containing the solution. A meniscus develops at the contact of the liquid and the substrate. As the substrate is withdrawn, the meniscus generates a continuous film on the substrate. The process is able to apply a coating to the inside and outside of complex shapes simultaneously.

The equipment is inexpensive, especially in comparison to any deposition techniques that involve vacuum. Coatings can be applied to metals, plastics, and ceramics. Typically, the coatings are applied at room temperature, although most need to be calcined and densified with heating. Dip films are typically one micron, uniform over large areas and adherent. The time-to-gel is especially important when it comes to coatings because film formation, drying, and creation of pores must be rapid. Optimum film formulations correspond to those solutions that lose tackiness quickly.

In most cases, the effect of the viscosity is far greater than the surface tension. Two simple relationships are that the film thickness increases with increasing withdrawal rate and, for a given withdrawal speed, the film thickness increases with an increase in oxide content. The process is frequently a batch process, certainly on the laboratory scale. However, the batch process can be scaled up. Repeated dipping builds up a thicker film.

For one-side coating, a technique that is often used is spin coating. In this case, the substrate, usually a silicon wafer, is placed on a spinner, rotated at perhaps 200 rpm while solution is dripped on the center of the substrate. As with dip coatings, a film between 50 and 500 nm results.

After the Sol-Gel Transition

Having selected a shape and designed the formulations accordingly, there are several further steps common to monoliths, fibers, and films. First of all, the gels must be dried. Using the example of silica, TEOS is less than 30% by weight silica and the solution is even less. From the time the solution is applied to the time it gels, there is about 50% weight loss. Then, as the gel dries there is another reduction in weight by one-half. To go along with the weight loss there is about 70% volume reduction.

Films can be dried quickly in air because of the one thin dimension. It has been shown repeatedly that all shrinkage is taken up in the thin dimension and not in the plane of the substrate. Yet, the films remain adherent and continuous and maintain complete surface coverage. To go from a tacky film to a hard film may take only a few minutes.

Following drying and shrinkage comes the heat treatment. It would be inaccurate to say that glass has been formed at room temperature by simply reacting, gelling, and drying the solutions. In this state, the materials have many of the characteristics of the corresponding glass, but they are more or less porous. Water and solvent escape through interconnected pores that remain open at the surface until the gels are fired to temperatures well above 600°C. When needed to fulfill the requirements of an application, the hard gel is heated to various degrees of collapse.

The microporosity in silica xerogels is not removed entirely until 1000°C.

Applications of Sol-Gel Optical Coatings

Sol-gel processing has a special relevance to optical coatings. In most cases, the applications are substitutions of a sol-gel coating for a coating obtainable by other means. Most optical coatings achieve their effect by selective absorption and interference. By depositing 1–14 or more layers of dielectric thin films, using two or more different compositions, a variety of antireflection (AR), half-mirror, hot-mirror and cold-mirror coatings can be designed. An early design was for rear-view mirrors for cars, where the coatings consisted of titania-silica-titania interference filters that gave the effect of total reflectance and replaced conventional metallizing. Another early application was solar reflecting films for windows. These coatings consisted of Pd-containing titania films which show selective absorption.

A sampling of optical coatings is given in Table 3. The application, the mechanism, and the oxide composition are listed. Generally, these coatings can be prepared by other deposition techniques. Those applications which are specific to sol-gel coatings relate to the microporous nature of the sol-gel processed films. In Table 3, there are antireflective coatings of several types. Both borosilicates and titania silicates have been developed for this application. Changes in the composition, changes in the microstructure, and changes in the porosity can be used to grade the index of refraction. Antireflection in the ultraviolet range has been accomplished with thoria and hafnia films. Broadband antireflection has been used for laser optics. The sol-gel coating technique provides control over composition and deposition thickness. The layers, being quarter wavelength in thickness, require precise control.

Table 3 Thin-film applications

Optical application	*Mechanism*	*Typical composition*
Color filters	Selective Absorption	Cr_2O_3–SiO_2
Mirror	Interference	14-layer TiO_2: SiO_2
Antiglare	Absorption	CoO–SiO_2
Antireflection		
Narrow	Graded porosity	SiO_2
Broadband	Interference	Three-layer
	1/4 wavelength	SiO_2–TiO_2:ZrO_2: SiO_2
	Graded porosity	SiO_2
IR reflector	Interference	Three-layer TiO_2:Ag:TiO_2

Sol-Gel Rigid Hosts

An exciting way of looking at sol-gel materials is to use the gel as a host. The important point to note is that the sol-gel materials are transparent. While most of the materials are porous, the porosity is on a scale that does not scatter visible light. Therefore, most light is transmitted. The appeal of the bulk shape host is that it can be molded to near-net shape and can be cut and polished.

Hybrids

Several approaches have been taken to prepare so-called hybrid gels incorporating organic and inorganic components. Those methods that mix the components on the nanometer scale include the infiltration of previously formed oxide gels with monomers, reacting of alkoxide and organic monomers, or organic polymers with alkoxides in mutual solvents. The products of these processes are variously called ormosils (organically modified silicates), ceramers (ceramic polymers), interpenetrating networks (IPNs) and nanocomposites.

The original route to hybrids was one where a gel was formed first as a rigid matrix. Monomer was infiltrated into the open porosity of the shaped gel and polymerized inside the gel using UV curing, for example. Since silica gel is the easiest gel to prepare in monolithic form, one combination that has been investigated widely is silica gel/polymethyl methacrylate (PMMA).

Silica and PMMA, which both have good visible light transmission and similar index of refraction, have been used in hybrids, although it turns out that the match in index of refraction is less critical on the nanoscale. They are also glassy materials with similar strength. PMMA has much higher fracture energy than silica and is often used as glazing in applications where impact resistance is a priority. However, PMMA has a much lower hardness than silica and is less resistant to abrasion. Ideally, silica–PMMA hybrid nanocomposites have the strength and impact resistance of PMMA, and the hardness of silica in one. One obvious application is transparent, lightweight windows.

Encapsulation

Sol-gel hosts have been used to encapsulate a variety of organic and inorganic molecules, chromophores, and biological agents. Whatever is incorporated into the gel can act in two ways, to

give information about the gel host or to be influenced by the gel in its interaction with light. For example, spiropyrans have been incorporate for photochromics, CdS for nonlinear optics, Nd for tunable lasers, and various enzymes for sensors. Early on, silica gel hosts were used to encapsulate the electro-optically active organic compounds 2-methyl-4-nitroaniline (MNA). In comparison to conventional optical cells, MNA doped silica hosts retained optical quality at higher temperature and were more abrasion resistant. Since this discovery, silica hosts, in particular, and sol-gel processing, in general, has been used extensively for encapsulating molecules and species that cannot be heated, but need to be protected in a rigid matrix.

Future Directions

As more and more is learned about the sol-gel process, the greater the number of possibilities for useful optical devices. In the selected examples given above, a key feature is that the sol-gel material is transparent. In addition, the sol-gel material is suitable for application to a variety of substrates. Also, the process is a low-temperature process that is compatible with polymers and organic chromophores. In summary, sol-gel processing has had a number of successes in its application to optical materials, and its use is likely to expand.

OPTICAL MICROLENSES

H Ottevaere and H Thienpont, Vrije Universiteit Brussel, Brussel, Belgium

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

In today's world of information processing the role of optics and opto-electronics is expected to become increasingly important as the performance of communication, processing, sensing, and display technologies is continuously evolving. Making these photonics technologies faster and smaller requires, at the same time, the introduction of massive parallelism and miniaturization. As a result, high-quality, high-precision, and low-cost microlens arrays are becoming indispensable components. Moreover, the introduction of micro-optics provides new degrees of freedom for the system design and, therefore, also for the functionality. It allows solutions which are not possible with purely conventional optics such as the integration of different micro-optical components and systems, hence reducing the additional mechanical assembly cost as required in conventional optics.

Since the beginning of the 1990s, several research groups and industrial research labs have been focusing their attention on the development of fabrication techniques for refractive and diffractive microlenses. Microlenses and microlens arrays are used for beam shaping purposes such as collimation and focusing (e.g., in combination with laserdiode arrays, detector arrays, and fibers), for illumination (e.g., in display systems and projection systems), and for imaging purposes (e.g., in photocopiers).

In this article we will mainly focus on refractive microlenses and we intend to provide an introductory guide to those basic geometrical and optical parameters that are used to characterize refractive microlenses. Indeed, some elementary principles of geometrical optics (the geometrical laws for optical propagation without the inclusion of diffraction) and wave optics (in wave optics the imaging is studied as a result of the propagation of a wavefront to the image

plane; diffraction effects can be explained on the basis of this wave theory) are required to understand the characterization and performance evaluation of these lenses. We, therefore, bring forward the basic nomenclature of refractive micro-optics and will highlight how the performance of an optical lens is affected when reducing its physical dimensions.

We start this article by introducing the imaging properties of both thick and thin lenses in the paraxial approximation. In the section on lens aberrations, we discuss the different primary aberrations that influence the imaging properties of a lens. Combined effects of aberrations and diffraction give rise to some frequently used lens performance criteria which we discuss in the section on diffraction. Different aspects have to be considered when discussing the quality of a lens, because each type of microlens application requires specific performances. It is, therefore, not possible to come up with a single figure of merit which satisfactorily evaluates the overall quality of a microlens. Moreover, one needs specific information about the characteristics of the light sources and detectors that are used in the system and also details about the imaging system geometry and the required imaging contrast. We review them in the section on quality criteria.

In the section on interference, we describe these phenomena and focus on two-beam interference that forms the basis of the photonic instrumentation that can be used to characterize discrete microlenses and microlens arrays. For a complete evaluation of a microlens it is essential to measure both its geometrical properties (diameter, sag, surface profile, etc.) and its optical performance (focal length, wave aberrations, etc.). In the final section of this article we introduce three interference-based instruments which are crucial to the full quantitative characterization of refractive microlenses: a noncontact optical profiler based on a Mirau interferometer, a transmission Mach–Zehnder interferometer, and a Twyman–Green interferometer.

Geometrical Optics

Introduction

Within the paradigm of geometrical optics or ray-optics, light travels from the source along straight lines or rays. When a light ray traverses an optical system consisting of several homogeneous media in sequence, the optical path is a chain of straight-line segments. Discontinuities in the line segments occur each time the light is refracted or reflected. The laws of geometrical optics that describe the direction of the rays are described below.

The law of refraction, also called Snell's law
The refraction of a ray at a 'well-polished' surface between two isotropic media, with indices of refraction n_1 and n_2, is given by

$$n_1 \sin \varphi_1 = n_2 \sin \varphi_2 \qquad [1]$$

where φ_1 and φ_2 are the angles between, respectively, the incident and the refracted ray and the normal to the surface.

The law of reflection
When a ray is reflected on a flat 'polished' interface dividing two uniform media, the reflected ray remains within the plane of incidence and the angle of reflection equals the angle of incidence.

Geometrical wavefronts can then be constructed from the optical rays propagating through the system. Locally they are orthogonal to the rays and the optical path lengths along all rays from one wavefront to another are equal. In regions where the wavelength is considered to be negligible, as compared to the dimensions of the relevant components of the optical system, geometrical wavefronts are close approximations of the physical wavefronts.

The Paraxial Approximation

The basic optics of image location and magnification is demonstrated by the application of paraxial or first-order optics, also called Gaussian optics. In the paraxial approximation, only those points and rays will be considered which lie in the immediate vicinity of the optical axis, so that all angles φ are small ($\varphi \leq 15°$). This assumption is true in lens systems with small object and image field sizes and small apertures of pupils. The terms involving squares and higher powers of the off-axis distances or of the angles, which the rays make with the optical axis, will not be discussed here. This leads to:

$$\sin \varphi = \tan \varphi = \varphi + O_{\geq 2}(\varphi) \approx \varphi \qquad [2]$$

With this assumption we can write the refraction law by the linear relation:

$$n_1 \varphi_1 = n_2 \varphi_2 \qquad [3]$$

Refraction at a spherical surface
In Figure 1 a spherical surface with a radius of curvature R forms an interface between two materials with indices of refraction n_1 and n_2. Two rays are shown emanating from an axial object point S. One is an axial ray, normal to the surface of the lens at its vertex V. The vertex of a lens is defined as the point on the refracting surface at the center of its free aperture. This assumes that the aperture is circular

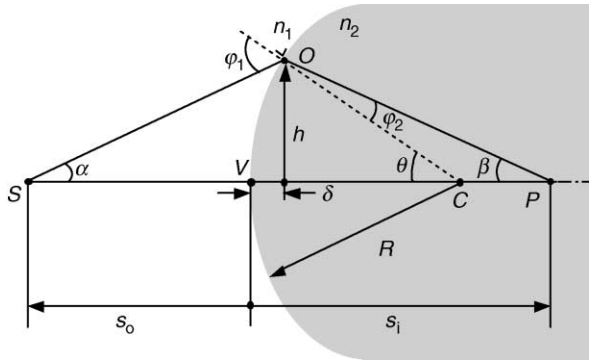

Figure 1 Refraction at a spherical surface.

and centered and the surface is spherical. More generally, if the surface is not spherical but has rotational symmetry, the vertex is the point where the axis of symmetry intersects the optical surface. It is refracted without any change in direction. The other ray is an arbitrary ray incident at O and refracting there according to Snell's Law.

We can rewrite the paraxial refraction law (eqn [3]) and derive a relation between the object and image distances, s_o and s_i, respectively.

From the triangles SOC and POC, we have:

$$\varphi_1 = \alpha + |\theta| \qquad |\theta| = |\beta| + \varphi_2 \qquad [4]$$

where $|\theta|$ and $|\beta|$ represent the absolute values of θ and β.

We also have:

$$\tan\alpha = \frac{h}{|s_o| + \delta} \qquad \tan|\beta| = \frac{h}{s_i - \delta}$$
$$\tan|\theta| = \frac{h}{R - \delta} \qquad [5]$$

As discussed above, for paraxial rays we may approximate the sine and tangent of an angle by the angle itself and one can show that the small distance δ may be ignored. In accordance with the sign convention the object distance, being to the left of the refracting surface, is to be taken as negative. Inserting eqns [4] and [5] into [3] results in:

$$\frac{n_2}{s_i} - \frac{n_1}{s_o} = \frac{n_2 - n_1}{R} \qquad [6]$$

This equation does not contain the angle α, so the image distance s_i is the same for all paraxial rays starting from S.

The spherical surface power $\wp$ is now defined as:

$$\wp \equiv \frac{n_2 - n_1}{R} \qquad [7]$$

We can relate this power of the surface $\wp$ to the object and image distance, by combining eqns [6] and [7]:

$$\frac{n_2}{s_i} - \frac{n_1}{s_o} = \wp \qquad [8]$$

The distance from the object point to the vertex of the refractive surface is called the front focal length f_{FFL}, if the image is at infinity ($s_i = \infty$). Equations [6] and [8] then give:

$$f_{FFL} = -\frac{n_1}{n_2 - n_1}R = -\frac{n_1}{\wp} \qquad [9]$$

Similarly, if the image is placed at the back focal length f_{BFL}, such that the object distance equals infinity ($s_o = \infty$), then:

$$f_{BFL} = \frac{n_2}{n_2 - n_1}R = \frac{n_2}{\wp} \qquad [10]$$

Thick lenses

A thick lens can be treated as a component consisting of two spherical refracting surfaces separated by a distance d between their vertices V_1 and V_2, as shown in Figure 2. The determination of the focal length as a function of the object and image distance and of the radii of curvature can also be solved using the matrix formalism.

The first and second focal points or the object and image foci, F_o and F_i, can be measured from the two vertices or poles and are called the front and the back focal length denoted by f_{FFL} and f_{BFL}, respectively (Figure 2). The incident and the emerging rays will virtually meet at points that belong to two curved surfaces. These surfaces, approximating planes in the paraxial region, are termed the primary and secondary principal planes, PP_1 and PP_2. Points where the primary and secondary principal planes intersect the optical axis are known as the first and second principal points, H_1 and H_2, respectively.

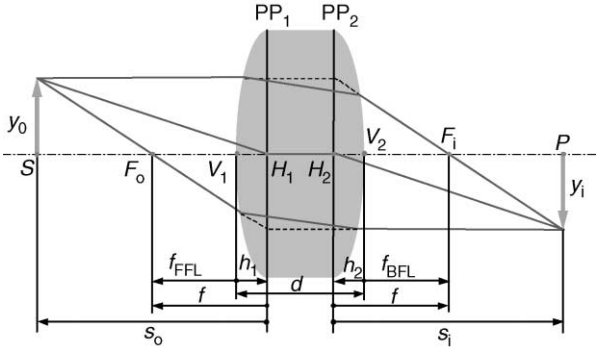

Figure 2 The thick lens geometry.

They provide a set of very useful references from which to measure several of the system parameters. To fully describe a system by its cardinal points, two more points are needed in addition to the two focal points, F_o and F_i and the two principal points, H_1 and H_2. These points are called the nodal points. However, they coincide with the principal points when the lens is surrounded on both sides by the same medium, for example, air. Note that h_1 and h_2 determine the positions of the principal points relative to the vertices V_1 and V_2, while f determines the focal point position relative to the principal points. One can show that these distances are given by:

$$h_1 = \frac{-R_1 n_m d}{n_l(R_2 - R_1) + (n_l - n_m)d}$$

$$h_2 = \frac{R_2 n_m d}{n_l(R_2 - R_1) + (n_l - n_m)d} \qquad [11]$$

$$f = \frac{n_m}{(n_l - n_m)\left[\frac{1}{R_1} - \frac{1}{R_2} + \frac{d(n_l - n_m)}{n_l R_1 R_2}\right]}$$

We now derive the Gaussian formulae that describe imaging through two surfaces which are rotationally symmetric about the same axis. We assume here that the lens, with refractive index n_l, faces the same medium of refractive index n_m on both sides (**Figure 3**). We can correctly use this hypothesis since the microlenses which we discuss throughout this work are mainly surrounded by air. Let R_1 and R_2 be the radii of curvature of the surfaces at their axial points, measured as positive when the surface is convex towards the incident light.

The image of a given object, formed by refraction at the first surface with radius of curvature R_1, becomes the object for refraction at the second surface. The image formed by the second surface with R_2 as radius is then the final image due to the action of the thick lens. We know from eqn [6] that the paraxial rays issuing from S at a distance s_{o1} from V_1 will meet at P', at a distance which we call s_{i1}. This gives:

$$\frac{n_l}{s_{i1}} - \frac{n_m}{s_{o1}} = \frac{n_l - n_m}{R_1} \qquad [12]$$

Thus, at the second spherical surface, eqn [6] becomes:

$$\frac{n_m}{s_{i2}} + \frac{n_l}{(s_{i1} - d)} = -\frac{n_m - n_l}{R_2} \qquad [13]$$

As discussed above, we have:

$$-\frac{1}{f_{FFL1}} = \frac{n_l - n_m}{n_m}\frac{1}{R_1}$$
$$\frac{1}{f_{BFL2}} = -\frac{n_m - n_l}{n_m}\frac{1}{R_2} \qquad [14]$$

where f_{FFL1} is the front focal length of the first refracting surface and f_{BFL2} the back focal length of the second refracting surface.

Eliminating s_{i1} in eqns [12] and [13] and inserting [14] yields:

$$d = \frac{n_l}{n_m\left(\frac{1}{s_{o1}} - \frac{1}{f_{FFL1}}\right)} - \frac{n_l}{n_m\left(\frac{1}{f_{BFL2}} - \frac{1}{s_{i2}}\right)} \qquad [15]$$

where s_{o1} is measured with respect to V_1 and s_{i2} is measured with respect to V_2. After some calculations this equation may also be put in the form:

$$s_{o1}s_{i2} - \frac{f_{BFL2}(n_l f_{FFL1} + d n_m)}{n_l(f_{FFL1} + f_{BFL2}) + d n_m}$$
$$s_{o1} - \frac{f_{FFL1}(n_l f_{BFL2} + d n_m)}{n_l(f_{FFL1} + f_{BFL2}) + d n_m} \qquad [16]$$
$$s_{i2} + \frac{d n_m f_{FFL1} f_{BFL2}}{n_l(f_{FFL1} + f_{BFL2}) + d n_m} = 0$$

Obviously eqn [16] is much too cumbersome to find image locations. However, we can transform and reduce the latter equation to the form:

$$\frac{1}{s_{i2} - h_2} - \frac{1}{s_{o1} - h_1} = \frac{1}{f} \qquad [17]$$

where h_1, h_2 and f are the unknowns.

Indeed, rewriting eqn [17] gives:

$$s_{o1}s_{i2} - (f + h_2)s_{o1} + (f - h_1)s_{i2} + f(h_1 - h_2) + h_1 h_2 = 0 \qquad [18]$$

Equations [16] and [18] will be identical if the coefficients of their corresponding terms are equal;

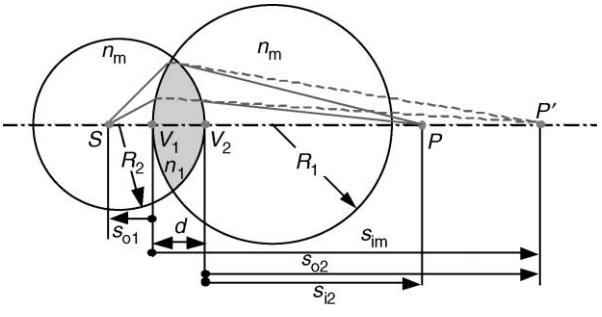

Figure 3 Refraction at both spherical surfaces of a thick lens.

that is when:

$$f + h_2 = \frac{f_{\mathrm{BFL2}}(n_{\mathrm{l}} f_{\mathrm{FFL1}} + dn_{\mathrm{m}})}{n_{\mathrm{l}}(f_{\mathrm{FFL1}} + f_{\mathrm{BFL2}}) + dn_{\mathrm{m}}}$$

$$f - h_1 = -\frac{f_{\mathrm{FFL1}}(n_{\mathrm{l}} f_{\mathrm{BFL2}} + dn_{\mathrm{m}})}{n_{\mathrm{l}}(f_{\mathrm{FFL1}} + f_{\mathrm{BFL2}}) + dn_{\mathrm{m}}} \qquad [19]$$

$$f(h_1 - h_2) + h_1 h_2 = \frac{dn_{\mathrm{m}} f_{\mathrm{FFL1}} f_{\mathrm{BFL2}}}{n_{\mathrm{l}}(f_{\mathrm{FFL1}} + f_{\mathrm{BFL2}}) + dn_{\mathrm{m}}}$$

These three equations may be solved for the three unknowns h_1, h_2, and f:

$$f = \frac{n_{\mathrm{m}}}{(n_{\mathrm{l}} - n_{\mathrm{m}})\left[\frac{1}{R_1} - \frac{1}{R_2} + \frac{d(n_{\mathrm{l}} - n_{\mathrm{m}})}{n_{\mathrm{l}} R_1 R_2}\right]}$$

$$h_1 = \frac{-R_1 n_{\mathrm{m}} d}{n_{\mathrm{l}}(R_2 - R_1) + (n_{\mathrm{l}} - n_{\mathrm{m}})d} \qquad [20]$$

$$h_2 = \frac{R_2 n_{\mathrm{m}} d}{n_{\mathrm{l}}(R_2 - R_1) + (n_{\mathrm{l}} - n_{\mathrm{m}})d}$$

Thus we see that the relation between the object position and the image position (eqn [16]) is expressed in the more convenient form of eqn [17] with the values of h_1, h_2, and f given by eqn [20]. Here h_1, h_2 and f depend on the constants of the system where, as shown in eqn [11], h_{i} represents the distance between the vertex V_{i} and the principal point H_{i}, and f is the focal length measured from a principal point on the axis and not from the vertex of the lens. If we now assume that:

$$s_{\mathrm{o}} = s_{\mathrm{o1}} - h_1, \qquad s_{\mathrm{i}} = s_{\mathrm{i2}} - h_2 \qquad [21]$$

we can write the thick lens equation as:

$$\frac{1}{s_{\mathrm{i}}} - \frac{1}{s_0} = \frac{1}{f} \qquad [22]$$

where the object and image distance, s_{o} and s_{i}, respectively, are measured from the principal points of the lens. We can conclude that the formula that describes imaging through two surfaces may be simplified to the thick lens formulation given in eqn [22] by choosing the principal points H_{i} instead of the vertices V_{i}, from which S and P are to be measured.

Thin lenses

The preceding eqn [20] takes a particularly simple form when the lens is so thin that the axial thickness of the lens d may be neglected. But obviously there exists no real lens with a thickness equal to zero. A thin lens is only a concept which is an extremely useful tool in optical system design. When a lens or an optical system has a zero thickness, the object and image calculations can be greatly simplified. In this case, the two principal points are coincident and are located where the thin lens is situated.

As a further simplification, we assume that the surrounding medium of the lens is air which means that $n_{\mathrm{m}} \approx 1$. When $n_{\mathrm{l}} = n$, we find:

$$\frac{1}{f} = \frac{1}{s_{\mathrm{i}}} - \frac{1}{s_{\mathrm{o}}} = (n-1)\left(\frac{1}{R_1} - \frac{1}{R_2}\right) \qquad [23]$$

These equations are often called the thin-lens equation and the lensmaker's formula, respectively, because the latter predicts the focal length of a lens, fabricated with a given refractive index and radii of curvature. This formula is very useful in the optical design process as a first-order approach to calculate the features of the thin lenses and results in a set of lens powers (or focal lengths) for the different lenses and in the spacings between them. Once the thin lens optical system is solved and the primary aberrations are corrected for, one can design the thick lens system. The corresponding thick lens system must have the same component powers and the lenses must be spaced apart by the same distances as for the thin lens design, but the thick lens spacings must be measured from the principal points of the lenses instead of from the vertices of the lenses.

Other lens characteristics

Another basic parameter of a refractive lens is its focal number $f\#$. The f-number, also called the speed of the lens, is defined as the ratio of its effective focal length and the lens aperture diameter D (Figure 4):

$$f\# = \frac{f}{D} \qquad [24]$$

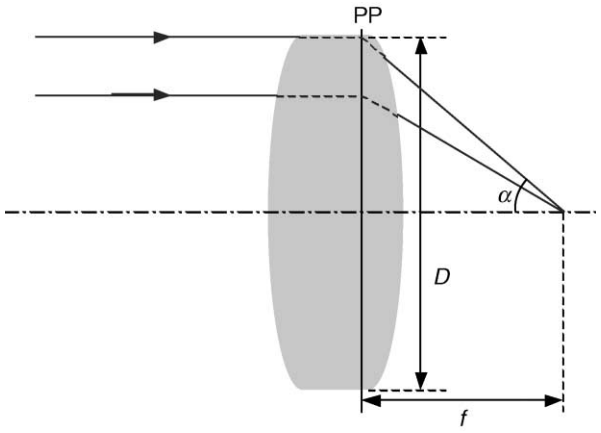

Figure 4 A lens with an aperture diameter D, a focal length f, and a semi-angle α.

The effective focal length f of a lens or often called the focal length is defined from a principal point on the axis of the lens and not from its vertex. Typical focal numbers for refractive microlenses range between 0.8 and 30.

The numerical aperture (NA), is another way of defining the same characteristic. It is described as the sine of the angular semi-aperture α in the object space multiplied by the refractive index n of the object space (Figure 4):

$$\mathrm{NA} = n \sin \alpha \qquad [25]$$

Both the focal number ($f\#$) and the NA are related in the paraxial approximation by

$$f\# = \frac{n}{2\mathrm{NA}} \qquad [26]$$

Lens Aberrations

Introduction to Third-Order Monochromatic Aberrations

An exact ray trace or a measurement on a real lens will certainly disclose inconsistencies with the corresponding paraxial description. Such deviations from the idealized Gaussian optics are known as aberrations. For monochromatic light there are five third-order or Seidel aberrations: three of them, namely spherical aberration, coma, and astigmatism, deteriorate the image by blurring it, while the remaining two, curvature of field and distortion, deform the image. An additional aberration, chromatic aberration, results from the wavelength dependence of the imaging properties of an optical system. We will not discuss the latter as this aberration can be minimized by selecting a lens material with a refractive index that only varies by a negligible amount over the wavelength range of interest.

For a brief discussion of aberrations we consider the case of a perfect lens focusing a collimated light beam. In this case, the lens transforms the incoming planewave into a spherical wave, also called the reference sphere. For a lens with aberrations, however, the real wavefront behind the lens shows deviations from the ideal spherical shape (Figure 5). The optical path length [AB] may be called the wavefront aberrations $\psi(x, y)$ and can be calculated as:

$$\psi(x, y) = W(x, y) - R(x, y) \qquad [27]$$

where $W(x, y)$ represents the spherical wavefront in the Gaussian approximation and $R(x, y)$ depicts the real wavefront. The wave aberration is given by the optical path difference along a ray between the

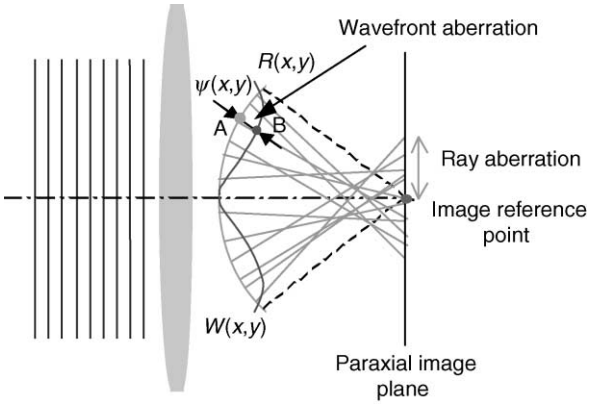

Figure 5 Relation between wavefront and ray aberration.

reference sphere and the real wavefront behind the lens. Alternatively, the aberrations can be described in terms of the ray aberrations. In this case, not all the rays intersect the paraxial image plane at the same point and the distribution of the ray intercepts around the paraxial image point can be used to measure the amount of light blur. These two ways of quantitatively describing the aberrations are apparently not independent of each other, the ray aberrations being the derivate of the wavefront aberrations.

There are several sets of suitable polynomials over which the wavefront aberrations can be expanded. The Zernike polynomials will be further used in this work (see, for example, the Mach–Zehnder and Twyman–Green interferometers in the section on Microlens testing).

For rotational symmetric optical systems, the most common approach is to expand the aberration function ψ to the fourth order as a power series in polar pupil coordinates. This corresponds to the third-order ray aberrations or primary aberrations. The different terms in the aberration polynomial ψ are to the fourth power of the object coordinate h' and the pupil coordinate r. In that case, the wavefront aberration polynomial ψ, as a function of the object coordinate h' and the polar pupil coordinates r and θ (Figure 6), is given by

$$\psi(h', r, \theta) = {}_0C_{40} r^4 + {}_1C_{31} h' r^3 \cos\theta + {}_2C_{22} h'^2 r^2 \cos^2\theta + {}_2C_{20} h'^2 r^2 + {}_3C_{11} h'^3 r \cos\theta \qquad [28]$$

The ${}_iC_{jk}$ coefficients are subscripted by the numbers that specify the powers of the term dependence on h', r and $\cos\theta$, respectively. These terms comprise the five monochromatic or Seidel aberrations as shown in Table 1.

Each aberration is characterized by its dependence on the deviation from the optical axis h', on the aperture of the refracting surface r, and on the

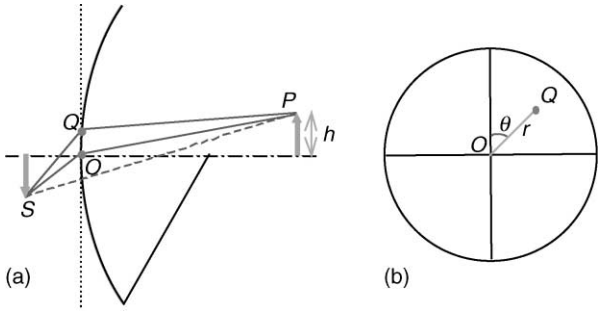

Figure 6 (a) Imaging of an off-axis point P; (b) frontal view of a portion of the wavefront.

Table 1 The five monochromatic or Seidel aberrations

r^4	Spherical aberration
$h'r^3 \cos\theta$	Coma
$h'^2 r^2 \cos^2\theta$	Astigmatism
$h'^2 r^2$	Curvature of field
$h'^3 r \cos\theta$	Distortion

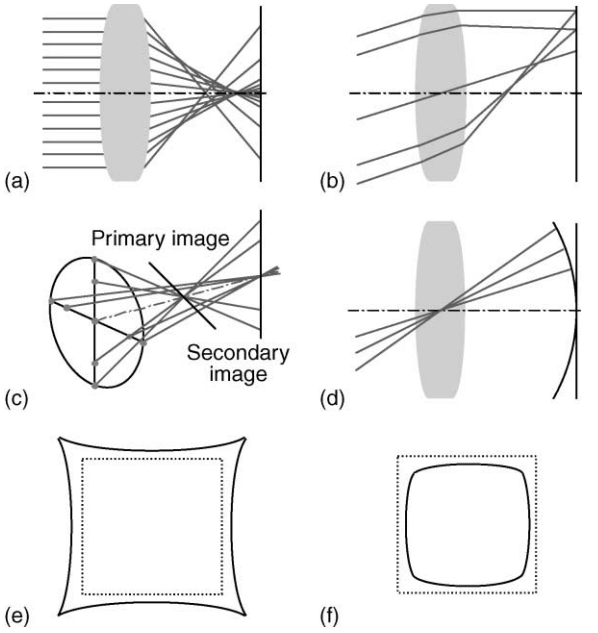

Figure 7 The primary aberrations: (a) spherical aberration – negative SA: the rays through the outer zones of the lens focus closer to the lens than the rays through the central zones; (b) coma – positive coma: the rays through the outer zones of the lens form a larger image than those going through the center; (c) astigmatism – negative astigmatism: the tangential or vertical fan of rays is focused to the left of the horizontal or sagittal fan; (d) curvature of field – negative curvature of field: images farther from the axis focus nearer to the lens than the on-axis images; (e) positive distortion – the magnification increases as the field angle increases; (f) negative distortion.

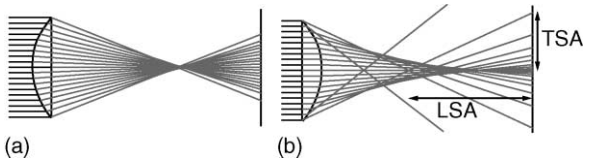

Figure 8 Ray diagram of a planoconvex lens ($D = 200$ μm; $f = 249$ μm) with planewave illumination incident on (a) the curved surface and (b) on the plane surface. LSA (longitudinal SA) represents the difference between the paraxial and the marginal focus while TSA (transversal SA) shows the radius of the spot in the paraxial focal plane.

symmetry around the optical axis θ. Equation [28] can be used to estimate how the aberration blurs change if the aperture or field of view of a lens is changed. In the following section we briefly describe each of these aberrations in terms of their visual effects.

Spherical Aberration

The first term in eqn [28], ${}_0C_{40}r^4$, is the only term in the third-order wave aberration that does not depend on the deviation h' from the optical axis. Thus, spherical aberration (SA) is the only monochromatic aberration that occurs on the optical axis and that exists even for axial object and image points. As shown in Figure 7a, SA results from the rays that enter via different zones of the aperture and are focused at different distances from the lens. It is evident from Figure 7a that the best focus is not at the paraxial plane. The best focus, however, is found at the location where the circular image blur is the same over the entire field of view and is called the circle of least confusion.

Because most applications consist of on-axis illuminated planoconvex microlenses, we will firstly focus our attention on how microlenses have to be positioned to minimize SA. When we consider a planoconvex lens with the curved surface towards the infinite conjugate for an incident parallel beam, both surfaces are contributing approximately equal amounts of ray bending. Figure 8a shows the ray diagram for a planoconvex lens as obtained with the ray-tracing program Solstis. Solstis is a commercial photonics design software, consisting of different modules, each of which is dedicated to a certain optical modeling approach. If, however, the flat surface is turned toward the incident rays, then the first surface does not bend the rays and all the ray-bending work is done by the second surface (Figure 8b). We can conclude here that the best orientation is that which distributes the ray bending equally between the two surfaces of the lens.

Because the ray blur varies with the third power of the lens aperture, lowering the aperture diameter will cause a rapid decrease in the extent of the spherical

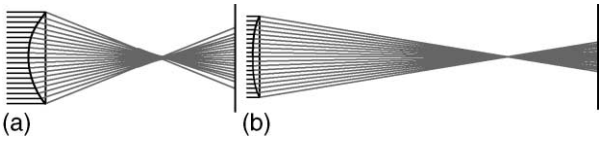

Figure 9 Ray diagram of a planoconvex lens (a) with a focal length *f* and (b) with a focal length *2f*.

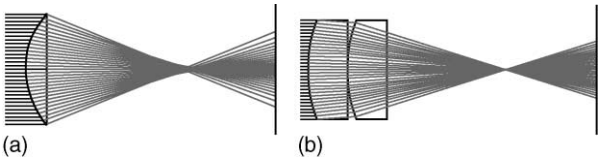

Figure 10 (a) Ray diagram for a planoconvex lens ($D = 200$ μm; $f = 249$ μm). (b) The spherical aberration is reduced with a factor 4 by splitting the optical power of the original lens and using a doublet ($D = 200$ μm; $f = 621$ μm for both lenses).

aberration blur. For a given aperture of the lens, the spherical aberration is a function of the focal length of the lens and increases with a decreasing focal length or an increasing NA (Figure 9).

A change in SA, contributing to the wave aberration, for a variation of the lens diameter D or the focal length f can be estimated with the following rules:

$$\text{Spherical aberration} \div D^4 \quad \text{for a constant } f$$

$$\text{Spherical aberration} \div 1/f^3 \quad \text{for a constant } D$$

However, by preserving the focal length and hence the optical power of the lens, the SA can be changed by varying the radii of the surfaces. This would be the same as physically bending a lens made of flexible plastic. In Figure 10 we have reduced the spherical aberration with a factor of four by splitting a lens into two elements, each with a longer focal length, keeping the total optical power of the elements the same as the original lens. This means that, in practice, high NA microlenses can be replaced by a number of microlenses reducing the SA significantly.

However, in optical systems, where only a small number of surfaces are allowed, aspherical surfaces can be used to correct the SA. In Figure 11 we show that making the lens shape elliptical while maintaining the other characteristics of the microlens ($D = 200$ μm; $R = 150$ μm) results in a reduction of the SA. The most common form of an aspheric surface is a rotationally symmetric surface with the sag, defined as:

$$z_{\text{conic}} = \frac{R^{-1}(x^2 + y^2)}{1 + \sqrt{1 - (1 + K)R^{-2}(x^2 + y^2)}} \qquad [29]$$

where R is the radius of curvature, K the conic parameter, and x and y the coordinates in the substrate plane. The meaning of K is given in Table 2.

In eqn [28] we have shown that the wavefront aberrations can be written as the sum of the Seidel or third-order aberrations. Furthermore, we have seen that only the SA contributes to the wavefront aberration when we illuminate the microlens on-axis ($h' = 0$). When we limit our experiments to on-axis illumination during the optical characterization of the microlenses, the wavefront aberrations are a measure for the SA. To prove this, we have calculated and plotted in Figure 12, the SA and the wavefront aberrations as a function of the focal length for a 200 μm lens ($n = 1.48$).

Both the SA and wavefront aberration values are obtained with the ray-tracing software Solstis. The wavefront aberration is calculated here as the optical path difference [BA] between a real wavefront surface and a spherical reference surface. From these results we can observe that for microlenses with an $f > 330$ μm or an NA lower than 0.3 only the spherical aberration contributes to the root-mean-square (RMS) wavefront aberration. The RMS or standard deviation σ of a number N of data x_i ($i = 1, \ldots, N$) with a mean value X can be written as $\sigma = \sqrt{\sum_{i=1}^{N} (X - x_i)^2 / N}$. For smaller focal length microlenses, however, we notice that higher-order aberrations appear and compensate the SA, resulting in a lower wavefront aberration compared to the SA. We can conclude that the wavefront aberration values represent the optical performance of the microlenses with a main contribution from the SA for on-axis illumination.

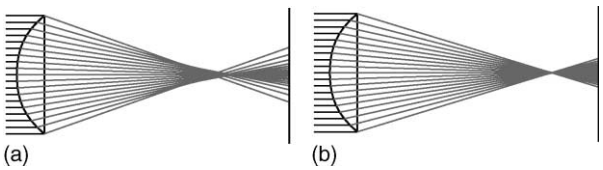

Figure 11 (a) Ray diagram of a spherical planoconvex lens ($D = 200$ μm; $R = 150$ μm; $K = 0$) with planewave illumination. (b) The spherical aberration is reduced by making the lens shape elliptical ($K = -0.57$).

Table 2 The surface type for different conic parameters *K*

Conic constant K	*Surface type*
$K = 0$	Sphere
$K < -1$	Hyperboloid
$K = -1$	Paraboloid
$-1 < K < 0$	Ellipsoid
$K > 0$	Oblate ellipsoid

Other Seidel Aberrations

Coma is an image-degrading aberration that increases rapidly with the lens aperture r. It indicates an off-axis aberration ($h' \neq 0$) that is nonsymmetrical around the optical axis ($\cos\theta \neq$ constant). Figure 7b illustrates the aberration due to a vertical fan of parallel rays refracted by a spherical lens. It results from a lens having different magnifications for rays passing different zones of its aperture. Each circular zone of the lens forms a circular image called the comatic circle. Every other fan of rays forms images that complete the comatic circle. The combination of all these circles causes a comet-shaped flare.

Astigmatism is the imaging of an off-axis point as two perpendicular lines at different distances. In this aberration the rays from a point object converge at a certain distance from the lens to a line which is called the primary image. This line lies in the sagittal plane and is perpendicular to the plane defined by the optical distance and the object point. At a somewhat different distance from the lens they converge to a second line, called the secondary image, which is parallel to the tangential plane. This effect is shown in Figure 7c. The elimination of astigmatism requires that the tangential and sagittal surfaces be made to coincide. The resulting surface is then called the Petzval surface. Although in that case astigmatism has been eliminated, the associated aberration, called curvature of field, remains. So off-axis images are focused on a curved saucer-shaped surface as drawn in Figure 7d, instead of on an ideal flat image surface.

The last of the five primary aberrations is distortion and causes straight lines which do not intersect the axis to be imaged as curved lines. This effect is not related to a lack of sharpness of the image but results from the fact that the magnification varies across the field and induces the image of a square object to be bowed outward (Figure 7e) or sagged inward (Figure 7f).

We have shown that three of the five Seidel aberrations (namely SA, coma, and astigmatism) are responsible for a lack of sharpness of the image. The other two (i.e., curvature of field and distortion) are related to the position and the form of the image. In general, it is impossible to design a system which is free from all the primary as well as the higher-order aberrations, and therefore, a suitable compromise as to their relative magnitude has to be made. In some cases, the effects of the Seidel aberrations are reduced by balancing them against aberrations of higher orders. In other cases, one has to eliminate certain aberrations completely, even at the price of introducing aberrations of other types. So far we have studied the aberration effects on the basis of geometrical optics only. However, if the aberrations are very small (wave aberrations of the order of a wavelength or less), diffraction starts to play an important role. That is why, in the next section, we will discuss the role of diffraction on the imaging quality of a lens.

Diffraction

Introduction

So far we have used simple geometrical optics to evaluate the effects of aberrations – deviations of the

wavefront behind the lens from the ideal shape – that influence the quality of an image generated by a lens. However, we know that even for an aberration-free lens, blur of the spot in the image plane occurs. This means that diffraction effects at the lens aperture can also influence the spot size and the point spread function (PSF), certainly because diffraction gains importance when miniaturizing optical components. Therefore, we have to introduce diffraction before we can bring forward the most important figures of merit for microlens performance and study its effects on imaging quality.

Fraunhofer and Fresnel Diffraction

In certain regions of space occupied by our optical lens system, the simple geometrical model of energy propagation is inadequate. In particular, deviations from this model can be expected in the immediate vicinity of the boundaries of shadows and in regions where a large number of rays meet. These regions are of great practical interest, as they include that part of the image space in which the optical image is situated. These deviations are manifested by the appearance of diffraction fringes. Also, the phenomena involving the superposition of coherent wavefronts cannot be treated with a geometrical model of energy propagation. Thus a more accurate treatment is necessary where the wave nature of light and diffraction are taken into account. Wave optics is such an approach with which the actual light intensity, that will be observed as a result of the propagation of a wavefront to the image plane, can be constructed. According to Huygens' construction, every point of a wavefront may be considered as a center of secondary disturbance, which gives rise to spherical wavelets. The wavefront at any later instance may be regarded as the envelope of these wavelets. Fresnel was able to account for diffraction by supplementing Huygens' construction with the postulate that the secondary wavelets mutually interfere. We discuss diffraction here, on the basis of wave theory, by the application of Huygens' construction together with the principle of interference. The latter principle, also called the Huygens–Fresnel principle, sufficiently describes the propagation of light in free space.

This Huygens–Fresnel principle may be regarded as an approximate form of the integral theorem of Helmholtz and Kirchhoff. Kirchhoff's theory makes an approximation to the diffraction of scalar waves. This scalar theory is adequate enough for the treatment of problems in instrumental optics where polarization effects are of minor importance and can be neglected. If we consider a strictly monochromatic electric field $\varepsilon(x, y, z, t) = E(x, y, z)\cdot e^{-i\omega}$ in any ideal isotropic dielectric, the space-dependent part will satisfy the homogeneous time-independent wave equation: $(\nabla^2 + k^2)E = 0$, also known as the Helmholtz equation where $k = \omega/c$. This theorem expresses the solution E of the Helmholtz equation at an arbitrary field point P, in terms of its solution E and its first derivatives $\partial E/\partial n$ at all points on an arbitrary closed surface surrounding P, provided the medium is a homogeneous dielectric:

$$E(P) = -\frac{1}{4\pi}\oiint_S \left[E\overline{\nabla}\left(\frac{e^{-iks}}{s}\right) - \frac{e^{-iks}}{s}\overline{\nabla}E \right]\bar{n}\,dS \qquad [30]$$

Here, s is the distance from point P to the point on surface S, n is the outward normal to S, and $k = \omega/c$ is the wave number in vacuum.

When we consider a monochromatic wave, from a point source P_o propagating through an aperture Ω in a plane opaque screen, and P is the point at which the light disturbance has to be calculated, the theorem can be reduced to an approximate but much simpler form (**Figure 13a**) on condition that we can assume that the linear dimensions of the aperture Ω, although large compared to the wavelength, are small compared to the distances of both P_o and P from the screen.

As a result of Kirchhoff's theorem we obtain:

$$E(P) = \frac{iA}{2\lambda}\iint_\Omega \frac{e^{-ik(r+s)}}{rs}[\cos(n,r) - \cos(n,s)]dS \qquad [31]$$

where A is a constant, λ the wavelength, and r and s are the distances from element dS on Ω to P_o and P, respectively. Equation [31] is known as the Fresnel–Kirchhoff diffraction formula. In case a more general field E_o is incident at the aperture Ω, replacing the point source $A\,e^{-ikr}/r$, an equivalent formulation, known as the Huygens integral, can be found:

$$E(P) = \frac{i}{\lambda}\iint_\Omega E_o(x_o, y_o, z_o)\frac{e^{-iks}}{s}\cos(n,s)dS \qquad [32]$$

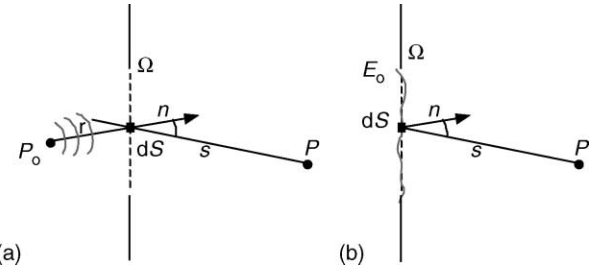

Figure 13 Geometry for evaluating (a) the Fresnel–Kirchhoff diffraction formula and (b) the Huygens' integral.

In the case of the Huygens integral an alternative Green's function is chosen, namely $G(P) = \exp(-jks)/s - \exp(-jkr)/r$ instead of $G(P) = \exp(-jks)/s$ used in the Fresnel–Kirchhoff diffraction formula. This then results in an obliquity factor $\cos(n,s)$ instead of $\cos(n,s) - \cos(n,r)$. If the distances of the points P_o and P are large compared to the dimensions of the aperture, the factor $[\cos(n,r) - \cos(n,s)]$ in eqn [31] will not vary appreciably over the aperture and may be replaced by 1. In this case, the optical beams are close to the optical axis and this is considered as the paraxial diffraction theory. In the phase factors, we can expand $r(x,y,z)$ and $s(x,y,z)$ as power series. If the quadratic and higher-order terms may be neglected in the series expansion ($r,s \gg \lambda$), one speaks of Fraunhofer diffraction, when the previous assumption is not fulfilled ($r,s \geq \lambda$), the quadratic terms cannot be neglected and one speaks of Fresnel diffraction. The regions where the Fresnel and Fraunhofer diffraction integral may be applied are called the near-field (NF) and far-field (FF) diffraction regions respectively. The Rayleigh range z_R marks the boundary between the NF and FF regions for the beam emerging from the aperture (Figure 14).

As an example, we discuss the diffraction of a uniform planewave by a circular aperture of diameter $2a$. The Rayleigh range for this circular aperture is given by

$$z_R = \frac{\pi a^2}{\lambda} \qquad [33]$$

The FF diffraction pattern ($z \gg z_R$) for a uniformly illuminated circular aperture is the well-known Airy disk pattern and is given by

$$E(r,z) \sim \frac{2J_1(2\pi a\theta/\lambda)}{(2\pi a\theta/\lambda)} \qquad [34]$$

where J_1 is the first-order Bessel function. This pattern has a single dominant central lobe surrounded by a series of increasingly weaker circular rings. The first zero of this pattern occurs at a half angle θ_1 or a radius r_1 in the FF, given by

$$\theta_1 = \frac{r_1}{z} \approx \frac{1.22\lambda}{2a} \qquad [35]$$

The NF or Fresnel diffraction patterns for a uniformly illuminated circular aperture ($z < z_R$) consist of a series of circular rings modulating a constant-amplitude background. When moving even closer to the aperture, the beam profile becomes more and more square and the frequency of the Fresnel ripples increases.

We now know that light is diffracted at the apertures of optical elements (lenses) and that this diffraction can affect its performance. Ideally, the focus of a planewave should be infinitely small, being the image of a point source located at infinity. But even in the ideal case, when no geometrical aberrations are introduced, diffraction will limit the lens performance and the focus of such diffraction-limited lenses will have a finite extension.

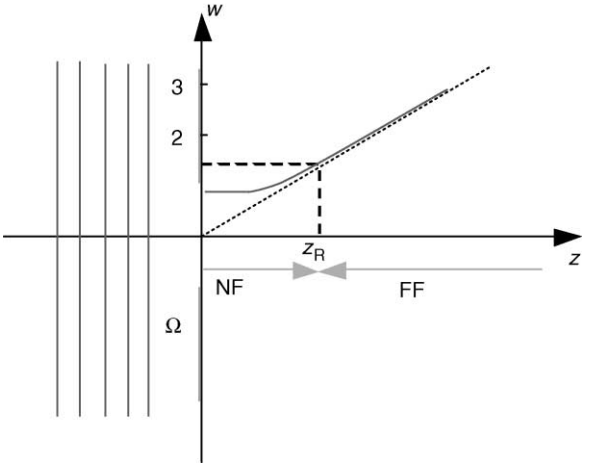

Figure 14 The Rayleigh range z_R marks the boundary between the NF and FF regions for a beam emerging from the aperture Ω.

Quality Criteria for Lens Performance

In this section we discuss some of the most important figures of merit for diffraction-limited lens performance. This survey raises the problems related to this issue. A more detailed overview can be found in the literature.

Diffraction in a Lens System: The Point Spread Function (PSF)

Diffraction at the lens aperture D causes a blur of the focus. The light distribution in the focal plane of an aberration free lens essentially arises from Fraunhofer diffraction at the aperture of the lens. From eqn [34] we know that the diffraction image for an aberration-free lens with a circular aperture D is the scaled Airy disk, given by

$$E(r,z) \sim \frac{\pi J_1(rD/\lambda f)}{(rD/\lambda f)} \qquad [36]$$

where λ denotes the wavelength of the illuminating light beam and f the focal length.

The normalized intensity of this pattern is called the diffraction-limited (PSF) of the lens:

$$\mathrm{PSF}(r,z) = |E(r,z)|^2 \qquad [37]$$

Although irradiance replaces nowadays the word intensity in optics, we will still use intensity to nominate the flow of energy per unit area per unit time. We can define the irradiance as $I \equiv \frac{1}{2}\varepsilon_0 c\langle \mathrm{E}^2\rangle$, with ε_0 and c the electric permittivity in vacuum and the speed of light, respectively. The radius of this pattern is known as the Rayleigh diffraction limit or Rayleigh resolution and is compared to the measured spot size in the image plane.

To include the effects of aberrations in the diffraction computation, we have to include both the phase profile and the amplitude of the real wavefront in the pupil of the lens. The pupil function $T(x, y)$ may be written as:

$$T(x,y) = E(x,y)\mathrm{e}^{\mathrm{i}k\psi(x,y)} \qquad [38]$$

where $E(x, y)$ represents the amplitude distribution over the exit pupil and $\psi(x, y)$ is the wavefront deformation on this pupil. Starting from the Huygens–Fresnel approach, the diffraction integral can be rewritten in the form of a Fourier transform:

$$E(r,z) \sim FT(\mathrm{e}^{\mathrm{i}k\psi(x,y)}) \qquad [39]$$

The PSF at the focal position can then be found by calculating the Fourier transform of the wavefront error ψ or the pupil function $T(x, y)$ of the lens and taking the complex square of the latter. Figure 15 shows the shape of the PSF of an ideal or diffraction-limited lens. When the lens aperture D decreases, the extension of the PSF increases proportionally, which means that it becomes easier to achieve diffraction-limited performance. Since the extension of the diffraction-limited PSF becomes larger, the constraints on the shape of the phase profile become less stringent. This has important consequences on the scaling behavior of lenses. In the extreme case, the microlens diameter becomes so small, that diffraction-limited imaging is possible without any specific phase profile in the lens pupil. This is also one of the reasons why small water droplets often form relatively good lenslets. For systems including micro-optic lenses, we therefore will have to find better criteria than the PSF of a diffraction-limited lens to evaluate or compare these optical components.

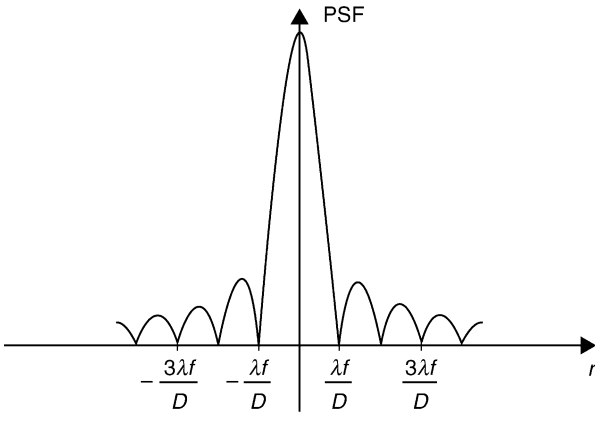

Figure 15 The 1D point spread function of an ideal lens.

The Rayleigh and Maréchal Criterion

The widely used Rayleigh criterion states that a system is diffraction-limited, as long as the maximum wavefront deviation $|\psi_{\max}(x)|$ is less than one quarter of a wavelength (Figure 16). It was shown by Rayleigh that for a system which suffers primarily from SA such that the wavefront deviation is less than a quarter wavelength, the intensity at the Gaussian focus is diminished by less than 20%; a loss of light that can usually be tolerated. Also in the presence of other commonly occurring Seidel aberrations is the quality of the image not seriously affected when the deviation is less than $\lambda/4$. This criterion, which determines the amount of aberration that can be tolerated in an image-formation system is, of course, only a rough guideline since the light distribution in the image does not only depend on the maximum deformation but also on the shape of the wavefront, and even more on the type of aberration. Moreover, the loss of light that can be tolerated depends on the particular use to which the optical component is put and more stringent tolerances have to be imposed for certain applications.

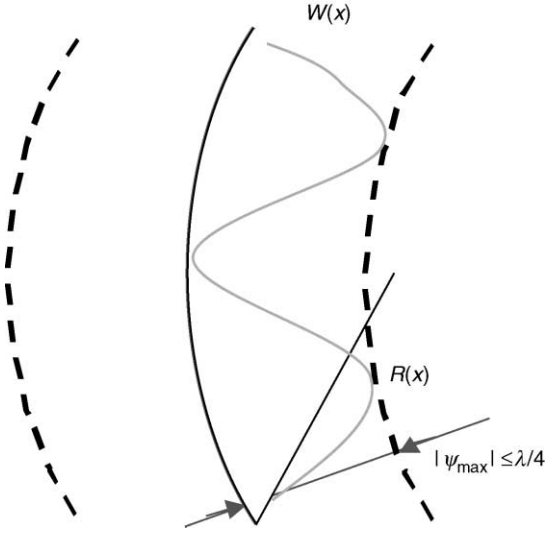

Figure 16 Illustration of the Rayleigh criterion.

Low-order aberrations merely cause a shift of light from the main lobe of the PSF to the side lobes. Higher-order aberrations additionally cause a broadening of the PSF and the correlation between the image quality and the maximum value of the wavefront aberration is usually lost. In the latter case, it seems more appropriate to formulate tolerance criteria restricting the average amount of aberration. Criteria of this type were considered by Maréchal, who used the relation that exists between the intensity at the center of the reference sphere and the RMS deviation of the wavefront from a spherical form.

This Maréchal criterion uses the following RMS wavefront aberration ψ_{RMS} to define the lens quality:

$$\psi_{\mathrm{RMS}} = \sqrt{\int |\psi(x)|^2 \, \mathrm{d}x - \left[\int |\psi(x)| \mathrm{d}x\right]^2} \leq \frac{\lambda}{14} \qquad [40]$$

This criterion is sensitive to statistical noise on the measured phase profile, while a criterion such as the Rayleigh criterion is little affected by it.

Strehl Ratio

For some applications not the imaging quality but the maximum deposited energy is the most essential feature. In such a situation, the Strehl ratio S is a suitable figure of merit. The Strehl ratio is defined as the normalized peak intensity of the PSF of the lens:

$$S = \frac{I_{\mathrm{real}}(0,0)}{I_{\mathrm{ideal}}(0,0)} = \left| \int\int \mathrm{e}^{\mathrm{i}k\psi(x,y)} \mathrm{d}x \, \mathrm{d}y \right|^2 \qquad [41]$$

$I_{\mathrm{real}}(0,0)$ and $I_{\mathrm{ideal}}(0,0)$ denote the intensities at the center of the real point image and the ideal PSF without aberrations, respectively. Even for small aberrations, which do not affect the extension of the PSF, the light intensity in the center peak can drop significantly (Figure 17). A Strehl ratio $S \geq 0.8$ is generally considered to correspond to diffraction-limited performance.

By a Taylor expansion of eqn [40], the relation between the Strehl ratio S and the Maréchal criterion can be written as:

$$S = 1 - \left(\frac{2\pi}{\lambda} \psi_{\mathrm{RMS}}\right)^2 \qquad [42]$$

If only low-order aberrations are taken into account, Rayleigh's $\lambda/4$ criterion also results in a Strehl ratio of $S = 0.8$. For large aberrations ($S \leq 0.3$), however, the behavior of the Strehl ratio becomes uncorrelated to the image quality due to interference effects.

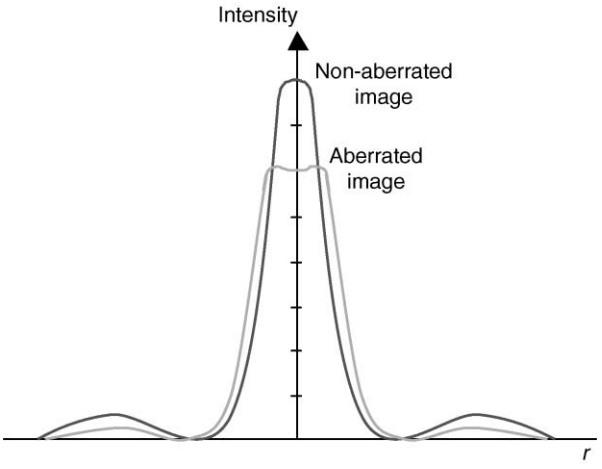

Figure 17 Strehl ratio criterion.

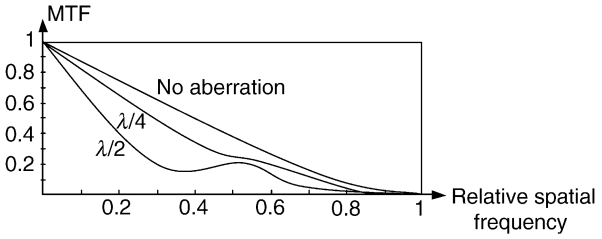

Figure 18 Modulation transfer function for a perfect lens and for small amounts of spherical aberration ($\lambda/2$ and $\lambda/4$).

Transfer Functions

Transfer functions are most commonly used for evaluating the image quality in lens design. As discussed above, the PSF is the Fourier transform of the wavefront error ψ. For simplicity we can assume that the modulus of the pupil function is 1. The PSF then follows from the Fourier transform:

$$PSF(\mu, \nu) = |\mathrm{FT}(\mathrm{e}^{\mathrm{i}k\psi(x,y)})|^2 \qquad [43]$$

The optical transfer function (OTF) is calculated from the PSF data by means of an inverse Fourier transformation:

$$\mathrm{OTF}(\vartheta, \rho) = \mathrm{FT}^{-1}[\mathrm{PSF}(\mu, \nu)] \qquad [44]$$

The OTF is a spatial frequency-dependent complex quantity whose modulus is the modulation transfer function (MTF) and whose phase is, of course, the phase transfer function (PTF). The former is a measure for the reduction in contrast from the object to the image over the whole spectrum. Figure 18 shows the normalized MTF for both a perfect lens and a lens subjected to some small amounts of spherical aberration. The PTF is, in most cases, not so conclusive concerning the optical behavior.

Therefore the wave aberrations, the PSF, the MTF, and the Strehl ratio are the characteristics that are usually provided as an output of lens design programs.

Interference

Many of the processes for the manufacturing of microlenses are not fully understood nor perfectly controlled. It occurs that one generates a microlens array and then measures its performance, hoping that by accurately repeating the processing conditions, a consistent result can be achieved. To achieve optimum conditions, it is therefore crucial to measure the geometrical and optical parameters of the microlenses. Most of the microlens measurement instruments are based on two-beam interference, the phenomena where light from a source is divided into two beams which are later on superposed again. The intensity in the region of superposition is found to vary from point to point between maxima which exceed the sum of the beam intensities and minima which may be zero.

Two-Beam Interference

We consider the interference of two waves, a reference and an object wave, represented by $\mathbf{E}_{\text{ref}}$ and $\mathbf{E}_{\text{obj}}$ respectively, where we take into account the vector properties of the electric fields. In the case of interference, both waves typically originate from a single source and recombine after traveling along different paths. For the moment we will consider only monochromatic linearly polarized waves of the form:

$$\mathbf{E}_{\text{ref}} = \mathbf{E}_{0\text{ref}}\, e^{i\Phi_{\text{ref}}(r) - i\omega t}, \quad \mathbf{E}_{\text{obj}} = \mathbf{E}_{0\text{obj}}\, e^{i\Phi_{\text{obj}}(r) - i\omega t} \qquad [45]$$

The total electric field intensity $\mathbf{E}$ at the output of the interferometer, according to the principle of superposition, is given by:

$$\mathbf{E} = \mathbf{E}_{\text{ref}} + \mathbf{E}_{\text{obj}} \qquad [46]$$

The total intensity at the output, being the time average of the square of the wave amplitude, can be written as

$$I = I_{\text{ref}} + I_{\text{obj}} + I_{\text{ref/obj}} \qquad [47]$$

with $I_{\text{ref}} \sim \langle \mathbf{E}_{\text{ref}}^2 \rangle; I_{\text{obj}} \sim \langle \mathbf{E}_{\text{obj}}^2 \rangle$ and $I_{\text{ref/obj}} \sim 2\langle \mathbf{E}_{\text{ref}} \cdot \mathbf{E}_{\text{obj}} \rangle$. Notice that if both $\mathbf{E}$-fields are perpendicular to one another, the interference term $I_{\text{ref/obj}}$ vanishes, while if we assume that both fields are parallel, we can restrict our discussion to scalar theory. Under the latter condition we can write the total intensity as:

$$I = I_{\text{ref}} + I_{\text{obj}} + 2\sqrt{I_{\text{ref}} I_{\text{obj}}} \cos(\Phi_{\text{obj}} - \Phi_{\text{ref}}) \qquad [48]$$

where the presence of the third term is indicative of the wave nature of light which can produce enhancement or diminution of the intensity through interference.

We can rewrite eqn [48] in Michelson's manner of writing:

$$I = I_0(1 + V \cos(\Phi_{\text{obj}} - \Phi_{\text{ref}}))$$
$$\text{where } I_0 = I_{\text{ref}} + I_{\text{obj}}, \quad V = \frac{2\sqrt{I_{\text{ref}} I_{\text{obj}}}}{I_{\text{ref}} + I_{\text{obj}}} \qquad [49]$$

with V the visibility or fringe contrast indicating the degree of modulation.

We can conclude that the measured intensity of a two-beam interferogram depends on the mean intensity I_0, the visibility V, and the phase difference $\Phi_{\text{obj}} - \Phi_{\text{ref}}$. There are a number of techniques to measure the three unknowns: the mean intensity, the visibility, and the interesting spatial phase variation. In the optical instrumentation, further discussed in this article, phase shifting interferometry (PSI) is used which requires a measurement of the intensity in each point of the aperture for at least three different reference phase values, in order to obtain three equations for the three unknowns (I_0, V, and $\Phi_{\text{obj}} - \Phi_{\text{ref}}$). In practice, the reference phase values are obtained by a piezodriven transducer (PZT) mirror and should be equally spaced over one phase cycle of 2π. It has been shown that the five-phase algorithm is the optimal choice as the calculation still remains simple and the second-order nonlinear response of the detector is eliminated. A charge coupled device (CCD) sensor then records the intensity of the resulting interference pattern for different relative phase shifts and converts the intensity data to wavefront phase data through integration.

Microlens Testing

In microlens (lens with a diameter lower than several millimeters) testing, it is essential to measure in a first step the shape or the surface profile of the microlenses or in cases where gradient-index lenses are concerned, their refractive index distribution. In addition, the paraxial parameters, such as the focal length, and the more complex properties like the wave aberrations and surface quality have to be characterized. As discussed in the introduction, massive parallelism and miniaturization ask for the fabrication of microlenses and microlens arrays. The most critical features of these lenslet arrays are the uniformity of the microlenses and their mutual positioning accuracy. As a variation of these properties deteriorates the optical

performance in most applications, dedicated test instrumentation is needed.

In the following, we discuss different measurement instruments designed to characterize all the geometrical and optical parameters of microlenses. First, we introduce an optical noncontact profiler which can be used to determine the diameter and the sag (the maximum height of the spherical lenscap) of the surface profile microlenses. In addition, it allows us to quantify the surface roughness on the top of the microlenses. With a transmission Mach–Zehnder (MZ) interferometer the wave aberrations and the focal length of the microlenses can be measured, while a Twyman–Green (TG) interferometer can be used for the measurement of the surface deviations of a microlens from an ideal spherical shape and for the measurement of the radius of curvature of the surface.

Surface Profile Measurements

Optical noncontact profiler

Principle. The surface profile of a microlens can be measured with a Wyko NT2000 noncontact optical profiler (Figure 19a). This surface profiler system uses two approaches to measure a wide range of surface heights. The PSI mode allows measuring fairly smooth and continuous surfaces (0.1 nm $<$ heights $<$ 160 nm) while the vertical scanning interferometry (VSI) mode can measure rough surfaces and heights ranging between 160 nm and 2 mm. We only discuss here the vertical scanning mode because the principle on which PSI is based has been explained above. As shown in Figure 19b, this noncontact profiler is based on a Mirau interference microscope where a white light beam passes through a beamsplitter which reflects half of the incident beam to a reference surface and transmits the other half onto the sample. The light reflected from the sample and from the reference surface then recombine at the beamsplitter to form interference fringes. The system measures the degree of the fringe modulation or the fringe contrast. Because white light has a short coherence length, interference fringes are present only over a very shallow depth for each focus position. The coherence length can be described here as the optical path distance (OPD) between two wavefronts of an interferometric system for which the phase remains correlated. Or in other words it is a measure of the range of heights over which the instrument will be able to obtain measurable interference fringes. Fringe contrast at a single sample point reaches a peak as the sample is translated through focus. During a measurement, the reference arm containing the interferometric objective moves vertically to scan the surface at varying heights. A linearized PZT precisely controls this motion. As the system scans downward, an interference signal for each point on the surface is recorded. Finally, a series of advanced computer algorithms is used to demodulate the envelope of the fringe signal and to extract the surface information.

The vertical resolution is approximately 3 nm RMS for a single measurement. The lateral resolution is a function of the total magnification, of the cursor position accuracy, and of the detector array size.

Measuring the geometrical lens dimensions. This profiler provides us with information on geometrical dimensions of microlenses. For each microlens we can derive from the contour plot (Figure 20) the sag and the diameter of the microlenses along the x and the y direction. As an example, we show in Figure 21, the

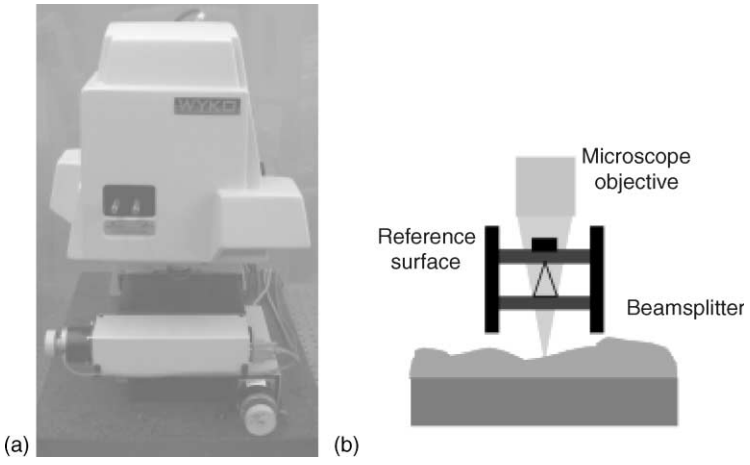

Figure 19 (a) Vertical scanning noncontact profiler (WYKO NT2000); (b) Working principle.

profiles of the cross-section of a 200 μm fused silica microlens ($NA = 0.05$; $D = 200$ μm) along the x and y directions.

The surface roughness on top of the microlens can also be derived from measurements with the noncontact profiler. As an example, we show the fringes on the vertex area (65×61 μm^2) of a 200 μm diameter lens as well as the average and RMS roughness on the vertex of the lens (Figure 22).

Measurement of the Optical Lens Performance

To investigate the optical properties of discrete microlenses one of the most accurate and reliable techniques is interferometry. It is well known that microlenses can be tested in transmitted light using instruments with a single pass geometry (e.g., MZ interferometer) as well as in reflected light interferometers using a double pass configuration (e.g., TG interferometer). The interferometers proposed in this section have been especially designed and constructed for microlens testing.

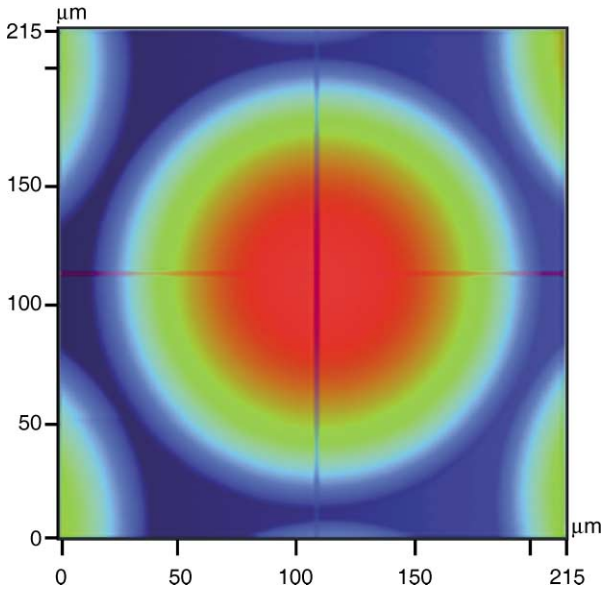

Figure 20 Contour plot of a 200 μm fused silica microlens as obtained with the noncontact profiler.

Mach–Zehnder (MZ) interferometer for transmitted light measurements

Principle. A MZ interferometer, constructed at the Erlangen–Nürnberg University, is used in this work for the measurement of microlenses in transmitted light. The interferometer is installed in a commercial Carl Zeiss Jena microscope, while fiber-optics is used for beam delivery. The scheme is shown in Figure 23. A polarizing beamsplitter (PBS) cube splits the beam of a HeNe laser while a halfwave plate at the entrance enables the balancing of the two interfering beams. The fibers are polarization preserving in order to keep the polarization in the two beams of the interferometer. The planewave of the object arm is either focused by an illumination microscope objective so that a spherical wave impinges onto the microlenses (this is the so-called spherical wave illumination) or the first microscope objective is removed so that a planewave illuminates the object (this is the so-called planewave illumination). By using a telescope consisting of the imaging microscope objective and an achromatic doublet, the expanded planewave then enters a second beamsplitter and is superimposed on a reference planewave generated by the second fiber and an expansion lens. This second beamsplitter is a nonpolarizing one. To force the two beams to interfere, the plane of polarization of the reference beam must be rotated by 90° which is achieved by twisting the fiber end accordingly. This solution has been chosen to avoid a polarizer in front of the CCD camera as it has been shown that the latter would decrease the optical quality. In addition one of the mirrors in the object

arm of the MZ is mounted on a PZT driver to enable phase shifting interferometry.

Focal length and array uniformity through plane-wave illumination. The MZ interferometer with planar wavefront illumination offers for slow lenses (NA < 0.1) the opportunity to measure also the total phase lag introduced by the lenses, as shown in Figure 24. This makes it possible to determine the focal length and hence the NA of the microlenses.

For certain applications of arrays of microlenses it is also important to know the uniformity of the lens array or at least of a part of the lens array. There are several different test methods (e.g., Smartt test, shearing test) which can provide a measure of the uniformity. One can even obtain the total phase retardation for a subsection of the microlens array (see Figure 25b).

Measuring the aberrations with spherical wave illumination. Wave aberrations of refractive microlenses can be determined with a spherical wavefront illumination (Figure 26). The measurement of the wave aberrations is carried out by using a PSI algorithm. This requires a measurement of the intensity in each point of the aperture for five different reference phase values. The result of a PSI evaluation is the phase distribution $\Phi(x, y)$ in the exit pupil:

$$\Phi(x, y) = \frac{2\pi}{\lambda} \psi(x, y) \qquad [50]$$

where $\psi(x, y)$ are the wave aberrations of the lens under test.

From these data, the software calculates the unwrapped phase distribution and by subtracting the tilt and defocus, the deviation from an ideal wavefront (phase/lambda) can be found. Fitting this

deviation to a fourth degree Zernike polynomial then gives the aberrations (phase/lambda). Besides the aberrations we also derive from the measured phase distribution other optical lens characteristics such as the modulation transfer function and the PSF.

Finally, we emphasise that the measurements should preferably be done in a cleanroom environment as the smallest dust particle on the lens surface decreases the optical performance.

Twyman–Green interferometer

Principle. For most applications microlenses have to feature a spherical or nearly spherical shape. The measurement of the deviations of the microlens surface from an ideal sphere is therefore very important. The basic principle comes down to a planewave which is focused by a high NA microscope objective in such a way that the focus coincides with the center of curvature of the microsphere under test. The light rays are reflected, and behind the microscope objective a nearly planewave carrying the surface deviations and misalignment errors, results. The vertex of the test surface is then imaged onto a CCD camera and the nearly plane object wave interferes with the plane reference wave. The evaluation here is also done with phase shifting interferometry by axially shifting the reference mirror with a piezo transducer.

The use of laser illumination allows us to obtain high contrast fringes. However, the high spatial and temporal coherence of the laser light also has important drawbacks, such as speckle noise and spurious fringes across the field. It is convenient to divide coherence into two classifications, temporal and spatial. The former relates directly to the finite bandwidth of the source, the latter to its finite extent in space. Therefore, polarization beamsplitter optics is commonly used to reduce the contribution of spurious reflections. The polarizing beamsplitter group additionally allows balancing the intensity between the object and the reference arm of the interferometer. Even so, the remaining scatter leads to poor and rough interference fringes. To further increase the fringe quality, the spatial coherence has to be reduced while the temporal coherence of the laser is preserved. This can be done by introducing a rotating scatterer in the light beam which gives a smoothing effect of the interference fringes.

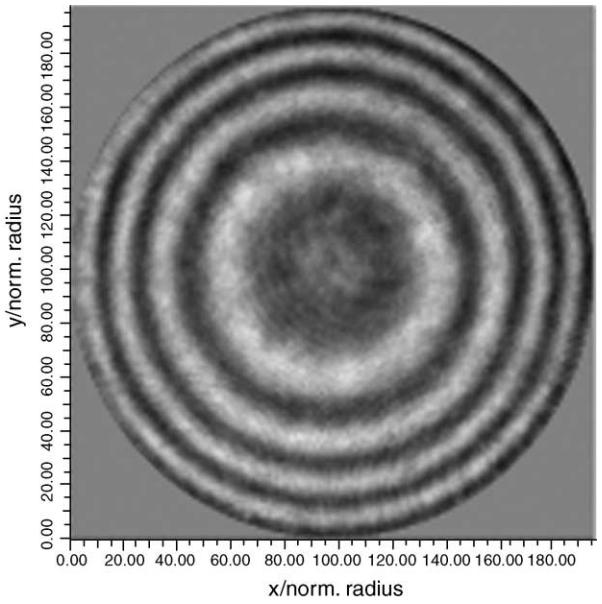

Figure 24 Interferogram of a 200 μm lens with an NA of 0.05 under planewave illumination.

Measurement of the deviations from sphericity. To determine the surface deviation of a microlens from a perfect sphere we make use of a TG

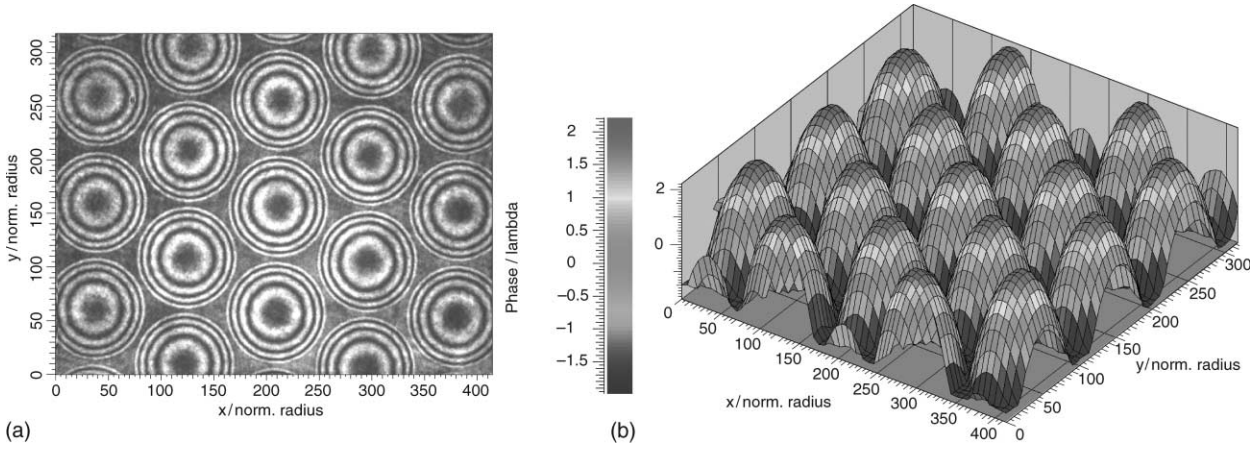

Figure 25 (a) Interferogram of an array of 200 μm diameter microlenses with an average NA of 0.05 and illuminated with a plane wavefront; (b) 3D representation of the phase lag (RMS 1.26λ, *PV* 4.37λ) for the same microlens array.

interferometer, constructed by the Erlangen-Nürnberg University (Figure 27). In this interferometer, the light of a HeNe laser is imaged onto a rotating scatterer by a microscope objective and the scattered light is collimated by an achromat. The collimated laser beam then passes a field stop which is sharply imaged by a 4f system onto the lens under test. The image of the field stop can be focused onto the surface under test by moving the field stop along the optical axis. Once the image of the field stop is sharply imaged onto the CCD array, one can translate the reference mirror until the reference image of this stop in its turn becomes sharp onto the CCD camera. Thus, two conditions have to be met to achieve high contrast fringes: the surface under test and the image of the field stop of both arms of the interferometer have to be sharp on the detector. The half wave plate in front of the PBS adjusts the splitting ratio at the PBS while the polarizer after the beamsplitter is necessary to force the two orthogonally polarized beams to interfere. Finally, the optics at the output of the interferometer gives a sharp image of the intermediate image of the lens surface onto the CCD camera. Analogous to the MZ interferometer, five phase images are grabbed and subjected to different algorithms, leading to the desired information.

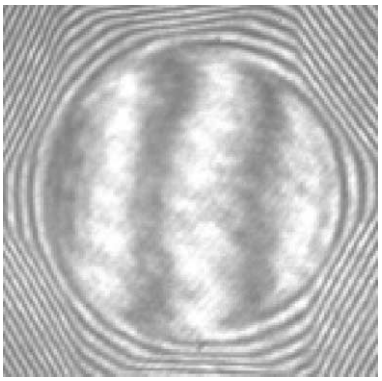

Figure 26 Interferogram of a microlens under spherical wavefront illumination: the resulting planewave is a measure for the wave aberrations.

A condensor objective transforms the radius of curvature of the spherical wavefront such that it matches the radius of curvature of the microlens. Hence, the wavefront impinges everywhere perpendicularly on the lens surface. This means that the sensitivity to surface deviations is independent on the surface position leading to high accuracy measurements. The TG interferometer allows us to test the sphericity of microlenses with diameters ranging

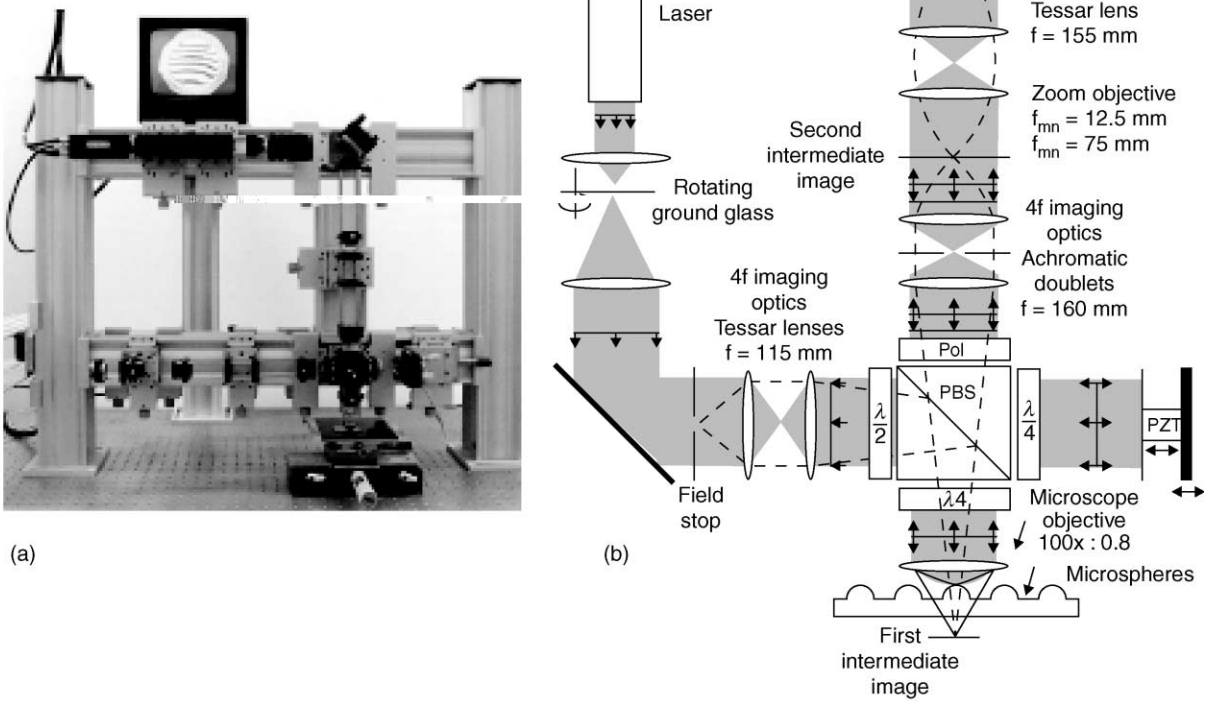

Figure 27 (a) Twyman–Green interferometer setup. (b) Detailed schematic overview of this interferometer.

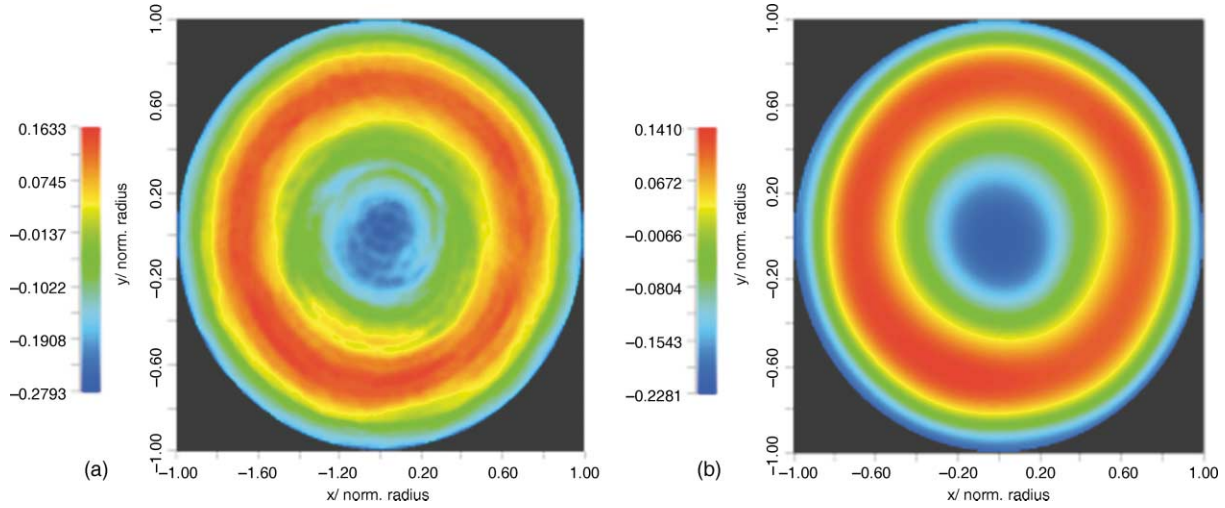

Figure 28 (a) Measured deviation from an ideal sphere (phase/lambda) for a 200 μm lens with an NA of 0.05 as obtained with a Twyman–Green interferometer. (b) Polynomial fitted surface deviation (phase/lambda) of this microlens.

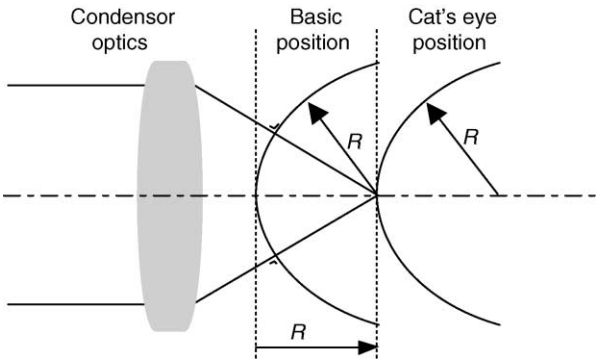

Figure 29 Necessary adjustments of the spherical microlens for radius measurements.

from 50 to 1000 μm and with a maximum radius of curvature of 1960 μm.

An example of a 200 μm fused silica microlens, with an NA of 0.05, is shown in Figure 28. The deviation from an ideal sphere can be derived from the unwrapped phase after subtracting the tilt and defocus. Fitting the deviation to a fourth degree Zernike polynomial then gives the surface deviation.

Measuring the radius of curvature. Using the TG interferometer it is also possible to determine the radius of curvature R of a microlens. To do this, the test object has to be shifted axially from the basic position, where the light rays impinge perpendicularly onto the surface and the focal length of the condensor objective coincides with the center of the sphere under test, to the so-called cat's eye position, where the focus of the impinging spherical wave is at the vertex of the sphere (Figure 29). For both positions straight, parallel, and equidistant interference fringes are obtained, only perturbed by aberrations due to the lens surface and the condensor objective. This forms the criterion for the adjustment of the two positions. The difference between these two positions then gives the radius of the microsphere. It should be mentioned that the cat's eye position causes an inversion of the object wavefront with respect to the reference wavefront, which results in a vanishing contrast with the partially coherent illumination. The latter can only be avoided by providing the necessary coherence. This implies that the rotating scatterer will have to be removed.

Summary of the Interferometric Instrumentation

Figure 30 summarizes the various instruments we discussed in this section: a noncontact optical profiler, a MZ and a TG interferometer. For each of these instruments, we highlight the measurands, the assumptions that are made, and the resulting optical lens characteristics. From this figure, it is clear that one can obtain a measure for the focal length and hence the numerical aperture and the focal number of a refractive microlens, with all three instruments. However, only the focal length obtained with the MZ interferometer is a direct measurement. The focal length obtained with the optical profiler is derived from the sag of the lens under the assumption of an ideal sphere while the radius of curvature measured with the TG interferometer allows to calculate the focal length as well. Nevertheless, the three values make an interesting comparison possible.

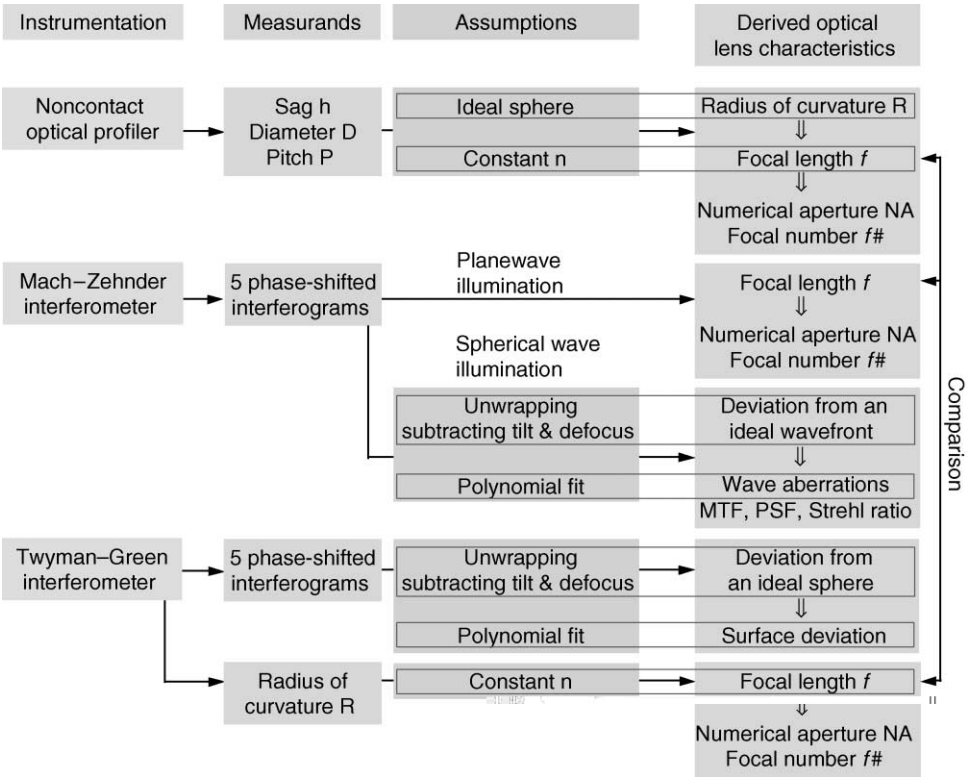

Figure 30 Overview of the instruments that we will use to quantitatively characterize the refractive microlenses: the measurands and the resulting optical lens characteristics.

Conclusions

In this article we introduced geometrical optics to discuss the imaging properties and the aberrations of refractive lenses, while wave optics was used to explain the effects of diffraction on the imaging properties of lenses. Next we put forward some commonly used quality criteria to assess lens performance and we pointed out the unique properties of microlenses. Finally, interference was briefly introduced to clarify the working principle of various instruments to quantitatively characterize refractive microlenses and microlens arrays: a noncontact profiler, a transmission MZ interferometer and a TG interferometer.

We can conclude that micro-optics is a key technology with many applications in various areas of tomorrow's information society. It enables new functionalities and applications previously unachievable with conventional optics and improves product performance, stability and robustness while reducing cost, volume, and weight. While in conventional optics discrete lenses are mounted to form optical systems using mechanical alignment equipment, for microlenses new integration approaches are available. For most of the applications, the integration of micro-optical components into fully functional systems is very important.

Thus micro-optics is a generic technology that allows the manipulation of light with micron and submicron scale structures and components. Micro-optics is therefore the technology to help provide the necessary tools to interface the macroscopic world we live in with the microscopic world of opto- and nano-electronic data processing. Micro-optic processing and fabrication technologies can be adapted to a wide variety of specialty optical materials such as plastics, polymers, semiconductors, sol-gels, and doped glasses. The application of these modified materials permits the widening of the field of photonic functionalities to virtually any region of the optical spectrum and beyond, such that a wealth of novel optical and photonic applications can be realized. Micro-optic processing technologies can be made compatible with scalable industrial mass-manufacturing and replication techniques.

Network, the Bilateral Scientific and Technological Cooperation Flanders-Poland, the Institute for the Promotion of Innovation by Science and Technology in Flanders (IWT), the IWT GBOU project 'Generic Technologies for Plastic Photonics', the Research Council (OZR) of the Vrije Universiteit Brussel and the EC Network of Excellence NEMO.

List of Units and Nomenclature

[AB]	optical path length
c	speed of light
d	lens thickness
D	lens aperture diameter
$\mathbf{E}$	electricfield
f	focal length
f_{BFL}	back focal length
f_{FFL}	front focal length
$f\#$	focal number
F_{i}	image focal point
F_o	object focal point
h_1	position of the first principal point relative to the vertex V1
h_2	position of the second principal point relative to the vertex V2
h'	deviation from the optical axis
H_1	first principal point
H_2	second principal point
I	intensity
k	wave number in vacuum
n	index of refraction
n_{i}	index of refraction of medium i
O	object point
P	arbitrary field point
P	image point
P	lens pitch
$\wp$	spherical surface power
r	aperture of the refracting surface
R	radius of curvature
$R(x, y)$	real wavefront
S	axial object point
S	Strehl ratio
s_0	object distance
s_i	image distance
V	lens vertex
V	visibility or fringe contrast
$W(x, y)$	spherical wavefront in the Gaussian approximation
y_{o}	object height
y_{i}	image height
z_{R}	Rayleigh range
α	angular semi-aperture
θ	symmetry around the optical axis
λ	wavelength of light
σ	standard deviation
φ_1	angle between the incident ray and the normal to the flat surface
φ_2	angle between the refracted ray and the normal to the flat surface
$\Phi_{\mathrm{obj}} - \Phi_{\mathrm{ref}}$	phase difference
$\Phi(x, y)$	phase distribution
$\psi(x, y)$	wavefront aberration
ω	angular frequency
Ω	aperture in a plane opaque screen
BFL	Back focal length
CCD	Charge coupled device
FF	Far-field
FFL	Front focal length
MTF	Modulation transfer function
MZ	Mach–Zehnder
NA	Numerical aperture
NF	Near-field
OPD	Optical path difference
OTF	Optical transfer function
PBS	Polarizing beamsplitter
PP	Principal plane
PSF	Point spread function
PSI	Phase shifting interferometry
PTF	Phase transfer function
PZT	Piezo-electric transducer
RMS	Root mean square
SA	Spherical aberration
VSI	Vertical scanning interferometry

Introduction

Many forms of optical parametric device (OPD) play significant roles as three-wave nonlinear-optical sources of tunable coherent light for laser-based science and technology. Any such device will fall into one of three categories, in increasing order of sophistication: optical parametric generator (OPG); optical parametric amplifier (OPA); and optical parametric oscillator (OPO). This article concentrates largely on nanosecond-pulsed OPOs, with particular emphasis on designs that facilitate their wavelength control and their optical power- or energy-efficiency. The two other important temporal manifestations of OPOs (ultra-fast pulsed and continuous-wave) are briefly outlined. OPDs serve as versatile sources of tunable, intense, coherent radiation covering the infrared, visible, or ultraviolet spectral regions. Their most obvious uses are associated with laser wavelength-conversion and/or tunability, resulting in a variety of spectroscopic applications. Four-wave nonlinear-optical parametric contributions, such as those involved in stimulated Raman scattering and highly nonlinear optical fibers, are also briefly considered.

What is an Optical Parametric Device?

An optical parametric device (OPD) is a source of coherent, laser-like radiation that is typically intense and tunable over a wide range of wavelengths. Its mechanism invariably depends on nonlinear optics, usually through a three-wave mixing process mediated by the nonlinear-optical susceptibility $\chi^{(2)}$ in a noncentrosymmetric crystalline medium. Three forms of OPD are illustrated in Figure 1, and also illustrated is a closely related (but distinct) nonlinear-optical device. Coherent light waves are represented by arrows, with their associated optical frequency ω_j and wave vector $\mathbf{k}_j$ (which are defined below). In Figure 1, input and output waves are shown as arrows on the left and right, respectively, with their breadth intended to indicate typical relative intensities.

An optical parametric generator (OPG) is the simplest form of OPD, with a single input wave (pump, P) from a laser generating two coherent output waves (signal, S; idler, I; $\omega_S \geq \omega_I$), as depicted in Figure 1a. The nonlinear-optical process itself is initiated by low-intensity parametric spontaneous emission/noise/fluorescence processes that occur naturally, effectively 'splitting' a pump photon into two new photons. Once a signal and/or idler wave has been generated, it can be coherently amplified by passing it through an optical parametric amplifier (OPA) together with input pump radiation, as depicted in Figure 1b. A further order of sophistication is reached in an optical parametric oscillator (OPO), as depicted in Figure 1c, where the

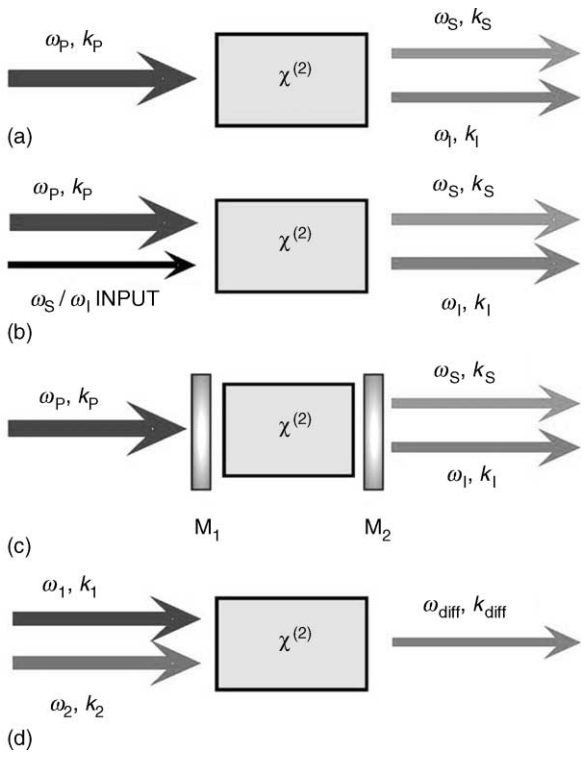

Figure 1 Schematic diagrams of three forms of optical parametric device (OPD): (a) optical parametric generator (OPG); (b) optical parametric amplifier (OPA); (c) optical parametric oscillator (OPO). Note that, by convention, optical frequencies of the signal (S) and idler (I) output waves are defined such that $\omega_S \geq \omega_I$. Also shown is a fourth closely related device: (d) difference-frequency generator (DFG). Nonlinear-optical media are denoted by their susceptibility $\chi^{(2)}$. Arrows are used to represent input and output waves, together with their optical frequencies ω_j and wave vectors $\mathbf{k}_j$. An OPO requires an optical resonator, comprising at least two aligned reflectors (M_1, M_2).

functions of an OPG and an OPA are combined by multipassing the optical waves involved inside a resonant optical cavity, formed by two or more appropriately aligned reflectors (M_1, M_2).

A difference frequency generator (DFG), as depicted in Figure 1d, is not an OPD, although the DFG source term is central to the nonlinear-optical mechanism of an OPD. In a DFG, two input waves (labeled 1 and 2) are combined coherently to generate a third output wave at the difference frequency of the two input waves: there are now two relatively high-power driving waves, rather than one, and photons are effectively 'joined', rather than 'split' as in the OPD case. Nevertheless, the outcome and utility of a DFG can be similar to that of an OPD. For instance, if coherent radiation is required at a particular infrared (IR) wavelength, it can be generated either as the idler wave of an OPD, with frequency $\omega_I = (\omega_P - \omega_S)$ *or* as the output wave of a DFG, with frequency $\omega_3 = |\omega_1 - \omega_2|$.

Many of the desirable attributes of OPDs in general, and OPOs in particular, arise from the fact that any such instrument is a nonlinear-optical device, not a laser. This allows versatile, flexible design features, such as methods of temporal and wavelength control that are not possible with lasers. The latter generally depend on population inversion of an optical gain medium, with associated optical lifetime and saturation limitations. On the other hand, optical parametric gain, oscillation and amplification are more amenable to modular system design because (as is explained below) they depend on nonlinear-optical coefficients and phase-matching conditions.

Nonlinear-Optical Origins of OPDs

Nonlinear optics involves interaction of a number ($\sigma > 2$) of optical waves in a medium with a nonlinear-optical susceptibility tensor $\chi^{(\sigma-1)}$. For inelastic optical processes, these waves (each with an angular frequency $\omega_1, \omega_2, \ldots, \omega_\sigma$) obey two conservation conditions, one for energy (or frequency):

$$\omega_1 + \omega_2 + \ldots + \omega_\sigma = 0 \qquad [1]$$

The other conservation condition (expressed in terms of wave vectors $\mathbf{k}_i$, with $i = 1, 2, \ldots, \sigma$, that have magnitudes $k_i = n_i\omega_i/c = 2\pi n_i/\lambda_i$, where n_i is the refractive index at vacuum wavelength λ_i and c is the speed of light) is for momentum:

$$\mathbf{k}_1 + \mathbf{k}_2 + \ldots + \mathbf{k}_\sigma + \Delta\mathbf{k} = 0 \qquad [2]$$

where $\Delta\mathbf{k}$ is the phase-mismatch between the σ interacting waves. Each frequency component and wavevector is ascribed a positive or negative sign, according to their phase relationships. Equation [2] defines phase-matching conditions in which $\Delta\mathbf{k}$ must be minimized to optimize the efficiency of the nonlinear-optical process of interest.

We shall consider below the two specific three-wave nonlinear-optical processes that are particularly relevant to this article, namely, those for an OPD (i.e., OPG, OPA, or OPO) or a DFG. Each of these is mediated by the nonlinear-optical susceptibility tensor $\chi^{(2)}$, which is nonzero in a crystalline medium only if it is noncentrosymmetric. Many such crystals are available. For example, lithium niobate ($LiNbO_3$) has been popular since the early days of pulsed tunable OPOs. Subsequent interest and activity in OPD technology have been stimulated by the availability of new nonlinear-optical materials such as BBO (β-barium borate, BaB_2O_4) and KTP (potassium titanyl phosphate, $KTiOPO_4$).

Additional recent impetus has come from quasi-phase-matched (QPM) nonlinear-optical media, such as periodically poled lithium niobate (PPLN) and PPKTP, tailored for specific wavelengths by periodic optical structuring of domains. QPM media offer compact, efficient, low-threshold alternatives to conventional birefringently phase-matched (BPM) media. Characteristics of BPM and QPM nonlinear-optical crystalline media are accessible *via* Arlee Smith's SNLO software package, accessible by internet at www.sandia.gov/imrl/XWEB1128/xxtal.htm.

For a three-wave OPD, which is of principal interest in this article, the energy and momentum conservation conditions of eqns [1] and [2] become:

$$\omega_P - \omega_S - \omega_I = 0, \qquad \mathbf{k}_P - \mathbf{k}_S - \mathbf{k}_I - \Delta\mathbf{k} = 0 \qquad [3]$$

where a laser input wave ('pump', frequency ω_P, wave vector $\mathbf{k}_P$) yields two coherent output waves ('signal', frequency ω_S, wave vector $\mathbf{k}_S$; 'idler', frequency ω_I, wave vector $\mathbf{k}_I$; $\omega_S \geq \omega_I$). Note that the idler frequency ω_I equals the difference $|\omega_P - \omega_S|$ between pump and signal frequencies. Equation [3] should be viewed in the context of sections (a–c) of Figure 1.

Equation [2] and the second half of eqn [3] apply strictly only to the conventional case of BPM media. In such media, the phase-matching condition $\Delta\mathbf{k} \approx 0$ is achieved by adjusting the angle and/or temperature of a birefringent nonlinear-optical crystal *via* its ordinary- and extraordinary-ray refractive indices. Such adjustments are used to optimize OPD conversion efficiency and thereby control the output signal and idler wavelengths, λ_S and λ_I. If it is assumed that the three waves are collinear and that $\Delta\mathbf{k}$ is exactly zero, then the signal frequency/wavelength is given simply in terms of the pump frequency/wavelength and the refractive indices n_i $(i = P, S, I)$ as:

$$\omega_S = \omega_P(n_P - n_I)/(n_S - n_I); \qquad \lambda_S = \lambda_P(n_S - n_I)/(n_P - n_I) \qquad [4]$$

An alternative to birefringent phase matching is the quasi-phase-matching approach first suggested by Nobel Laureate Nicolaas Bloembergen and co-workers in 1962. This approach has been realized experimentally only in the last few years, *via* QPM nonlinear-optical media such as PPLN or PPKTP. Equation [2] and the second half of eqn [3] need to be slightly modified to include QPM grating contributions.

In the corresponding case of a DFG (which, we repeat, is not an OPD), the energy and momentum conservation conditions of eqns [1] and [2] become:

$$|\omega_1 - \omega_2| - \omega_{diff} = 0, \qquad \mathbf{k}_1 - \mathbf{k}_2 - \mathbf{k}_{diff} - \Delta\mathbf{k} = 0 \qquad [5]$$

where two laser input waves (frequencies ω_1, ω_2; wave vectors $\mathbf{k}_1$, $\mathbf{k}_2$) yield one coherent output wave at the difference frequency $\omega_{diff} = |\omega_1 - \omega_2|$ (with wave vector $\mathbf{k}_{diff}$), as depicted in Figure 1d. As above, phase matching is defined by $\Delta\mathbf{k} \approx 0$ for BPM media and, in the case of QPM media, there is an additional grating contribution in the second half of eqn [5].

Finally, we mention briefly two other important forms of nonlinear-optical device arising from four-wave mixing processes that are mediated by the nonlinear-optical susceptibility $\chi^{(3)}$ which can be non-zero, even in isotropic or centrosymmetric media such as gases, liquids, optical fibers, and all classes of crystal. Optical parametric processes of this type contribute to stimulated Raman scattering (SRS), involving an optical medium with Raman-active resonance frequencies ω_R that coincide with the difference between two optical frequencies. This is particularly useful in providing a relatively straightforward source of coherent radiation, Raman-shifted at discrete intervals from the frequency ω_L of an input pump laser (either tunable or fixed-wavelength). Four-wave parametric processes are involved, such as that in eqn [1] with $|\omega_1| = |\omega_3| = \omega_L, |\omega_2| = \omega_L - \omega_R$, and $|\omega_4| = |\omega_1| + |\omega_3| - |\omega_2| = \omega_L + \omega_R$, where ω_R is the characteristic Raman frequency of the nonlinear-optical medium used in the Raman shifter (e.g., high-pressure hydrogen, deuterium or methane gas). These Raman-shifted intervals, both added to (anti-Stokes) and subtracted from (Stokes) the laser frequency ω_L, are integer multiples of ω_R. Other nonlinear-optical Raman parametric processes give rise to various forms of nonlinear Raman spectroscopy, such as CARS (coherent anti-Stokes Raman spectroscopy), and to Raman fiber-optical amplifiers, used in optical telecommunications.

Another promising area of developing OPD technology entailing $\chi^{(3)}$ nonlinearities concerns OPGs, OPAs, and OPOs based on highly nonlinear optical fibers, with either pulsed or cw pump lasers. Such processes use two pump waves (P) to generate tunable signal (S) and idler (I) output waves, such that $\omega_I = 2\omega_P - \omega_S$.

Nanosecond-Pulsed OPOs – Design and Wavelength Control

Here we consider pulsed OPOs that operate on nanosecond (ns, 10^{-9} s) time-scales, and design

Table 1 Some elements of OPO applications to spectroscopy

Key properties	*Options*	*Comments on instrument/technique*
Wavelength range: what forms of spectra need to be measured?	UV/visible (0.2–0.7 μm) Near IR (0.7–4.0 μm) Longwave IR (>4.0 μm)	Many nonlinear-optical OPO materials are available, but less well developed for longwave IR applications
OPO phase matching: BPM or QPM?	Birefringent phase matching (BPM) Quasi-phase matching (QPM)	BPM is well established and preferred for high-power operation. Various low-threshold QPM media are now available for both pulsed and cw OPOs
Temporal: continuous-wave (cw) or pulsed?	Pulsed for power and timing Cw for narrowest bandwidth	Ultrafast (ps, fs) OPO output pulses are relatively broadband, owing to the Fourier transform limit
Optical bandwidth: broad or narrow?	Broadband (free-running) Single longitudinal mode	The Fourier transform limit is 44 MHz ($0.0015\ cm^{-1}$) for an ideal 10 ns pulse Cw OPOs offer even lower $\Delta\nu$. Ultrafast-pulsed OPOs are inevitably broadband: e.g., $\Delta\nu \geq 0.44$ THz ($\geq 15\ cm^{-1}$) for a 1 ps pulse
Mode of recording of spectra: continuous tuning or multiplex?	Scan narrowband signal/idler OPO output wavelength Free-running OPOs operate broadband in multiplex case	Wavelength control yields continuously tuned narrowband spectra. Multiplex spectra use dispersed detection or multi-wavelength spectroscopic tailoring
Wavelength control: intracavity elements or injection seeding?	Intracavity gratings or étalons Injection seeding of signal or idler by a tunable low-power coherent light source	Intracavity-element designs yield broad tunability but can be complicated. Injection seeding facilitates narrowband, mode-hop-free spectra and tailored multi-wavelength experiments

The above options determine ways to use OPOs for spectroscopic applications, such as: (1) linear absorption (e.g., with a multipass cell); (2) cavity ringdown (CRD) absorption spectra; (3) high-resolution spectra ($\Delta\nu \approx$ MHz or kHz); (4) nonlinear-optical (e.g., coherent Raman); (5) atmospheric remote sensing (e.g., DIAL); (6) fast (μs, ns) and ultrafast (ps, fs) processes.

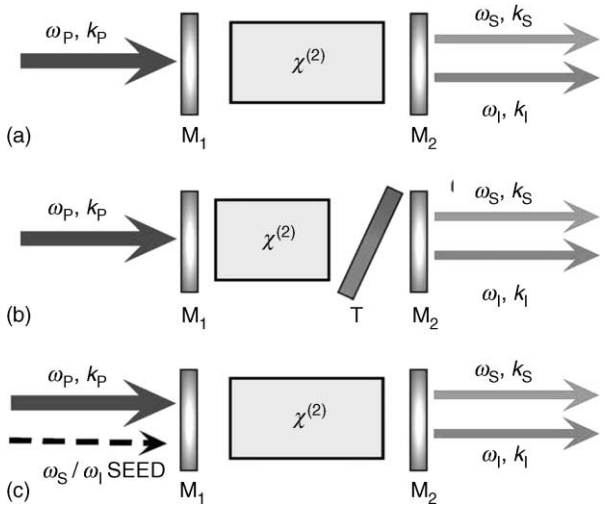

Figure 2 Schematic diagrams of three forms of optical parametric oscillator: (a) free-running OPO (with no active wavelength control), similar to **Figure 1c**; (b) OPO with an intracavity tuning element (T); (c) injection-seeded OPO.

features that make them fit for one of the principal applications of OPDs, namely, spectroscopy. Options that determine ways to use OPOs for spectroscopic applications are summarized in Table 1. Some design and wavelength-control features used in ns-pulsed OPOs are depicted schematically in Figure 2. Some of these applications and features are shared with other forms of OPO, notably the ultrafast-pulsed OPOs and cw OPOs that are considered much more briefly in later sections.

The first OPO, demonstrated by Giordmaine and Miller in 1965, was ns-pulsed; it was based on $LiNbO_3$, tunable over the range ~0.96–1.16 μm, spanning a signal- and idler-wavelength range of ±0.1 μm on either side of the degeneracy point defined by the 529 nm pump radiation (from a frequency-doubled, Q-switched Nd:$CaWO_4$ laser). This advance occurred soon after lasers were discovered and the potential of nonlinear optics had been realized through harmonic-generation processes such as frequency doubling. Pioneering work by Stephen Harris, Robert Byer and their co-workers at Stanford University soon established ns-pulsed OPOs as practical sources of tunable coherent light for significant applications such as spectroscopic sensing of chemical processes, in industrial or environmental diagnostics and in basic science. Such ns-pulsed OPOs had an impressive impact in the 1970s, followed by sporadic progress in much of the 1980s, and a dramatic resurgence of interest and activity since the late 1980s.

This irregular rate of progress is attributable to the availability of suitable high-quality nonlinear-optical crystals (as mentioned above), as well as high-performance pump lasers and advanced tunable OPO system designs.

In a typical ns-pulsed OPO, the pump laser delivers sufficient optical energy to enable parametric gain to build up from noise during the pump–pulse duration, exceeding the threshold for oscillation. To maximize gain, the parametric (signal and/or idler) waves are amplified by multipassing them during the pump pulse in an optical resonator, as depicted in Figures 1c and 2. Light travels ~3 m during a 10 ns pump pulse, so that the parametric waves can make ~15 round trips of a 10 cm linear OPO cavity.

A simple free-running OPO, comprising an optical cavity with input and output mirrors M_1 and M_2 but with no wavelength-selective elements, is depicted in Figure 2a. The output radiation from such an OPO generally has a relatively broad optical bandwidth – typically ~5 cm^{-1} (~150 GHz) or more – depending on several factors: refractivity, dispersion, and absorption of the OPO medium; wavelengths λ_P, λ_S, and λ_I; type of phase matching (BPM or QPM, whether collinear or not); crystal dimensions and orientation; cavity reflectivity and effective number of passes of the resonated wave; optical bandwidth, divergence, pulse duration and pulse energy of the pump radiation. Free-running pulsed OPOs represent one extreme of operational simplicity, yielding relatively broadband output radiation suitable for low-resolution or multiplex spectroscopy. Additional OPO wavelength-control measures are usually necessary for higher-resolution spectroscopic applications.

At the other extreme of operational complexity, intracavity wavelength-selective elements, such as gratings and/or étalons, provide a traditional way to control OPO output wavelength and to achieve narrow optical bandwidths. One such approach is depicted in Figure 2b, where a tuning element T (in this case, a tilted étalon or filter; in other designs, an intracavity diffraction grating replacing the output cavity mirror M_2) is inserted in the cavity. Such approaches were used in early pulsed $LiNbO_3$ OPO designs that were continuously tunable in the near IR with an optical bandwidth of ~0.1 cm^{-1} (~3 GHz), but these were often difficult to operate and were damage-prone (with intracavity losses from gratings and étalons causing the operating threshold to approach the damage threshold of OPO nonlinear-optical materials such as $LiNbO_3$).

Continuous narrowband tunability, preferably on a single-longitudinal-mode (SLM) basis, is a desirable performance characteristic of pulsed OPOs amenable to high-resolution spectroscopy. A commercially viable approach to this ideal was achieved by Walter Bosenberg and Dean Guyer in their advanced KTP OPO/OPA system, which includes a master OPO stage with a grazing-incidence grating. This is continuously tunable under computer control in the near IR (1.3–4 μm) with narrow optical bandwidth – ~0.02 cm^{-1} (~600 MHz) or better. Such a high-performance tunable coherent IR source has been used for various forms of laser spectroscopy (cavity ringdown, degenerate four-wave mixing, long-path absorption, etc.), including investigations of chemically reactive media, combustion diagnostics, and studies of processes in molecular beams.

A popular alternative approach to OPO wavelength control is injection seeding by a low-power tunable coherent source such as a tunable diode laser (TDL). This approach is depicted in Figure 3; in practice, a ring cavity is often used to avoid

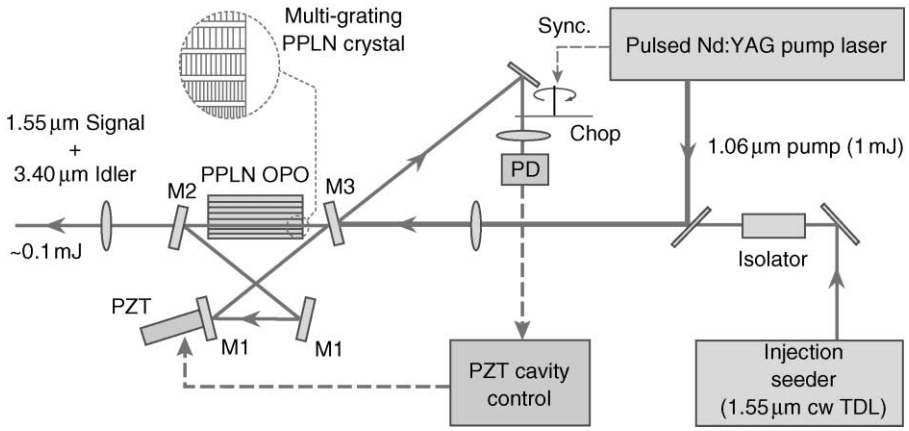

Figure 3 Schematic diagram of an injection-seeded tunable PPLN OPO system with active cavity control, developed in the author's laboratory. Legend: PD = photodetector, PZT = piezoelectric translator, TDL = tunable diode laser, M_{1-3} = cavity reflectors; the inset shows the QPM multi-grating structure of the PPLN nonlinear-optical crystal.

feedback from the OPO to the seed laser. A significant advantage of injection seeding is that OPO construction is simplified by putting the wavelength-control function into a module that is effectively separate from the optical generation and amplification functions. For example, a high-performance, TDL-seeded PPLN OPO system developed in the author's laboratory is illustrated in Figure 3. It features a multigrating QPM gain medium that is temperature-adjustable up to 250°C, and is pumped at a wavelength of 1.064 μm by a ns-pulsed, SLM Nd:YAG laser. An active cavity control scheme devised by Yabai He enables the SLM near-IR signal and idler outputs from this OPO (at ~1.5 μm and ~3.5 μm, respectively) to be tuned continuously without mode hops over optical frequency ranges of ~250 cm^{-1} (~7.5 THz) with a SLM optical bandwidth of <0.004 cm^{-1} (<120 MHz), as has been confirmed in assorted applications to molecular spectroscopy. The PPLN OPO can by itself generate only moderate output pulse energy (~0.1 mJ, approximately 70% of which is signal radiation), since the 1.064 μm Nd:YAG pump laser pulse energy is limited to ~1 mJ to avoid the optical damage threshold of the PPLN crystal. For higher-power applications, a further portion of the Nd:YAG laser energy (~200 mJ/pulse) can be used to pump an OPA stage based on BPM $LiNbO_3$, thereby generating SLM signal and idler output pulse energies of ~1.3 mJ and ~0.7 mJ, respectively.

An alternative approach to injection-seeded tuning of ns-pulsed OPOs (used extensively by the author's group in the context of BPM media such as BBO and $LiNbO_3$) entails passive control of the OPO cavity by slightly misaligning one of its reflectors. This facilitates continuous tuning of the injection-seeded OPO signal and idler outputs by decreasing the effective finesse of the OPO cavity, so that it is then not necessary to lock the OPO cavity length to the seed wavelength. This mode of operation is simpler optically and electronically than active control of the OPO cavity. The method depends on the OPO cavity having a series of high-order transverse modes to smooth out the sharp, widely separated resonances that occur when the OPO cavity is well aligned; a resulting disadvantage is that the multiple transverse modes tend to cause some degradation of output beam quality. Nevertheless, this approach has proved useful for many applications of tunable OPOs, with seeding by either pulsed dye lasers or SLM TDLs.

This passive, misaligned-cavity approach to injection seeding of ns-pulsed OPOs is particularly well suited for spectroscopic applications requiring a coherent source that simultaneously generates two or more adjustable output wavelengths. Such a TDL-seeded, dual-wavelength BBO OPO has been used in the author's laboratory for coherent-Raman spectroscopic measurements of nitrogen (N_2) in furnace air; the relative intensity of the two spectroscopic features provides an instantaneous, turbulence-immune estimate of the temperature of gas in the furnace, within a single shot of the OPO's pump laser (i.e., within ~10 ns). This is an example of so-called spectroscopic tailoring, in which an OPO generates a structured set of two or more discrete output wavelengths, each of which is set to be on- or off-resonance with characteristic features in spectra of molecular target species of interest.

Dual-wavelength injection seeding of ns-pulsed OPOs is relevant to atmospheric remote sensing by DIAL (differential absorption lidar), with TDL-seeded OPO output switched between on- and off-resonance IR wavelengths on alternate shots of the pump laser; range-resolved measurements have been made of key atmospheric species such as methane (CH_4) and water vapor (H_2O). Figure 4 illustrates a proposed extension of the spectroscopic tailoring concept, applicable to dual- and multi-wavelength remote sensing applications by long-path absorption or DIAL. This multiplex system comprises a multi-wavelength passive-cavity pulsed OPO, injection-seeded by a set of single-mode TDLs and a computer-controlled fiber-optic switch to code and decode the resulting multiplex spectroscopic signals.

A significant frontier for narrowband pulsed OPOs entails extending the spectral output range beyond the present readily attainable near-IR limit of ~4 μm (as provided by materials such as BBO, KTP, $LiNbO_3$, PPLN, and PPKTP). This extension yields high-performance tunable coherent spectroscopic sources at longwave-IR wavelengths where many of the strongest molecular fundamental IR absorption bands are located. OPOs that target the longwave IR depend on availability of suitable nonlinear-optical materials and coherent pump sources at sufficiently long wavelengths (typically >2 μm). One of the most promising longwave-IR OPO materials is zinc germanium phosphide ($ZnGeP_2$), pumped at 2–3 μm by solid-state crystal lasers such as those based on holmium or erbium. An étalon-tuned narrowband (~0.1 cm^{-1}) $ZnGeP_2$ OPO, itself pumped at 2.55 μm by a broadband (~15 cm^{-1}) Nd:YAG-pumped $LiNbO_3$ OPO, is able to cover the wavelength range 3.7–8 μm and has been used to record spectra of H_2O vapor in the 6.2 μm region. Pulsed OPOs based on gallium arsenide (GaAs) also have great potential; they can be pumped at wavelengths as short as 1 μm and

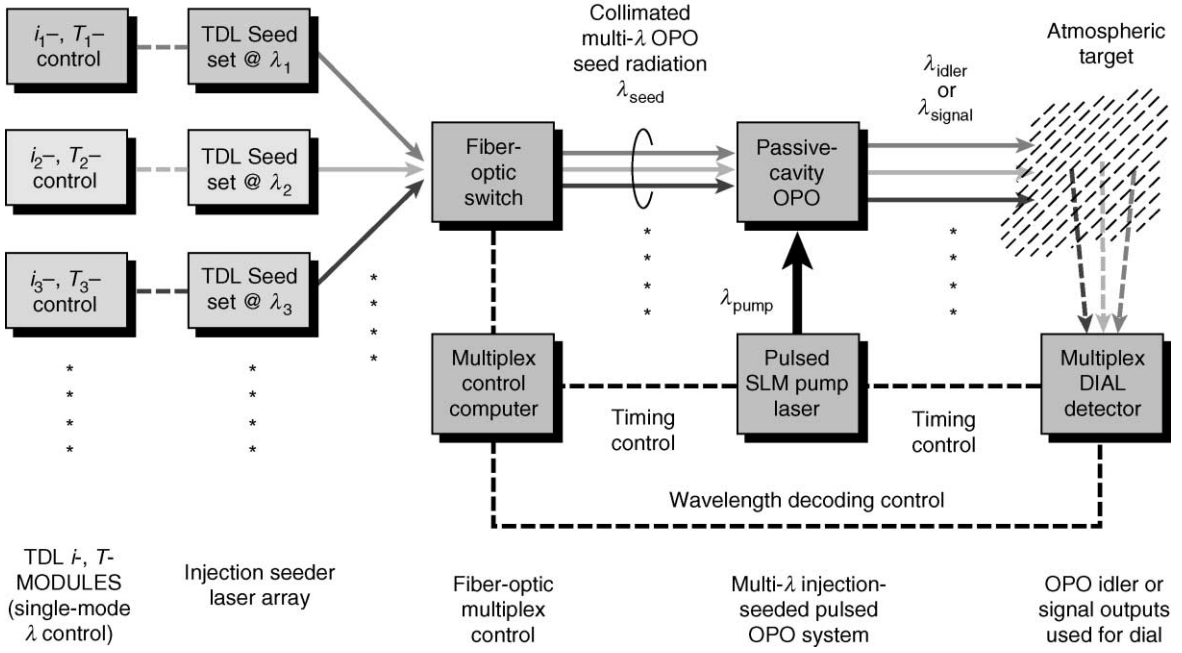

Figure 4 Schematic diagram of a multi-wavelength pulsed OPO system employing spectroscopically tailored injection seeding. This design has been proposed by the author for atmospheric remote sensing by DIAL (differential absorption lidar) or long-path absorption.

offer (so far unrealized) tunability out to ~16 μm. Despite its cubic structure and lack of birefringence, GaAs serves as a QPM nonlinear-optical medium in the form of orientation-patterned films.

Another approach to operating continuously tunable OPOs is to vary the wavelength of the pump laser, while fixing other phase-matching parameters such as temperature of the gain medium and crystal angle or QPM grating pitch. Suitable tunable pump laser sources that have been used to pump ns-pulsed OPOs include Ti:sapphire and tunable fiber lasers.

The various wavelength-control strategies outlined above illustrate some of the distinctive attributes of OPOs. It should be recognized that the signal and idler wavelengths of an OPO are distinctly different from that of the pump laser itself, thereby opening up fresh regions of the electromagnetic spectrum. Even if an OPO is injection-seeded (e.g., by a cw TDL) at its signal or idler wavelength, it still generates complementary idler or signal radiation at a new wavelength and (in the case of a pulsed OPO) it also pulse-amplifies the original seed light. Moreover, the nonlinear-optical parametric relationships between the pump, signal, and idler waves in an OPO allow various wavelength-control approaches (e.g., spectroscopic tailoring by multi-wavelength injection seeding) that are simply not attainable in tunable lasers.

Ultrafast-Pulsed OPOs

Given the relatively high peak power of very short (sub-ns) pulses of coherent laser light, it might seem quite easy to use such light to pump the gain medium of an OPD and to exceed its OPO threshold. However, such a task is not at all straightforward, because an ultrafast light pulse, on the time-scale of picoseconds (ps, 10^{-12} s) or femtoseconds (fs, 10^{-15} s), does not stay in one place long enough to enable a coherent parametric wave to build up from noise in the nonlinear-optical medium. Light travels a distance of only ~0.3 mm in 1 ps, which does not allow it to make multiple traversals of the nonlinear-optical medium and build up coherent signal and idler waves. This problem is overcome by synchronous pumping (also used in some ultrafast lasers), in which a train of many consecutive ultrafast pulses from a pump laser interact sequentially with a single signal or idler pulse circulating within the OPO cavity. The mode-locking interval of the pump laser (essentially the round-trip transit time in the laser cavity) must therefore equal the round-trip time of the down-converted (signal or idler) pulse in the OPO cavity. The situation is aggravated when sub-ps (e.g., ~100 fs) pump pulses are used, because the pump and signal (or idler) waves have sufficiently different group velocities that they undergo

'temporal walk-off', becoming separated in time after traversing a relatively short length (typically 1–10 mm for 100-fs pulses) of the nonlinear-optical medium.

Practical ultrafast OPOs were introduced around 1990 and their utility grew as improved pump lasers, nonlinear-optical materials (e.g., KTP, PPLN), and OPO cavity designs became available. Research on ps- and fs-OPOs is now a hot topic, and numerous broadly tunable commercial systems are on the market. Ultrafast OPO-based spectroscopy is becoming extremely important in applications to biology and medicine, where many key processes occur on ps- and fs-time-scales.

Continuous-Wave OPOs

The first cw OPO, reported in 1968, operated in the near-IR and was based on barium sodium niobate ($Ba_2NaNb_2O_5$ – known popularly as 'banana'); it was soon followed by visible cw OPOs based on $LiNbO_3$. However, there was not much more substantial progress on practical cw OPOs for another 20 years, until several technological advances had been made: low-threshold QPM nonlinear-optical gain media, such as MgO:$LiNbO_3$ and KTP; efficient, wavelength-selective cavity designs; all-solid-state cw pump lasers (e.g., diode-pumped crystal lasers or MOPA diode systems). More recently, QPM media (such as PPLN and PPKTP) have provided a further stimulus to efficient, compact cw OPOs.

Most ns-pulsed OPOs use singly resonant (SROPO) designs in which the cavity resonates at either the signal or idler wavelength (but not both), doubly resonant (DROPO) schemes in which both signal and idler resonate are often needed to meet the more demanding pump threshold requirements of cw OPOs. Continuous tuning of a DROPO without longitudinal mode hops needs multiparameter approaches, either dual-cavity (with separate signal- and idler-resonant arms) or concerted tuning of pump and signal/idler wavelengths. Efficient cavity designs for cw OPOs include those that are pump-enhanced (i.e., the cavity is resonant at the pump wavelength as well as the signal and/or idler) and intracavity arrangements in which the laser and OPO gain media share a common cavity. Progress is also being made on cw OPOs based on highly nonlinear optical fibers. With such developments, cw OPOs now have great potential as tunable spectroscopic sources, through their narrow optical bandwidth and their compactness.

OPGs and DFGs – Dispensing with the Optical Cavity

Most of this article has focused on OPOs, in which parametric processes are generated by pumping a nonlinear-optical medium in an optically resonant cavity. As already explained, such a cavity is used to enhance the optical parametric gain by multipassing the signal and/or idler radiation. In some cases, the cavity also contributes to wavelength control, temporal characteristics, beam quality, etc. However, not all optical parametric and related devices need a cavity, as is evident from the OPG, OPA, and DFG schematics in **Figures 1a, b,** and **d**.

The use of one or more OPA stages, to supplement the intracavity amplification already present in an OPO itself, is widespread in tunable OPO/OPA systems. Moreover, in some applications (e.g., spectroscopic measurements where optical power is not at a premium) of pulsed OPDs, it is found that a single pass of a (relatively long) nonlinear-optical crystal results in a useful OPG (without an OPO cavity). For instance, Scott Bisson, Thomas Kulp, Peter Powers and co-workers have developed and used several OPD systems of this type. A cavity-free OPG/OPA system that is pumped by a 1 kHz Nd:YAG laser, based on 'fan' PPLN (tuned by continuous transverse variation of the QPM grating pitch), and spectrally filtered by a high-finesse étalon, generates ~10 μJ/pulse of idler radiation. This OPG/OPA radiation has been used to measure narrowband ($\Delta\nu < 0.1\ cm^{-1}$) cavity-ring-down spectra of CH_4 gas.

Likewise, various tunable DFG devices (closely related, but not identical, to OPDs) have been used in many spectroscopic applications. For instance, a DFG system developed by Frank Tittel and colleagues at Rice University took the near-IR output of two room-temperature TDLs (at 1.55 μm and 1.32 μm, respectively), mixed them in a BPM nonlinear-optical medium such as $AgGaSe_2$, and generated 8.7 μm mid-IR radiation for long-path absorption studies of sulfur dioxide (SO_2), an important atmospheric pollutant. The same group has also used QPM media (e.g., PPLN) for DFG mixing of TDL outputs in the 0.8 μm–1.6 μm range, yielding output at ~3.5 μm to monitor gases such as H_2O, CH_4, and formaldehyde (H_2CO); such DFG devices have been used in NASAs Lunar-Mars Life Support Test program.

Relative to OPGs and DFGs, OPOs and OPAs offer higher output power and coherence, both of which are advantageous in some applications (e.g., remote spectroscopic sensing of the atmosphere). Nevertheless, OPGs and DFGs still have a useful role to play, as indicated above.

Concluding Remarks – When to Use an OPD?

Coherent light sources based on optical parametric generation, amplification, and oscillation represent a significant application of nonlinear optics. Such devices can in turn address as many applications as lasers themselves, at least in principle. However, the fact that OPDs need to be pumped by a laser tends to limit their use to situations that take advantage of their wavelength-conversion and tunability capabilities. The most obvious areas of application of an OPO or any other OPD are therefore those in which the wavelength of the output radiation is critical (e.g., spectroscopy, as indicated in various parts of the above text).

From time to time, there have been suggestions that OPOs would largely displace established tunable lasers such as dye and Ti:sapphire lasers. In the early 1990s, one major laser manufacturer ventured to advertise its new OPO-based instrument with the slogan, "Goodbye to Ti: and Dye". However, such a projected monopoly for OPOs has not eventuated and most laser spectroscopy facilities now depend upon a balanced combination of OPOs together with various forms of tunable laser (including semiconductor lasers, which are almost ubiquitous).

Optical Parametric Oscillators (Continuous Wave)

S Schiller, Heinrich-Heine Universität Düsseldorf, Düsseldorf, Germany

Introduction

A continuous-wave optical parametric oscillator (cwOPO) is a frequency conversion device in which a continuous-wave (cw) laser field (pump) of frequency ω_p is partially converted into two cw waves of lower frequencies ω_s, ω_i (historically denoted by signal and idler) inside an optical cavity. The three frequencies are related by $\omega_i + \omega_s = \omega_p$. The cavity contains a nonlinear medium with a second-order susceptibility and the mirror reflectivities are chosen such that at least one of signal and idler resonates in the cavity. The conversion efficiency from pump power to signal or idler power or both can be larger than 10%. The frequencies of signal and idler waves can be tuned by means similar to conventional lasers, i.e., by changing the spectral dependence of the cavity

loss and by tuning the cavity length. Additional tuning parameters specific to OPOs are the pump frequency and the refractive indices of the nonlinear medium for pump, signal and idler. CwOPOs provide a unique combination of features that makes them suitable sources for a variety of spectroscopic applications. Today's cwOPOs can exhibit the following features:

- spectral coverage from the near-infrared (0.7 μm) to the mid-infrared (5.2 μm); for a single device two optical octaves can be covered without change of optical components;
- high output power (up to several W);
- high pump power conversion efficiency (>30%) and good wall-plug efficiency;
- nearly diffraction-limited output beams (modes are close to lowest-order transverse electromagnetic (TEM_{00}) modes)
- single-frequency output, absence of frequency jumps (mode hops);
- narrow free-running linewidth (<6 kHz);
- high absolute frequency stability (<100 MHz drift per hour);
- continuous frequency tuning exceeding 10 GHz;
- rapid, stepwise tuning over several THz; and
- transportability.

cwOPOs complement their pulsed relatives (*see* **Optical Parametric Devices:** Optical Parametric Oscillators (Pulsed)) nanosecond and synchronously pumped pulsed parametric oscillators (*see* **Optical Parametric Devices:** Overview).

Basic Principle

The operation of a cwOPO is most simply described for a singly resonant OPO (SRO) (see Figure 1 and Figure 2a).

Without loss of generality we take the signal wave to be the resonant wave. When a higher-frequency pump wave (power P_p, angular frequency ω_p) and a lower-frequency (signal) wave (power P_s, angular frequency ω_s) traverse a $\chi^{(2)}$ medium (*see* **Fiber and Guided Wave Optics:** Nonlinear Optics), a transfer of power from the pump wave to the signal wave occurs, described by a power gain:

$$\Delta P_s = GP_s = EP_pP_s \qquad [1]$$

This parametric amplification expression is valid as long as $\Delta P_s \ll P_s, P_p$, i.e., in the limit of small gain and small pump depletion. The (unsaturated) gain coefficient E is a function of: the medium's indices of refraction, orientation and length L, the frequencies

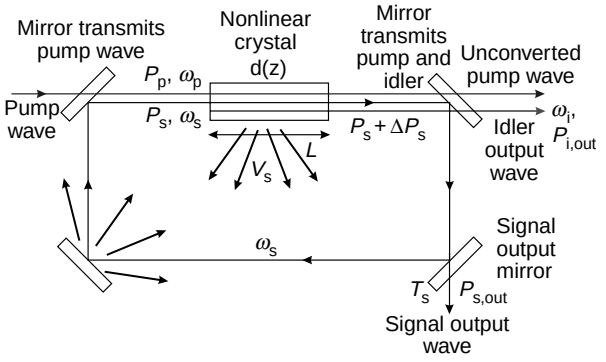

Figure 1 Schematic of a singly resonant cwOPO (SRO) in ring configuration. The signal wave (ω_s) is resonated, the idler wave (ω_i) is not. In the nonlinear crystal, the pump wave overlaps with the signal and idler waves; here they are shown displaced with respect to each other for clarity. The signal wave's attenuation coefficient per roundtrip, S_s, is the sum of loss inside the nonlinear crystal, V_s (indicated by arrows), and transmission through mirrors, here represented by a single mirror of transmission T_s. Scatter and absorption losses at mirrors (indicated by arrows) are included in V_s.

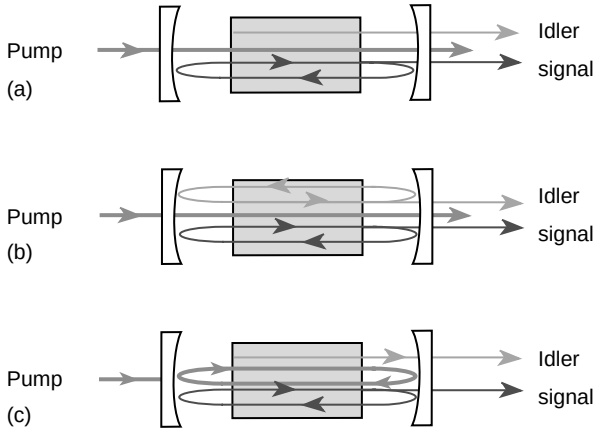

Figure 2 Common types of cwOPOs. (a) basic SRO. (b) Doubly resonant OPO (DRO). Standing-wave cavities are shown. (c) SRO with enhancement of the pump wave (PR-SRO); a common-cavity configuration is shown.

ω_s, ω_p, and the spatial modes and overlap of the two beams.

If the wave ω_s is made to circulate inside a cavity and the power attenuation per roundtrip, S_sP_s is smaller than the power gain per roundtrip (eqn [1]), a sustained oscillation is possible. This is satisfied when the input pump power P_p exceeds the threshold:

$$P_{p,in}^{th} = S_s/E \qquad [2]$$

As the pump power P_p is increased above $P_{p,in}^{th}$, conversion of pump power to idler power occurs, implying that the pump power decreases within the medium. Qualitatively, the average pump power $\langle P_p \rangle$

along the medium remains at the level $P_{p,in}^{th}$, so that the roundtrip fractional power gain remains constant, $G \simeq E\langle P_p\rangle \simeq EP_p^{th} \simeq S_s$. This ensures that the device reaches a stationary state. The circulating signal power P_s increases steadily with increasing pump power, and so does the signal power emitted from the OPO, T_sP_s, which is equal to the 'useable' fraction of the roundtrip power gain, $(T_s/S_s)GP_s$.

The parametric process that allows the signal wave to experience gain (eqn [1]), also generates an idler wave (difference frequency generation). Its power at the end of the medium is given by the Manley–Rowe relation:

$$P_i = \frac{\omega_i}{\omega_s}\Delta P_s \qquad [3]$$

An OPO also requires a process that starts the oscillation. Spontaneous parametric fluorescence provides this trigger. Due to this quantum effect, a pump wave traversing a $\chi^{(2)}$ medium will generate a flux of signal photons even if there is no signal wave present at the crystal input face. In the photon picture, a tiny fraction (on the order 10^{-9} for a 1 W pump) of the pump photons spontaneously annihilate, creating pairs of signal and idler photons (photon splitting). The idler photons have a frequency $\omega_i = \omega_p - \omega_s$, so that photon energy conservation holds. The process may be thought of as being stimulated by the vacuum fluctuations of the electromagnetic field at the signal and idler frequencies. Some of the signal photons are emitted into the cavity mode, so that after a roundtrip they can serve as a seed for further (stimulated) photon splitting. The process repeats, and the signal wave builds up exponentially in time to a macroscopic level if the pump power is above threshold. The spontaneous (as well as the parametric amplification) process is strongest when momentum conservation is essentially fulfilled, $k_p \simeq k_s + k_i$, where $k = \omega n(\omega)/c$.

In the photon picture, the relation (eqn [3]) is a statement that signal and idler photons are always created in pairs.

Types of OPOs

OPO types may be classified according to the number of waves that resonate within cavities. Typically, a realizable roundtrip loss coefficient is on the order of $S_s = 1\%$ (to which the linear absorption of the nonlinear crystal and mirror transmissivities contribute) and the gain coefficient $E \sim 0.1\%/\mathrm{W}-1\%/\mathrm{W}$ for Gaussian waves, depending on the pump wavelength, crystal type, etc. This leads to SRO threshold powers on the order of 1 to 10 W. Until the early 1990s, solid-state pump lasers of this power level and single-frequency output were unavailable. This led to the interest in and development of cwOPOs in which more than one of the three waves is resonated (Figure 2). The corresponding external threshold powers are

$$\begin{aligned} P_{p,in}^{th} &\simeq S_sS_i/4E \text{ for a doubly-resonant OPO} \\ &\qquad (\text{DRO, Figure 2b}) \\ P_{p,in}^{th} &\simeq S_sS_p/E \text{ for a pump-resonant SRO} \\ &\qquad (\text{PR-SRO, Figure 2c, see eqn [35]}) \\ P_{p,in}^{th} &\simeq S_sS_iS_p/E \text{ for a triply-resonant OPO (TRO)} \end{aligned} \qquad [4]$$

Here $S = T + V$ is the fractional power attenuation per roundtrip, arising from the mirror transmission T and absorption/scatter loss V. While the mirror transmission maintains power in a given spatial mode, the loss V removes optical power completely and is the fundamental cause for the nonunity efficiency of the frequency conversion process. Typically, each additional resonant enhancement lowers the threshold power by one to two orders.

Examples for threshold values reported in the literature are: 1.9 W for a 920 nm-pumped SRO, 4 mW for a 0.5 μm-pumped DRO, and 140 mW for a 1 μm-pumped common-cavity PR-SRO. DROs can therefore be pumped even by low-power diode lasers. TROs (where pump, signal, and idler are resonated) are not of importance due to their higher complexity.

Output Power

As an example, the signal and idler output powers for a PR-SRO that resonates the signal are (for a derivation, see Appendix B):

$$P_{s,out} \simeq T_sP_s(0), \qquad P_{i,out} \simeq (\omega_i/\omega_s)S_sP_s(0) \qquad [5]$$

where the circulating signal power is

$$P_s(0) \simeq \frac{\omega_s}{\omega_p}\frac{4T_p}{S_sS_p}P_{p,in}^{th}\left(\sqrt{\frac{P_{p,in}}{P_{p,in}^{th}}} - 1\right) \qquad [6]$$

T_p is the input mirror transmission for the pump wave, and T_s is the output mirror transmission of the signal wave. Signal and idler output powers have the same dependence on pump input power and increase monotonically with $P_{p,in}$. The conversion efficiencies reach a maximum four times above threshold, i.e., when $P_{p,in} = 4P_{p,in}^{th}$. There, the signal and idler photon (quantum) conversion efficiencies $\omega_pP_{s,out}/P_{p,in}\omega_s$ and $\omega_pP_{i,out}/P_{p,in}\omega_i$ exceed 25% and 50%, respectively, if the mirror transmissions T_p, T_s for pump and signal

are chosen larger than the respective loss V_p, V_s. This can be achieved in practice, of course, at the expense of a higher threshold.

Nonlinear Materials

While the fundamental developments in cwOPOs were performed using birefringently phase-matched nonlinear crystals ($MgO:LiNbO_3$, LBO, KTP, $KNbO_3$) (*see* **Materials for Nonlinear Optics:** Liquid Crystals for NLO), and substantial spectral coverage is possible with these crystals, most cwOPOs are now operated with quasi-phase-matched (QPM) nonlinear crystals (*see* **Nonlinear Optics, Application:** Phase Matching). The most commonly used material is periodically poled (PP) $LiNbO_3$ (PPLN), other crystals used are PPKTP and $PPLiTaO_3$, crystals. Their use has led to a substantial widening of the spectral coverage, opening in particular the wavelength range $\lambda > 1.6$ μm, a reduction of the required pump powers thanks to their much higher nonlinearities compared to birefringently phase-matched crystals, and a simplification of (gross) tuning through the use of multigrating structures (containing several sections of differing Λ periods side by side within the same crystal). The above PP crystals exhibit a loss of 0.1%/cm at wavelength around 1 μm, and can be coated with broadband dielectric antireflection coatings, in order to maximize the overall transmission. Another important aspect is that the crystals withstand long irradiation times with high-power focused cw light. For PPLN, operation temperature above 100°C is chosen in order to prevent photorefractive effects.

Spectral Coverage

An example of particularly wide spectral coverage reported in the literature is a cwOPO pumped by a frequency-doubled $Nd:YVO_4$ laser ($\lambda_p = 532$ nm) using a multigrating PPLN crystal. With grating periods $\Lambda = 6.5–9.6$ μm, the range 660–1030 nm (signal wave) and 1100–2800 nm (idler wave) was covered. A cwOPO with a Nd:YAG pump source emitting at the fundamental wavelength ($\lambda_p = 1064$ nm) and a multigrating PPLN crystal ($\Lambda = 25.5–31.2$ μm) achieved a range of 1.45–1.99 μm (signal) and 2.3–4.0 μm (idler).

For idler wavelengths beyond 4 μm, idler absorption by the crystals types above becomes relevant, leading to a reduction in the gain G (this effect is not considered in the treatment given in the Appendix) and to an increase of the threshold. To a certain extent, this can be compensated with powerful cw pump lasers. For example, a 1064 nm pumped PPLN-SRO achieved idler emission in the range 3.6–4.7 μm at 11 W pump power. Also, an 850 nm pumped PR-SRO covered an idler range 4.3–5.3 μm when pumped with 750 mW.

In the future, cwOPOs will certainly profit from the development of novel QPM materials with wider IR transparency range.

Frequency Control

The small-signal gain $G(\omega_s)$ of a parametric interaction in a cwOPO is analogous to the homogenously broadened gain in a laser medium. In contrast to it, however, spatial hole-burning cannot occur. Therefore, mode competition is generally strong in a cwOPO, which will oscillate on a single longitudinal mode: the one for which the difference (or ratio) between 'unsaturated' parametric gain G and total loss S is largest (Figure 3). This is equivalent to the condition of minimum threshold.

The functions $G(\omega_s)$ and $S(\omega_s)$ are therefore important characteristics of a cwOPO. Oscillation can only occur for a frequency ω_s that is very close to a cavity mode frequency $\omega_q = 2\pi qc/OPL(\omega_q)$, where q is the integer mode number, and $OPL(\omega_s)$ is the round-trip optical path length at the frequency ω_s.

To tune a cwOPO to a particular signal/idler frequency pair, a coarse tuning is initially performed

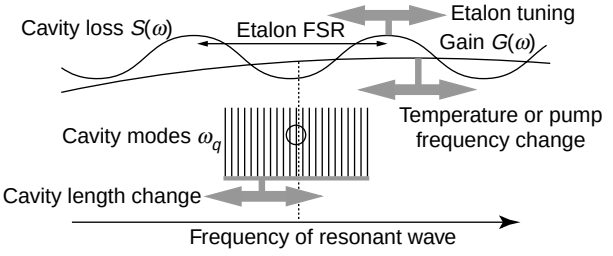

Figure 3 Frequency selection and tuning in a SRO (or PR-SRO) containing an etalon. Oscillation occurs on the signal cavity mode (circled) closest to the frequency where the difference between the small-signal gain G and the loss S is largest (dashed line). The frequency of this mode or the mode number q can be changed by changing the parameters indicated near the thick double arrows. The parameter changes shift the line(s) 'attached' to the corresponding double arrow. Changing the temperature leads to a rough setting of the oscillation frequency. Tilting the etalon allows mode-hop tuning of signal and idler frequencies. Fine tuning by a small amount can be done by changing the cavity length. The frequency of the idler is not shown here; it is always given by the difference between pump frequency and the frequency of the oscillating mode. Thus, tuning of the pump frequency generally leads to a tuning of the idler frequency. For modest pump tuning the amount of signal tuning however depends on SRO type: no signal tuning in a basic SRO and in a dual-cavity PR-SRO, while in a common-cavity PR-SRO pump and signal frequencies are correlated and thus pump tuning leads to signal tuning. FSR: free spectral range.

by tuning the corresponding phase mismatch ΔkL (L is the crystal length) approximately to zero. Taking into account a modulation of the nonlinear susceptibility of the crystal with period Λ, the quantity $\Delta k = k_p - k_s - k_i \pm 2\pi/\Lambda$ describes the deviation from momentum conservation in the photon splitting process. When using a multigrating QPM crystal, the first tuning consists in the selection of a grating of appropriate period Λ, which is moved into the pump wavepath. This is followed by tuning the photon momenta via the refractive indices of the nonlinear medium, which is usually accomplished by temperature tuning, or alternatively by angle-tuning of the crystal. These steps place the maximum of $G(\omega_s)$ to the vicinity of the desired frequency. Options for tuning the emission exactly to the desired frequency are described below for the different OPO types.

Because external perturbations change parameters that enter in $G(\omega_s)$, $S(\omega_s)$, and ω_q, the value of the oscillating frequency will also change in time. The change will be continuous over a certain range of the parameters, but if their perturbation is large enough, a mode hop can occur: the oscillation on the initial mode q will eventually cease and another mode q', for which $G(\omega_{q'}) - S(\omega_{q'})$ is larger, will oscillate instead. A variety of parameters is affected by perturbations: pump power, pump beam direction, cavity length, crystal temperature, and pump frequency.

When such perturbations are applied on intentionally, the OPO output frequencies can be tuned, scanned, or adjusted. The tolerable change in the various parameters before a mode-hop occurs, and the sensitivity of the output frequencies to changes in the parameters depends on the particular cwOPO type. One important approach to suppress mode-hops consists in adding elements into the cavity, such as an etalon, that modify the function $S(\omega)$, typically by modulating it spectrally.

SRO

In the following, we assume that the signal wave is resonated. The SRO is the simplest cwOPO type. The oscillation nominally occurs at the cavity frequency that is closest to the gain maximum, as described above. In practice, environmental disturbances will cause mode-hops on a time-scale of minutes. For this reason, an etalon is added to the cavity. Mode-hop-free oscillation, for several hours, is then achieved.

Typical nonlinear crystals exhibit parametric gain with spectral widths of hundreds of GHz. In contrast, the cavity mode spacing (free spectral range, FSR) c/OPL is on the order of 1 GHz. The tuning range achievable by a cavity length change (using, e.g., a piezo translator) is therefore, at most, one free spectral range (equal but opposite for signal and idler); then a mode-hop to the neighboring cavity mode occurs, with a signal/idler frequency jump by one FSR in the opposite direction to the previous tuning. This process repeats itself as the cavity length is tuned further. It is, therefore, not possible to easily and reliably access a large frequency range by using the cavity length as tuning parameter.

As shown in Figure 3, if an etalon of linewidth smaller than the gain bandwidth is added to the cavity, it becomes the dominant influence (etalon FSRs on the order of one hundred to a few hundred GHz have been used). This means that shifting the etalon's transmission maximum (i.e., the cavity loss S) in frequency space (by tilting a solid etalon or changing the spacing of an air-spaced etalon) as indicated by the double-headed arrows in Figure 3, forces the signal to mode-hop to an adjacent mode, with a corresponding idler frequency hop in the opposite direction. As the etalon is tuned further this occurs repeatedly. This discontinuous 'mode-hop tuning' is useful for tuning the SRO output frequencies over a significant range (e.g., 100 GHz) and allows to reach a desired frequency within one cavity free spectral range.

Continuous tuning of both signal and idler waves is obtainable, if the pump laser is not frequency tunable, by changing the cavity length and synchronously tuning the etalon. This can be achieved by a feedback or feedforward system that controls the etalon angle or spacing. Up to 38 GHz tuning for signal and idler were achieved in this way.

When a tunable pump is available, one can tune the pump frequency while keeping the cavity length and the etalon angle fixed. This keeps the signal cavity mode fixed, and thus the nonresonant wave's frequency (usually the idler) is tuned by an amount equal to the pump frequency change. Continuous tuning ranges exceeding 50 GHz have been obtained in this way. For such pump tuning ranges, the shift of the gain curve, indicated by a double-arrow in Figure 3, is usually sufficiently small that it can be neglected. The use of a widely tuneable pump laser is also possible. A (discontinuous) idler tuning of 9 THz around 3.3 μm has been demonstrated, covered in just 0.3 ms thanks to a large pump tuning rate. In such a case of large pump tuning range, the gain shift is important, causing a significant tuning also of the signal.

The advantages of the basic SRO as compared to other cwOPOs are mainly the simpler tuning behavior, the possibility of continuous tuning without necessitating a tunable pump laser, and the possibility to achieve a very wide tuning range without optics

change, since only the spectral range covered by one of the two parametric waves must be provided as a high reflectivity coating on the cavity mirrors. Moreover, in the simplest implementation, it is possible to operate without any electronic servo control of cavity elements, at the expense of a reduced power and frequency stability. In terms of spectral properties (linewidth, frequency stability, time between undesired mode-hops) the SRO does not offer particular advantages compared to other cwOPO types, even if actively stabilized (see below). The disadvantage of the basic SROs based on Gaussian modes is the high threshold, necessitating expensive high-power (several W) cw lasers. This disadvantage is likely to disappear with progress in laser development. The alternative of waveguide SROs is mentioned below.

PR-SRO

In a PR-SRO, the pump wave is also resonated, leading to a substantial reduction of threshold. For example, it is possible to generate mid-IR radiation (3 μm range), even with much more affordable 1 W-level Nd:YAG pump lasers.

One implementation is the common-cavity PR-SRO (Figure 4). The cavity length is either locked to the pump laser frequency or vice-versa. If a frequency-stable pump laser is used, the first solution is favorable, since then both signal and idler waves have a stability comparable to that of the pump laser. With an etalon (coated so as to be transparent for the pump wave) inside the cavity, mode-hop-free operation for several hours has been demonstrated.

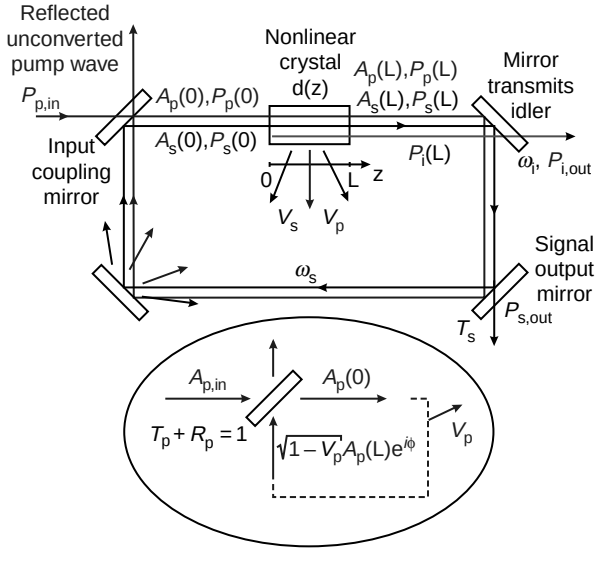

Figure 4 Schematic of a pump-resonant SRO with a common cavity for pump and signal waves. The inset shows the pump wave fields incident on and leaving the input coupling mirror. The arrow symbolizes pump wave loss during the round trip.

Mode-hop tuning in a PR-SRO with cavity-to-laser lock can be achieved:

(i) by tuning the etalon at constant pump frequency: the signal mode-hops from mode to mode, the idler tunes equally but in opposite direction;
(ii) by tuning the pump frequency at constant etalon position: the cavity length must follow and therefore the signal tunes by $\Delta\omega_s = (\omega_s/\omega_p)\Delta\omega_p$, while the idler frequency tunes by $\Delta\omega_i = (\omega_i/\omega_p)\Delta\omega_p$. This continues until the signal must mode-hop back, causing an equal but opposite frequency jump in the idler. The pump tuning is thus completely transferred to the idler.

Continuous signal and idler tuning is performed by tuning the pump frequency and synchronously adjusting the etalon angle. Thus, a limitation of the common-cavity PR-SRO concept is that continuous tunability necessitates a tunable pump laser.

In a dual-cavity, PR-SRO pump and signal waves resonate in separate cavities. The pump cavity is usually stabilized to the pump frequency and an etalon is placed into the signal cavity for better stability against mode-hops. This configuration combines the tuning simplicity of a basic SRO with a low-threshold power. For example, a threshold for a 1 μm-pumped PPLN dual-cavity PR-SRO at the 0.4 W level was obtained.

Mode-hop tuning (in opposite directions) of the frequencies of both parametric waves in steps of the cavity's FSR can be performed by changing the etalon angle (Figure 3). A range exceeding 50 GHz (at constant output power) has been achieved. Continuous signal and idler wave tuning (by equal but opposite amounts) is possible by changing the signal cavity length (Figure 3). However, the range is limited to the FSR of the cavity, typically on the order of 500 MHz, then the frequencies mode-hop back. It is expected that wider continuous tuning should be possible by synchronous etalon and cavity length scan. If a tuneable pump laser is employed, continuous tuning of only the idler frequency is possible by keeping the etalon and signal wave cavity length fixed; the pump tuning range is fully transferred to the idler.

DRO

In contrast to an SRO, this device type requires both parametrically generated waves to be resonant in the cavity. Here we consider only DROs with a common cavity for both signal and idler waves (dual-cavity DROs have also been demonstrated).

Because of the added resonance condition, mode-hops of the oscillating mode pair occur already upon a very small change (~1 nm) in the cavity length. Under normal environmental conditions such changes are unavoidable and therefore a 'free-running' DRO does not produce frequency-stable output. However, by active control of one additional parameter of the OPO system the mode-hops can be effectively suppressed. A practical solution is to actively control the length of the cavity via the position a of one of the cavity mirrors so that a particular mode pair, q_s, q_i, continues to oscillate; this is achieved by maximizing the OPO output power or by minimizing the detuning of one of the two resonant waves from its respective cavity mode frequency. This control system ensures that energy conservation and the two resonance conditions are simultaneously satisfied:

$$\begin{aligned} &\omega_s + \omega_i = \omega_p \\ &\omega_s = 2\pi c q_s/\mathrm{OPL}(d, \omega_s, T) \\ &\omega_i = 2\pi c q_i/\mathrm{OPL}(d, \omega_i, T) \end{aligned} \qquad [7]$$

Experimentally, mode-hop-free oscillation exceeding 10 h was achieved by such active stabilization.

Another system parameter may then be used to tune both signal and idler frequencies. The tuning coefficient for the crystal temperature T is small, but tuning the pump frequency is an efficient way. The tuning coefficient is approximately $\Delta\omega_s = (\omega_s/\omega_p)\Delta\omega_p$, and accordingly for ω_i.

Continuous tuning of signal and idler frequencies over 10 GHz by pump tuning was achieved. This range was limited by the available continuous tuning range of the pump laser. Mode-hop tuning can be induced by mechanical perturbations: by tapping on the DRO cavity, mode-hop tuning over 220 GHz has been demonstrated.

Linewidth and Frequency Stability

For high-resolution spectroscopy a narrow linewidth for signal or idler is desirable. One contribution to the linewidth of a cwOPO arises from the unavoidable spontaneous parametric fluorescence, similar to the Schawlow–Townes limit in lasers due to spontaneous emission. This contribution is negligible if the OPO operates at power levels of practical interest. Thus, other sources of classical noise dominate the linewidth of cwOPOs. As discussed above, the frequency of cwOPOs depends (on a fine scale) on pump frequency and cavity optical path length. Both parameters fluctuate: the pump laser has a finite linewidth as well as frequency jitter, and the cavity optical path length fluctuates due to acoustic noise affecting the mirror positions, to air pressure fluctuations, temperature fluctuations of the crystal and of the cavity structure.

With careful construction and shielding, many of these noise sources can be minimized. Furthermore, it is highly favorable to use pump lasers of narrow linewidth and high intrinsic frequency stability (e.g., diode-pumped monolithic solid-state lasers), or actively frequency-stabilized lasers. Note that this special requirement on the pump source does not exist for lasers.

In an SRO, the linewidth and frequency stability of the signal are mostly determined by the stability properties of the cavity. The idler spectral properties then follow entirely from the signal and pump spectral properties through $\omega_i = \omega_p - \omega_s$. Since the idler is usually the wave of interest, this implies that the SRO cavity and the pump laser must both have a stability appropriate to the spectroscopic application.

If the SRO cavity is not sufficiently stable (e.g., because of insufficient temperature stability of the oven containing the nonlinear crystal), the frequency fluctuation/drift of the signal and idler can be substantial, tens to hundreds of MHz within minutes being typical.

To avoid mode-hops also on long time-scales, the cavity length (or the etalon angle) can be actively stabilized so as to maximize the idler's output power. This ensures that the cavity mode position and the frequency of maximum difference between gain and loss are kept equal.

If a frequency-stable pump wave is used, it is possible to transfer these characteristics by stabilizing the SRO cavity length to the pump wave frequency. In an SRO without resonant pump one can make use of the residual reflection of the pump wave by the cavity mirrors that leads to interference with the pump wave reflected from the pump input mirror. This was implemented in a SRO pumped by a high-power diode-pumped internally doubled Nd:YVO_4 laser (532 nm) of high intrinsic frequency stability. Signal and idler drifts of less than 50 MHz/h were achieved. At the same time, a very small 20 kHz linewidth of the (resonant) signal radiation was obtained. Similar levels were obtained for a PR-SRO with a common cavity for pump and signal wave.

In a PR-SRO with dual-cavity configuration, the same requirements of minimization of disturbances to the parametric wave's cavity arise as in a basic SRO. Using a highly frequency-stable kHz linewidth monolithic pump laser, together with the above-mentioned idler power maximization control, frequency drift values for both parametric waves at the

level of 30 MHz/h were obtained and a short-term linewidth below 6 kHz.

In a single-cavity DRO, the linewidth and frequency stability of the parametric waves are essentially determined by the pump wave properties (see discussion in the section on DRO above). Here, too, the use of narrow-linewidth, high-frequency-stability pump lasers has led to excellent signal/idler characteristics. For example, less than 40 kHz linewidth and <40 MHz per hour drift were obtained with a DRO pumped by an externally doubled monolithic Nd:YAG laser of 10 kHz linewidth.

If further narrowing of linewidth or reduction of frequency drift is desired, the OPO output frequencies can be stabilized to a stable cavity, atomic, or molecular transition. Locking to a cavity has been demonstrated for a DRO.

Applications

CwOPOs are most interesting as sources of radiation in the IR range beyond 2 μm, especially in the 3–5 μm range, where vibrational transitions of many molecules occur. In comparison to other sources of coherent radiation (color center laser, quantum cascade laser, lead-salt diode laser, CO overtone laser, difference frequency generation), cwOPOs provide a unique combination of desirable features.

A simple application of cwOPOs would be as a source providing a power level/output wavelength/mode quality combination not available from other sources. Possible applications are vibrational spectroscopy in the condensed phase, where a narrow linewidth is not required. The excellent beam quality provides a high spatial resolution.

Concerning high-resolution spectroscopy (mostly in the gas phase), methods demonstrated in conjunction with cwOPOs include:

- Absorption spectroscopy;
- Doppler-free saturation spectroscopy;
- Photo-acoustic spectroscopy (PAS);
- Hole-burning spectroscopy;
- Coherent atomic spectroscopy;
- Cw cavity ring down spectroscopy (cw-CRDS).

Trace gas detection using PAS or cw-CRDS is a particular application where cwOPOs have reached excellent sensitivity (minimum detectable concentrations as low as 1 part in 10^{11}). The high output power and/or the narrow linewidth are specific features that make such sensitivity possible.

Quantum-Optical Properties

The pairwise production of signal and idler photons is at the heart of the parametric process. This perfect quantum correlation is to a certain extent also maintained in the output waves of a cwOPO. In particular, the intensity fluctuations of signal and idler waves emitted by a DRO are strongly (albeit never perfectly) quantum correlated if their output coupler transmissions significantly exceed their respective roundtrip losses. For these 'twin beams' the spectral density of the fluctuations of their power difference can be less than the spectral density of the fluctuations of the power of an individual wave (squeezing). Making use of this correlation permits to increase the obtainable sensitivity in spectroscopic measurements for a given power level of the wave interacting with the sample.

Device Development Trends

CwOPOs using solid-state pump lasers have become commercially available. In the near future, some likely developments will be miniaturization and optimization in order to reduce the influence of perturbations, further extension of continuous and mode-hop tuning ranges and the wider use of diode lasers as pump lasers, leading to cost reduction. To access a larger range of molecules in spectroscopy, extension of the emission range well beyond 5 μm is also of significant interest. Novel nonlinear materials and pump lasers of wavelength longer than the often employed Nd:YAG lasers will become of importance in this development.

Two specific lines of development complementary to the bulk cwOPOs described above are waveguide and intracavity cwOPOs (ICSRO). If pump, signal and idler waves are confined in a waveguide (*see* **Photonic Crystals:** Photonic Crystal Lasers, Cavities and Waveguides) the parametric gain coefficient is a few orders higher than for free-space Gaussian waves, due to the small mode cross-section and the scaling with the square of the crystal length, compared with the linear scaling in case of Gaussian beams (see eqn [36]). Values are on the order of $E \sim 1/W$ at $\lambda_p = 1.5$ μm leading to low thresholds even for SROs, with pump lasers of comparatively long wavelength. For example, in a SRO consisting of a 9 cm long titanium:PPLN waveguide, a threshold below 300 mW for a 1.5 μm pump was achieved. The idler emission range was 3.1–3.4 μm. The potential for mass production and, therefore, cost minimization is clear.

An ICSRO consists of an SRO internal to the cavity of a cw laser, where the high circulating laser power is taken advantage of for pumping. An ICSRO is thus similar to a PR-SRO but there is no need to implement a control system for the frequency lock between pump laser and pump cavity nor to mode-match the pump wave to the SRO cavity mode.

Appendix A

Three-Wave Mixing in a $\chi^{(2)}$ Medium with Focused Waves

The wave equation in a nonlinear medium reads

$$\Delta\vec{E} - \mu_0\mu_r\frac{\partial^2}{\partial t^2}\vec{D}_{\mathrm{L}} = \mu_0\mu_r\frac{\partial^2}{\partial t^2}\vec{P}_{\mathrm{NL}} \qquad [8]$$

The displacement field $\vec{D}_{\mathrm{L}}$ is related to the electric field $\vec{E}$ by linear response. $\vec{P}_{\mathrm{NL}}$ is the nonlinear polarization. We deal with nonmagnetic media ($\mu_r = 1$) and choose the principal axis system as coordinate system. The Fourier transform of, for example, the x-component of the wave equation then reads:

$$\begin{aligned}\Delta E_x(\omega,\vec{r}) + \mu_0\omega^2\varepsilon_0\varepsilon_x(\omega)E_x(\omega,\vec{r}) \\ = -\mu_0\omega^2 P_{\mathrm{NL},x}(\omega,\vec{r})\end{aligned} \qquad [9]$$

In the following, we take into account only second-order nonlinear effects, so the nonlinear polarization reduces to $P_{\mathrm{NL}} = P^{(2)}$. The fields to be considered are monochromatic, propagate in the z-direction and are linearly polarized along x. The notation can then be simplified to:

$$E_x(\omega,\vec{r}) = E(\vec{r})\mathrm{e}^{\mathrm{i}kz}, \quad P_{\mathrm{NL},x}(\omega,\vec{r}) = P^{(2)}_{\omega}(\vec{r}) \qquad [10]$$

with the wavevector $k = \omega n(\omega)/c$ and the refractive index for the polarization under consideration $n^2_{\omega} = n(\omega)^2 = E_x(\omega)$. The electric field is obtained as $\vec{E}(t,\vec{r}) = \frac{1}{2}\mathrm{Re}(E(\vec{r})\mathrm{e}^{\mathrm{i}(kz-\omega t)})\hat{x}$.

Since the parametric gains are small in cw conversion, the derivative of the envelope $E(\vec{r})$ changes only little over a propagation distance on the order of a wavelength $2\pi/k$. Inserting eqn [9] into eqns [6] and [8] and neglecting the term $\sim \mathrm{d}^2E(\vec{r})/\mathrm{d}z^2$, yields the paraxial or slowly varying envelope wave equation:

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + 2\mathrm{i}k\frac{\partial}{\partial z}\right)E(\vec{r}) = -\mu_0\omega^2 P^{(2)}_{\omega}(\vec{r})\mathrm{e}^{-\mathrm{i}kz} \qquad [11]$$

The electric field envelope can be expanded in a complete set of Gaussian TEM_{mn} – mode functions ψ_{mn}:

$$E(\vec{r}) = \sqrt{\frac{\omega}{n_{\omega}}}\sum_{m,n=0}^{\infty} A_{mn}(z)\psi_{mn}(\vec{r}) \qquad [12]$$

These mode functions are defined to satisfy the paraxial wave equation in absence of nonlinearity (vanishing right-hand side in eqn [11]) and the orthonormality properties

$$\int\int_{-\infty}^{+\infty}\psi^*_{mn}(\vec{r})\psi_{m'n'}(\vec{r})\mathrm{d}x\,\mathrm{d}y = \delta_{mm'}\delta_{nn'} \qquad [13]$$

A particular mode function set is characterized by position (along z) and size of the waist, which can be chosen arbitrarily. The functions $A_{mn}(z)$ are slowly varying amplitude functions. The power in a particular mode can be calculated from:

$$P_{mn}(z) = \frac{\omega|A_{mn}(z)|^2}{2\mu_0 c} \qquad [14]$$

where c is the speed of light *in vacuo*. Inserting eqn [12] into eqn [11], multiplication with $\psi^*_{m'n'}(\vec{r})$, and integration over x, y yields:

$$\frac{\mathrm{d}A_{m'n'}(z)}{\mathrm{d}z} = \mathrm{i}\frac{\mu_0 c}{2}\sqrt{\frac{\omega}{n_{\omega}}}\mathrm{e}^{-\mathrm{i}kz}\int\int_{-\infty}^{\infty}P^{(2)}_{\omega}(\vec{r})\psi^*_{m'n'}(\vec{r})\mathrm{d}x\,\mathrm{d}y \qquad [15]$$

If all electric fields are linearly polarized, the Fourier amplitudes of the nonlinear polarization can be written as:

$$\begin{aligned}P^{(2)}_{\omega_{\mathrm{s}}}(\vec{r}) &= 2\varepsilon_0 d(z)E_{\omega_{\mathrm{p}}}(\vec{r})E^*_{\omega_{\mathrm{i}}}(\vec{r}) \\ P^{(2)}_{\omega_{\mathrm{i}}}(\vec{r}) &= 2\varepsilon_0 d(z)E_{\omega_{\mathrm{p}}}(\vec{r})E^*_{\omega_{\mathrm{s}}}(\vec{r}) \\ P^{(2)}_{\omega_{\mathrm{p}}}(\vec{r}) &= 2\varepsilon_0 d(z)E_{\omega_{\mathrm{s}}}(\vec{r})E_{\omega_{\mathrm{i}}}(\vec{r})\end{aligned} \qquad [16]$$

where d is the tensor element appropriate to the particular combination of linear polarizations of the three waves. (In eqn [16], $\omega_{\mathrm{i}} + \omega_{\mathrm{s}} = \omega_{\mathrm{p}}$.)

The mode amplitude equations for the three interacting waves follow from eqns [10], [15], and [16] as:

$$\begin{aligned}\frac{\mathrm{d}A_{mn}\begin{Bmatrix}\mathrm{p}\\ \mathrm{s}\\ \mathrm{i}\end{Bmatrix}(z)}{\mathrm{d}z} &= \mathrm{i}\frac{d(z)}{c}\begin{Bmatrix}\sqrt{\omega_{\mathrm{p}}/n_{\mathrm{p}}}\mathrm{e}^{-\mathrm{i}\Delta kz}\\ \sqrt{\omega_{\mathrm{s}}/n_{\mathrm{s}}}\mathrm{e}^{+\mathrm{i}\Delta kz}\\ \sqrt{\omega_{\mathrm{i}}/n_{\mathrm{i}}}\mathrm{e}^{+\mathrm{i}\Delta kz}\end{Bmatrix}\int\int\mathrm{d}x\,\mathrm{d}y \\ &\quad\times\begin{Bmatrix}\mathrm{E_s}(\vec{r})\mathrm{E_i}(\vec{r})\\ \mathrm{E_p}(\vec{r})\mathrm{E_i}(\vec{r})^*\\ \mathrm{E_p}(\vec{r})\mathrm{E_s}(\vec{r})^*\end{Bmatrix}\psi_{mn}\begin{Bmatrix}\mathrm{p}\\ \mathrm{s}\\ \mathrm{i}\end{Bmatrix}(\vec{r})^{*+\infty}\end{aligned} \qquad [17]$$

The quantity $\Delta k = k_{\mathrm{p}} - k_{\mathrm{s}} - k_{\mathrm{i}}$ is the wavevector mismatch. Here, the envelope of each wave has an expansion of the form in eqn [12] with its respective (independent) set of mode functions.

Appendix B

Steady-State Description of the cwOPO

The general eqns [17] are applicable to any type of cwOPO. Below and at threshold at least two of the three waves have given modes, i.e., the corresponding function $E(\vec{r})$ is known up to a slowly z-dependent amplitude: the resonant parametric wave has a mode defined by the cavity geometry and mirrors, while the pump wave mode is defined by the used focusing optics. This knowledge allows to obtain an analytic expression for the threshold of any OPO type and for an arbitrary cavity.

Above threshold two cases can be distinguished:

(i) in a basic SRO the pump mode itself becomes a function of pump power, due to its depletion by signal and idler wave, and only a numerical solution can be given; and
(ii) if two or more waves resonate in one or more cavities (DRO, PR-SRO, TRO), an analytic solution is possible even above threshold.

In the following, the PR-SRO is treated. Figure 4 shows a schematic of a common cavity PR-SRO and the notation; the treatment below also holds for the dual cavity PR-SRO. Without loss of generality, the signal wave is taken to be the signal. For the sake of simplicity, below a further assumption about the spatial mode of the idler will be made.

The pump and signal waves are given by TEM_{00} modes of the cavity (or cavities):

$$E_p(\vec{r}) = \sqrt{\frac{\omega_p}{n_p}} A_{00p}(z)\psi_{00p}(\vec{r})$$
$$E_s(\vec{r}) = \sqrt{\frac{\omega_s}{n_l}} A_{00s}(z)\psi_{00s}(\vec{r}) \qquad [18]$$

In the case of a common-cavity PR-SRO, pump and signal resonate in the same cavity and therefore their modes have the same waist position and Rayleigh ranges $z_R = kw^2/2$, (w is the waist). In the case of a dual-cavity PR-SRO the modes are in principle independent.

Although the idler wave is in general not purely TEM_{00}, it may be approximated by a TEM_{00} mode, whose mode parameters are determined by an optimization criterion. We can then introduce the overlap function:

$$O(z) = \int\int dx\, dy(\psi_{00p}(\vec{r}))^* \psi_{00s}(\vec{r})\psi_{00i}(\vec{r})_{-\infty}^{+\infty} \qquad [19]$$

Under these assumptions, the infinite set of mode eqns [17] reduces to just three coupled equations ($A \equiv A_{00}$):

$$\frac{dA_p(z)}{dz} = -i\xi(z)A_s(z)A_i(z)e^{-i\Delta kz}O(z) \qquad [20]$$

$$\frac{dA_s(z)}{dz} = -i\xi(z)A_p(z)A_i^*(z)e^{i\Delta kz}O(z)^* \qquad [21]$$

$$\frac{dA_i(z)}{dz} = -i\xi(z)A_p(z)A_s^*(z)e^{i\Delta kz}O(z)^* \qquad [22]$$

where

$$\xi(z) = \frac{d(z)}{c}\sqrt{\frac{\omega_p\omega_s\omega_i}{n_p n_s n_i}} \qquad [23]$$

Two phasematching cases have to be considered: for birefringent phasematching, $d = \text{const}$ and ξ is independent of z. In QPM, the d-coefficient is modulated periodically along z with period Λ. It suffices to consider only the particular term of its Fourier series expansion that gives the smallest wavevector quasi-mismatch. When only the first term is relevant, this is referred to as first-order QPM and $d(z) \simeq \frac{1}{2}\hat{d}(g_1 e^{i2\pi z/\Lambda} + \text{c.c.})$. This case can be taken into account by replacing $d(z)$ in eqn [23] by $d_{eff} = \frac{1}{2}\hat{d}g_1$, and in eqns [20]–[22] the relevant wavevector mismatch becomes $\Delta k = k_p - k_s - k_i \pm 2\pi/\Lambda$, where, for usual materials, the minus sign applies.

We solve eqns [20]–[22] by expanding in powers of the nonlinearity ξ. This is appropriate due to the small gain and implies that the resonant pump and signal wave amplitudes do not change substantially (relative to the respective average amplitude) along the crystal length and around the cavity.

Integrating eqn [22] after approximating the amplitudes on the right-hand side by their values at $z = 0$ yields:

$$A_i(z) = -i\xi z A_p(0)A_s^*(0)I^*(z)$$
$$I(z) = \frac{1}{z}\int_0^z dz' O(z')e^{-i\Delta kz'} \qquad [24]$$

We insert this result into eqns [20] and [21] and approximate $A_s(z)$ and $A_p(z)$ by their values at $z = 0$. The result is

$$A_p(z) = A_p(0) - \frac{1}{2}(\xi z)^2 D^*(z)A_p(0)|A_s(0)|^2 \qquad [25]$$

$$A_s(z) = A_s(0) + \frac{1}{2}(\xi z)^2 D(z)A_s(0)|A_p(0)|^2 \qquad [26]$$

$$D(z) = \frac{2}{z^2}\int_0^z \mathrm{d}z' z' I(z') O(z')^* \, \mathrm{e}^{\mathrm{i}\Delta k z'} \qquad [27]$$

This completes the calculation of the propagation through the nonlinear medium. Now we proceed to calculate the propagation around the cavity.

Since the signal wave is resonant with the cavity, we can immediately write the self-consistency equation for the roundtrip:

$$|A_s(0)| = \sqrt{R_s(1 - V_s)}|A_s(L)| \qquad [28]$$

The roundtrip cavity reflectivity and roundtrip loss for the signal wave are denoted by R_s and V_s. At the input mirror (see lower part of Figure 4), characterized by a transmission $T_p = 1 - R_p$, the interference of the injected pump wave $A_{p,in}$ and the internally circulating pump wave must be considered:

$$A_p(0) = \sqrt{T_p}A_{p,in} + \sqrt{R_p(1 - V_p)}A_p(L)\mathrm{e}^{\mathrm{i}\phi} \qquad [29]$$

V_p is the pump roundtrip loss. Evaluating eqn [26] at $z = L$ and comparing with eqn [28] yields:

$$|A_p(0)|^2 = \left[\frac{1}{\sqrt{R_s(1 - V_s)}} - 1\right]\frac{1}{\frac{1}{2}(\xi L)^2 \mathrm{Re}\, D(L)} \qquad [30]$$

Here the imaginary part of $D(z)$ was neglected since $|\xi L A_p(0)|^2 \ll 1$. Expression [30] shows that the intracavity pump power is clamped at a fixed value, equal to the value at threshold, independent of the input power.

In eqn [29] we can assume $A_{p,in}$ to be real without loss of generality, yielding the relation:

$$\sqrt{T_p}\frac{A_{p,in}}{A_p(0)} = 1 - \sqrt{R_p(1 - V_p)}\mathrm{e}^{\mathrm{i}\phi}\frac{A_p(L)}{A_p(0)} \qquad [31]$$

where $\phi = \omega_p \mathrm{OPL}(\omega_p, T)/c$. The pump wave is assumed to be exactly resonant; this means that $A_p(0)$ is maximum. The phase ϕ must therefore be such that:

$$\mathrm{e}^{\mathrm{i}\phi}\frac{A_p(L)}{|A_p(0)|} \in \mathbb{R} \qquad [32]$$

Together, with eqn [25], we obtain:

$$\left|\frac{A_p(L)}{A_p(0)}\right|^2 = \left|1 - \frac{1}{2}(\xi L)^2 D^*(L)|A_s(0)|^2\right|^2 \qquad [33]$$

The right-hand side is evaluated neglecting the contribution proportional to ξ^4; inserting the result in eqns [31] and [32] gives:

$$\sqrt{T_p}\frac{A_{p,in}}{|A_p(0)|} = 1 - \sqrt{R_p(1 - V_p)} + \sqrt{R_p(1 - V_p)}\frac{1}{2}(\xi L)^2 \mathrm{Re}\, D|A_s(0)|^2 \qquad [34]$$

Equations [30] and [34] represent the steady-state solution of the PR-SRO: they give the circulating pump and signal powers, from which all desired quantities can be computed.

The external threshold is found by setting $A_s(0) = 0$ and assuming small losses, T_p, $V_p \ll 1$

$$P_{p,in}^{th} \simeq \frac{T_p + V_p}{T_p}\cdot(T_p + V_p)\cdot\frac{(T_s + V_s)}{E} \qquad [35]$$

with the nonlinearity

$$E = \frac{2\mu_0 d^2}{\pi c^2}\frac{\omega_s \omega_i}{n_p n_s n_i}L^2 \,\mathrm{Re}\, D(L) \qquad [36]$$

Note that $\mathrm{Re}\, D(L) = |I(L)|^2$. The second factor in eqn [35] is responsible for the reduction of threshold due to pump resonance. The last factor is the internal pump threshold and constant circulating pump power level:

$$P_p(0) \simeq \frac{(T_s + V_s)}{E} \qquad [37]$$

which is also equal to the threshold of a basic SRO. The nonlinearity may be written as

$$E \simeq \frac{4\mu_0 d^2}{\pi c^2}\frac{\omega_s^2 \omega_i^2}{n_p^2 \omega_p} L h_{PA} \qquad [38]$$

with the dimensionless focusing function h_{PA}. A detailed calculation shows that the value of h_{PA} cannot exceed 1.1 and is close to its maximum when the phase mismatch $\Delta k L$ is approximately zero and the pump and signal focusing by the cavity is such that their Rayleigh range $z_R \simeq L/2$.

The OPO will select the signal cavity mode frequency ω_s and idler spatial mode that minimizes the threshold eqn [35]. Note that this is not necessarily equivalent to a maximization of E, since T_s and V_s may also be dependent on signal frequency, for example, because of the presence of an etalon inside the cavity.

The circulating signal power as derived from eqns [30] and [34], is given in eqn [6].

The signal power extracted from the cavity is $P_{s,out} = T_s P_s(L) \simeq T_s P_s(0)$, while the (fully extracted) idler power is given by:

$$P_{i,out} = P_i(L) = \frac{\omega_i}{\omega_s} E P_s(0) P_p(0) \qquad [39]$$

Advantages and Applications of Ultrashort Pulsed OPOs

The advantages of ultrashort pulsed optical parametric oscillators (OPOs) are twofold: on the one hand, it is possible to generate tunable laser radiation with a pulse duration in the femtosecond and picosecond time domain; on the other hand, the short pulses give rise to a high peak intensity of the electric field of the pump wave inside the nonlinear medium. Due to the fact that the OPO single-path gain coefficient reads as:

$$\eta = \frac{P_{\text{Signal}}}{P_{\text{Pump}}} = \frac{8\pi^2 d_{\text{eff}}^2 L^2 I_{\text{P}}}{\varepsilon_0 n_{\text{P}} n_{\text{S}} n_{\text{I}} c \lambda_{\text{S}}^2} \frac{\sin^2(\Delta k L/2)}{(\Delta k L/2)^2} \qquad [1]$$

where I_{P} is the pump intensity, Δk is the phase mismatch between pump, signal, and idler, n_{P}, n_{S}, n_{I}, are the refractive indices at the pump, signal, and idler wavelengths, respectively, and L is the length of the nonlinear medium with an effective nonlinear coefficient d_{eff}, the efficiency grows proportional to the intensity of the pump.

Ultrashort pulsed OPOs can provide widely tunable femtosecond or picosecond pulses, covering the spectral range from the visible to the mid-infrared, which have many applications, such as time-resolved spectroscopy, pump-probe measurements, semiconductor analysis, photochemistry, optical ranging, data transfer, and data processing with high carrier frequency, white-light generation, etc.

Synchronous Pumping

The key issue in operating ultrashort-pulse OPOs is synchronization between the pump pulses and the signal pulses. Consider the following sequence: a pump pulse enters the OPO cavity and generates spontaneously downconverted light at the signal wavelength (see Figure 1, inset). These signal photons travel inside the OPO cavity, entering the nonlinear medium again after exactly one cavity round trip. This light will act as seed light for another downconversion process if a second pump pulse enters the nonlinear medium at exactly the same instance (see Figure 1). The presence of the signal pulse will lead to a much more efficient stimulated downconversion process.

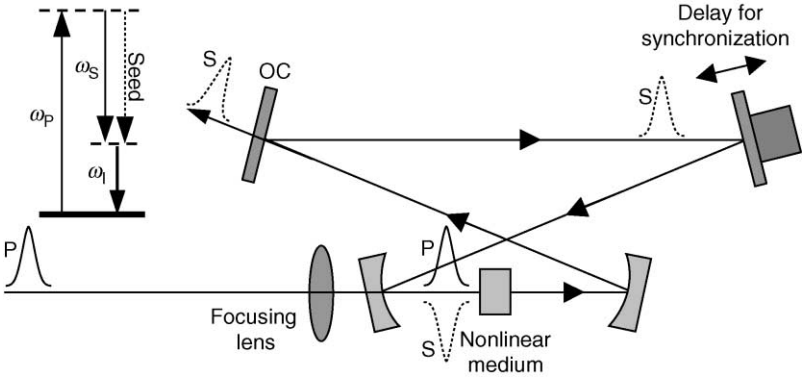

Figure 1 Synchronous pumping of a typical ring-cavity OPO: P, pump pulses; S, signal pulses; OC, output coupler; ω_P, ω_S, ω_I, frequencies of the pump, the signal, and the idler, respectively. Inset: energy level diagram for optical parametric oscillation.

This requires the repetition rate of the pump oscillator and the OPO to be synchronized precisely. Therefore, this pump scheme is called *synchronized pumping*. If the temporal separation between the pump pulses does not exactly equal the roundtrip time of the signal pulses inside the OPO cavity, the generation efficiency will decrease dramatically as the temporal pulse overlap is reduced.

Dispersion in Nonlinear Media and Optical Glasses

Maintaining synchronicity between the pump pulses and the signal pulses is a necessary, but not sufficient prerequisite for successful operation of an ultrashort-pulse OPO. The signal pulses will be temporally broadened during their repeated trip through the nonlinear medium. This will lead to problems, as the newly generated signal pulses are still rather short (as they have been generated by a short pump pulse), but the previously generated signal pulses, which should act as seed pulses and ideally have a similar pulse duration as the pump pulses, have already been broadened temporally, due to dispersion in the nonlinear medium and other intracavity optical elements. Meanwhile, temporal walk-off between the signal (idler) and the pump pulses will take place, resulting in reduced conversion efficiency and broadened signal pulses. Group velocity dispersion (GVD) and group velocity mismatch (GVM) are normally used to characterize the dispersion in nonlinear medium.

The group velocity of the laser pulses propagating in a nonlinear optical medium is defined as:

$$v_G = \frac{c}{n - \lambda \dfrac{dn}{d\lambda}} \qquad [2]$$

where c is the velocity of light in vacuum, n is the refractive index of the nonlinear medium at the center wavelength λ of the laser pulses. Then the GVD can be written as:

$$\frac{dv_G}{d\lambda} = \frac{\lambda v_G^2}{c} \frac{d^2 n}{d\lambda^2} \qquad [3]$$

In most cases, we evaluate the GVD of the optical materials using the group velocity dispersion parameter (k''), which is defined as:

$$k'' = \frac{d^2 k}{d\omega^2} = \frac{\lambda^3}{2\pi c^2} \frac{d^2 n}{d\lambda^2} \qquad [4]$$

where $k = n\omega/c$ is the wave vector, ω is the frequency of the incident wave, and consequently:

$$\frac{dv_G}{d\lambda} = \frac{2\pi c v_G^2}{\lambda^2} \frac{d^2 k}{d\omega^2} \qquad [5]$$

Due to GVD in the nonlinear medium, the spectral components in the broadband spectrum of an ultrashort pulse will travel at different group velocities and will consequently be delayed differently in the crystal, therefore the pulses will become temporally broadened or become chirped. This linear chirp induced pulse broadening effect can be characterized quantitatively by the following formula:

$$\tau_P = \tau_{P0} \sqrt{1 + \left(\frac{z}{z_d}\right)^2} \qquad [6]$$

where τ_{P0} is the incident pulse duration, τ_P is the pulse duration after the pulse propagates in the nonlinear medium over a distance of z, and z_d is called the characteristic length and defined as:

$$z_d = \frac{\tau_{P0}^2}{4 \ln 2 |k''|} \qquad [7]$$

In frequency conversion processes, such as second-harmonic generation (SHG), sum-frequency

generation (SFG), difference frequency generation (DFG), optical parametric oscillation (OPO), or optical parametric amplification (OPA), three waves interact with each other while propagating through the nonlinear medium. Due to dispersion of the material, different waves propagate at different group velocities. This effect is generally called group velocity mismatch. In cases of interaction on the femtosecond scale, the interacting pulses may get separated after propagating some distance in the medium, which means that there is a reduced effective interaction length. The GVM is a quantitative evaluation of this effect, which is defined as:

$$\Delta v_{\mathrm{G}} = \left(\frac{1}{v_{\mathrm{G,i}}} - \frac{1}{v_{\mathrm{G,j}}} \right)^{-1} \qquad [8]$$

where $v_{\mathrm{G,i}}$ and $v_{\mathrm{G,j}}$ are the group velocities of the two interacting waves i and j. The effective interaction length L_{eff} for wave i and wave j can thus be calculated by the following formula:

$$L_{\mathrm{eff}} = \tau_{\mathrm{P}} |\Delta v_{\mathrm{G}}| = \tau_{\mathrm{P}} \left| \left(\frac{1}{v_{\mathrm{G,i}}} - \frac{1}{v_{\mathrm{G,j}}} \right)^{-1} \right| \qquad [9]$$

where τ_{P} is the incident pulse duration at full width at half maximum (FWHM). It is assumed that wave i and wave j have a similar pulse duration. This temporal walk-off will lead to two effects. First, the interacting pulses will get separated and the conversion efficiency will be reduced. The second effect is the broadening of the signal pulses. In the case of sub-100 fs operation, to restrict the broadening in pulse length to less than ~10%, the crystal length should be smaller than $L_{\mathrm{eff}}/2$.

Figure 2 shows the GVD of some typical OPO crystals, including KTP, KTA, RTA, CTA, PPLN, PPKTP, and LBO. Their Sellmeier equations are as summarized in Appendix A. In addition to the wavelength of the incident beam, the GVD is also dependent on the polarization of the incident beams and the type of phase matching.

We give the GVM values between the pump and the signal (P–S), the signal and the idler (S–I), and between the pump and the idler (P–I) for a KTP crystal in Figure 3.

Intracavity Dispersion Compensation and Extra Cavity Pulse Compression

In order to tackle the problem of intracavity dispersion, corrective elements have to be placed inside the cavity in order to compensate the chirp. There have been several solutions to this problem, namely the combination of intracavity prism pairs, chirped mirrors, chirped grating periods (for quasi-phase matching) with oppositely chirped pump pulses, and glass plate dispersion compensators. Certainly, a shorter crystal length will yield a smaller GVM and GVD, but will also give a smaller nonlinear conversion efficiency due to the shorter crystal length (see eqn [1]).

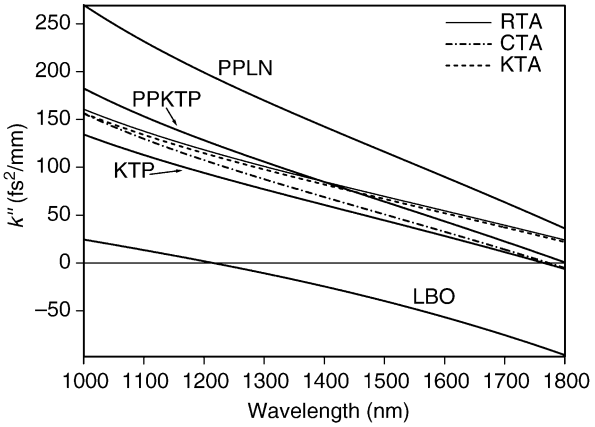

Figure 2 Group velocity dispersion characteristics of some typical OPO crystals.

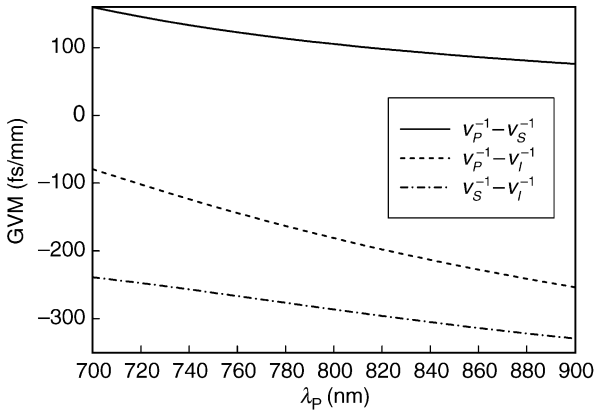

Figure 3 GVM between the interaction waves of a KTP OPO versus pump wavelength (λ_{P}).

Pump Sources

As pump pulses, mode-locked femtosecond or picosecond lasers are used. The requirements on pulse durations are determined by the desired pulse durations of the OPO signal and by the phase-matching bandwidth of the correspondingly used crystal. Shorter pump pulses normally lead to higher pump power thresholds due to shorter temporal overlap between the interacting pulses. It can also lead to higher instability of the OPO operation due to its higher sensitivity to the cavity length fluctuations. Generally, larger pump bandwidth means larger bandwidth of the signal. Consequently, a potentially shorter signal pulse duration can be achieved if the

intracavity dispersion is perfectly compensated. Sometimes it is advantageous for stability to operate the OPO in the slightly negative total GVD regime. In a quasi-phase-matched (QPM) OPO, the phase-matching bandwidth is so large that only a narrow pump bandwidth is required to phase-match a large bandwidth of the signal. Therefore, a pump depletion hole can be commonly observed with the oscillation of the OPO.

Design of Ultrashort Pulsed OPOs

Design of an OPO device may involve the design of the cavity length, cavity mirrors, focal length for focusing the pump beam, intracavity dispersion compensation scheme, frequency stabilization module, crystal length, and some other design depending on the special configuration of the OPO, for example, a heating module (an oven) is required for a PPLN OPO and temperature control module is required for a temperature phase-matched LBO OPO. For an ultrashort pulsed OPO, the most important designs include the design of the crystal length, the design of intracavity dispersion compensation components, and the frequency stabilization control.

Crystal Length

Several factors have to be taken into account when designing a crystal length. The design of a crystal length should be a compromise of all of these considerations. What is special for a femtosecond or picosecond OPO is the dispersion and temporal walk-off between the interacting pulses in the crystal:

1. Effective interaction length: Pump pulse duration, estimated signal pulse duration, temporal walk-off between the pump and the signal give a limit of the crystal length that is characterized by eqn [9].
2. Pulse broadening due to GVM and GVD from the OPO crystal and other intracavity optical glass elements should be estimated. It is reasonable that shorter crystal length is always favorable for ultrashort pulse generation. The crystal length should be as short as possible while maintaining an acceptable conversion efficiency. When designing the crystal length, the available dispersion compensation device should be considered simultaneously.

Dispersion Compensation

For a crystal with a given material and length, the intracavity dispersion can be calculated. The compensation device should introduce an amount of negative GVD such that the total intracavity GVD is equal to or slightly smaller than zero at the desired center wavelength of the signal pulses. Meanwhile, the compensation should be relatively uniform (for instance having a GVD fluctuation of $<50\ \mathrm{fs}^2/\mathrm{mm}$) over the bandwidth of the expected signal spectrum. Then a compensation method (as described above) should be chosen and corresponding device should be designed.

Piezo-Driven Mirror and Frequency Stabilization

To achieve fine tuning of the cavity length, one of the cavity mirrors should be mounted onto a piezoelectric translation stage. When feeding back the signal output of the OPO to this piezo-driven mirror, forming a closed loop to compensate for the drift of the cavity length, a stabilization of the OPO repetition rate is achieved. If the signal is dispersed by a grating, a change in cavity length will also lead to a change in the output spectrum. Using a split photodiode, the difference signal of the dispersed spectrum can be utilized as the measured signal in the feedback loop.

Tuning Characteristics and Methods

Tunability is one of the most important advantages of the OPO over other ultrashort pulsed lasers. A large variety of tuning methods make the OPO more practical and versatile in many applications. For birefringently phase-matched OPOs, the tuning of the signal wavelength can be achieved through changing the pump wavelength (pump wavelength tuning), using an intracavity wavelength selection element (such as a birefringent filter), changing the temperature of the crystal when its refractive index is sensitive to the temperature change (temperature tuning), or changing the orientation of the OPO crystal (angle tuning). Some more methods can be utilized for a QPM OPO, for example through changing the poling period of the crystal (grating period tuning). A special method for an ultrashort pulsed OPO is the so-called cavity length tuning.

As has been discussed above, in synchronous pumping, the OPO must have the same cavity length as the pump laser, so that the signal pulse arrives simultaneously with the pump pulse at the crystal to get the most efficient interaction. Because of dispersion of the nonlinear crystal, the signal will be delayed differently at different wavelengths. In other words, signal pulses have different round-trip times in the cavity at different center wavelengths. When the cavity length of the OPO is changed slightly, the signal has to change its wavelength to keep constant optical path length or constant round-trip time. Cavity length tuning can be achieved easily by tuning

the voltage on a piezoelectric transducer (PZT), onto which one of the cavity mirrors is mounted. Therefore, this method is the most common and frequently used to tune the signal wavelength of a synchronously pumped OPO. This is also the basis for stabilizing the operation of a synchronously pumped OPO.

High-Repetition-Rate (HRR) Operation

Synchronously pumping an OPO at high repetition rate produces a high-repetition-rate signal pulse train which extends the application fields of the OPO. Using high-repetition-rate laser pulses (e.g., >1 GHz) as the pump is a straightforward method to run the OPO at a high repetition rate. But a high repetition rate means an extremely short cavity length. For instance, the cavity length is about 30 cm at 1 GHz repetition rate. Such a short cavity length leads to a large mode of the signal beam waist in the crystal. Mode matching between the signal and the pump beams requires that the transverse mode of the pump beam should be slightly larger than that of the signal beam within the interaction zone to maintain stable and efficient oscillation of the OPO. Large modes of the signal and the pump beams mean low interacting intensities, increasing the pump threshold significantly. Using smaller curvature radius of the curved mirrors and shorter focal length of the focusing lens might reduce the mode sizes at the focus in the nonlinear medium, but this will introduce extremely serious astigmatism when the signal beam is reflected from a strongly tilted curved mirror with a quite small curvature radius. In addition to exact synchronous pumping, there are at least two methods to realize high-repetition-rate operation of an OPO. First, pumping at low repetition rate while using a shorter cavity length of the OPO (L_{OPO}) than the pump laser (L_P) with $L_{OPO} = L_P m/N$, where m and N are both integers and $m < N$, as demonstrated in Figure 4a, which is called lower-order synchronous pumping. However, applying this technique, the signal pulses experience more round-trip losses, also resulting in a much higher pump threshold and periodically varying intensities of the output pulses. Second, pumping the OPO at high repetition rate while using a much longer cavity length of the OPO than the pump laser with $L_{OPO} = L_P N/m$, where m and N are both integers and $m < N$, is called higher-order pumping, as demonstrated in Figure 4b. In higher-order synchronous pumping, the signal pulse train has the same repetition rate as the pump, while the mode-matching problem is removed through a long OPO cavity.

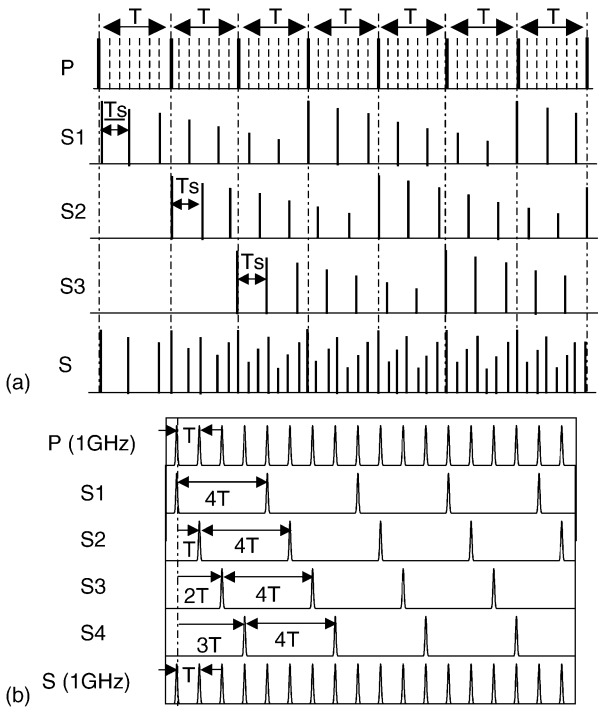

Figure 4 (a) 3/7-order synchronous pumping. Three signal pulse trains (S1–S3) are produced, each having a repetition period (Ts) 3/7 that of the pump pulse train (P): Ts = 3/7 *T*. The pump repetition rate is multiplied by a factor of 7 in the signal pulse train (S). (b) Fourth-order synchronous pumping at 1 GHz. The signal pulse train (S) is a combination of four pulse trains (S1–S4), each having a repetition period (4*T*) 4 times that of the pump pulse train (P).

Introduction

Modern optical systems find many applications in sensing, recording, storage, and transmission of data. These applications stimulate the development of many new optical devices, components, materials, and applied technologies. The basic element of an optical system is the light. The physical implications of the light in optical systems are very analogous to those of electricity, hence, light signals are quite similar to electric signals. High-speed spatial light components are being developed for more stringent applications in coherent optical processing systems, where they may be used in the input plane or in the Fourier transform plane. Research in this area is directed towards the design of robust and compact correlators.

Novel transforms for information processing (also known in electronics) include Fourier and wavelet transforms. Such optical transformations serve as the basic platform for linear optical system processing. Optical devices and systems for information processing include spatial light modulators, which are used to implement optical information processing systems. There are holographic applications in information processing, display systems, memory systems, optical computing systems, and imaging systems. Such devices and systems are based on applications of novel materials for information processing. Optical and digital techniques are used for optical system design, optical computing, image processing, and even for encryption and security systems.

The imaging system is an optical system and integrates hardware as well as software. Figure 1 presents a general model of an extensive imaging system. The starting point of the system is the object (or the light source). An imaging device, such as camera or optical sensor detects the energy radiated in electromagnetic waves from the light source. The image (or series of images – video) formed in the imaging device depends on the received irradiance of the image propagated through the imaging path and is correspondingly diminished from that in the object plane. The properties of the optical medium (transmission path) such as atmospheric properties, background light, motion, and vibration in both the object and the image planes, and the quality of the imaging device, all affect the quality of the images.

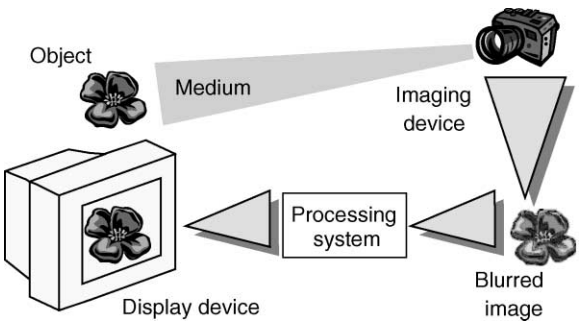

Figure 1 General description of an imaging system.

There are atmospheric phenomena that give rise to attenuation of the irradiance of the propagating image, thus reducing the contrast of the final image, as well as atmospheric phenomena that cause blurring of detail. Both types of phenomena degrade image quality.

Image blurring caused by vibration is a factor whose influence on resolution is often significant in imaging systems that involve mechanical motion. In order to obtain a well processed imaged, as similar as possible to the ideal image (the source), image processing techniques such as image enhancement, restoration, and filtering are implemented in an optical processing system which is a combination of software (algorithms) and hardware (electronic and optical components). The processing procedure involves mathematical and especially optical transformations. The output of the processing system is presented by using a display device or hardcopy. The development of imaging systems (imaging devices and displays) which include integrated optical components and processing units, assist in improving image quality at early stages, and as a result reduce the need of unique processing systems and may serve as the standalone device.

The key issues which must be addressed in the design, evaluation, and implementation of practical systems for optical processing, are provided here in a detailed review. Thus, the review is focused on imaging where considerations such as optical transformations, optical computing, effects of diffraction, scatter, absorption, and design on the performance of optical systems, imaging and the optical transfer function (OTF) for image restoration, and filtering, are all discussed in detail.

Digital Processing and Control

The Fourier transform properties of Fraunhofer diffraction permit data processing operations carried out optically that can, in many situations, be more advantageous than digital signal processing. The primary advantages of optical techniques over electronic analog and digital signal processing, are best realized when the information to be processed has two degrees of freedom. Optical systems correspondingly can have two degrees of freedom. Thus, for handling pictorial data, they can be intrinsically superior to electric or electronic systems, which have only time as an independent variable. This two-dimensional (2D) processing property can be particularly valuable in radar applications where previously velocity and position data had to be processed separately in order for sufficient accuracy in the estimation of each set of data to be obtained.

Many of the basic operations that can be performed by optical computers can also be done with electronic systems. However, if large quantities of wideband data are to be processed, the electronic techniques can often be prohibitively expensive and time consuming. The optical computer is faster than a digital computer because it operates on signals that are functions of positions, not time. The input to an optical data processor is a pattern of light irradiance that varies over some area, not light irradiance that varies as a function of time.

Thus, optical data processing can be very appropriate for such lengthy operations as the calculation of complicated Fourier transforms and the processing of side-looking radar signals. In addition to mathematical operations such as differentiation, integration, and producing Fourier transforms, the two classes of applications for which optical signal processing is most often used are filtering and correlation.

Optical Computing

Optical computing (OC) means the use of light as a primary means for carrying out numerical calculations, reasoning, artificial intelligence, etc. The history of OC is linked to that of radar systems. OC systems received a great push from the invention of laser in 1960. In the 1960s, the first schemes for all-optical digital computers were proposed. Since the 1990s, researchers have been pursuing the development of computers based on optical technology, and emphasis has shifted to optical interconnection of arrays of semiconductor smart pixels. OC provides the first in-depth review of the possibilities and limitations of optical data processing. The partial listing of those points that make OC appealing are direct image processing, massive parallelism and connectivity, immunity to electromagnetic interference (EMI), speed, size, and cost. There are three distinct trends in OC: special purpose analog optical systems, general purpose digital optical systems, and hybrid optical/electronic systems.

Innovations such as the electro-optic spatial filter, the 2D spatial light modulator, and the variable electro-optic mirror provide the fundamental building blocks for both analog optical computing (AOC) and digital optical computing (DOC) technologies. Optical techniques can provide solutions and a number of ways of extending the information processing capability of electronics. The optical processors have to be compatible with existing electronic systems. Free space digital optics is one

direction that provides some valuable solution. DOC requires the use of nonlinear optics.

All-optical processing refers to optically based processors employed nonlinear optical resources either of liquid crystal spatial light modulators (SLMs) or nonlinear interference filters (NLIFs). Electro-absorption devices are a bridge between all-optical demonstrators and optically interconnected smart pixels (logic and local on-chip interconnection is electrical whereas chip to chip interconnection is optical). Optically interconnected smart pixels have several advantages like faster data acquisition and low power consumption. A major breakthrough in nonlinear optics is essential to increase the use of optics within computing and the manufacture of optical digital computers.

An optically bistable device used for photonic switching is the self electro-optic effect device (SEED). It is the analogous component for the transistor in optical processing. A SEED consists of multiple elements, biased by an external voltage, which creates an external field that shifts the wavelength of the onset of absorption, thus varying the intensity of the transmitted light. SEEDs rely on changes in the optical transmission of a semiconductor induced by an applied electric field. SEEDs can be configured in pairs (connected electrically) so that a beam of light switching one device can cause a complementary switch in the transmission of the other. Hence, a small change in the intensity of one beam can cause a large change in intensity of the other. This kind of configuration is known as symmetric SEEDs, and acts like an electronic flip-flop and permits logic operations NAND and NOR to be carried out on pairs of optical input signals. With symmetric SEEDs, the higher the input optical power, the faster the switching speed. Cellular logic image processor (CLIP) is implemented using the symmetric SEEDs. CLIP computer architecture is designed to permit parallel information processing, in which logic operations are performed on each element of the array simultaneously.

Holography

Holography is a photographic method of recording information (two mutually coherent beams) about an object, in which one beam is the object beam and the other a reference beam, which enables the construction of objects in three dimensions. Holography relies on the encoding of the object formation in a set of complex interference fringes formed by the interaction of a plane coherent reference wave with the wavelets diffusely scattered by the object.

The microscopic interference fringes recorded on a high resolution photographic plate after development and processing become a hologram. Hologram applications assist the study of small deformations of objects, to replace conventional optical elements such as lenses and beamsplitters, for data/information storage, and use of photo-refractive materials in analog computing, object recognition, and correlation, etc.

The purpose of recording a hologram is not optical data processing but rather a lensless method of forming an image. The uniqueness of a hologram as compared to an ordinary photographic image, for example, is that the latter contains amplitude information only. A hologram, because it involves interference of the complex field amplitude (CFA) of a given scene with a reference beam, records both amplitude and phase of the CFA of the given scene as seen within its field of view (FOV) by a square-low photosensitive device such as a film.

The film is exposed within its region of linearity whereby transmission is proportional to irradiance for a given time exposure. The transparency resulting from the film is the hologram. To view the holographic image, the hologram is illuminated with a reference wave, which causes the CFA of the given scene (both amplitude and phase) to be reconstructed. Since hologram reconstruction involves the CFA of the given scene in its entirety, depth information is included as well. Furthermore, it is even possible to view the holographic scene from different physical points of view and to see around objects in the scene. This ability, however, is limited by the solid angle subtended by the object when the hologram is recorded. Hologram reconstruction cannot supply more information than that recorded in the hologram itself.

Image Processing

Figure 1 demonstrates a general behavior of an imaging process. The 'Processing System' block in Figure 1 is expanded and presented in more detail by Figure 2. Figure 2 demonstrates in a flow chart, a general process occurring within the processing system. The input to the processing system is a degraded image (or set of images or video signal) such as blurred image, noisy image, image with clutters, multi-spectral image, etc. The input depends on exterior (environmental conditions) and interior (optical, electronic, and mechanical) effects of the imaging system. It may be generated as an analog signal or digital signal. As a result, the output of the imaging system is expected to be a processed (filtered, enhanced, estimated, restored, cleared, etc.) image.

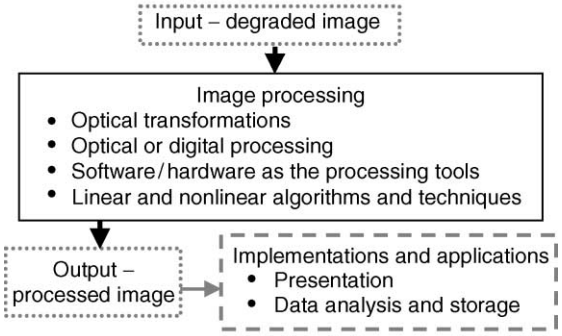

Figure 2 Image processing.

Implementations and applications depend on the output obtained by the imaging system. The output can be presented by a display device and/or hardcopy. The output can be stored for future assignments and may also serve for data analysis such as detection, recognition, and identification of patterns and other details of interest (mapping, target acquisition, defects and imperfections in the human body, meteorology, security, intelligence, etc.).

Spatial units are reciprocal to time, and are cycles/seconds or Hz. The spatial units are also reciprocal to the domain of the information being sought. Spatial signals are 2D or even 3D on occasions. 2D spatial transforms may actually exist physically in the spatial plane. Novel transforms for information processing include Fourier and wavelets transforms. Such optical transformations serve as the basic platform for linear optical system processing. Image processing techniques are based on the image spatial frequencies. In most techniques the degraded image is transformed using an optical transformation, as a primary stage before any other process is being conducted. Optical (inverse) transformations also serve as the last processing tool before the output. Practically, optical transformations are involved and integrated in most processes related to image processing.

Image processing refers to both digital and optical image processing, and also considers algorithms and techniques, which are implemented by an integration of software and hardware. Image processing is an extremely broad field. It considers digital image processing, 2D and 3D image processing and pattern recognition, real-time processing, neural networks, image enhancement/improvement, image restoration, estimation, filtering for noise removal, linear and nonlinear filtering techniques for variety of implementations, optimum filtering, etc. Image processing also include varieties of algorithms such as linear and nonlinear algorithms, algorithms for pattern recognition, linear and nonlinear techniques for pattern recognition, neural networks based algorithms, etc. Both optical and electronic implementations (hardware) are still under investigation. Nevertheless, image processing based on software presents reliable results and hence, can be transformed into hardware components, which may become an integrated part of the processing hardware.

Optical Transformations

Mathematical transformations are applied to signals to obtain further information from the signal that is not readily available in the raw signal. Most of the signals, in practice, are time-domain signals in their raw format. That is, whatever that signal is measuring, is a function of time. In many cases, the most important information is hidden in the frequency content of the signal. The frequency spectrum of a signal is basically the frequency components (spectral components) of that signal. The frequency spectrum of a signal shows what frequencies exist in the signal.

There are many transforms that are widely used, often by engineers and mathematicians, in solving problems in science and engineering. Fourier, Laplace, Hilbert, Wigner distributions, Radon, and wavelet transforms, constitute only a small portion of a huge list of transforms that are available. Every transformation technique has its own area of application, with advantages and disadvantages.

Fourier Transform

The Fourier transform (FT) is probably the most popular linear transform being used. The FT, a pervasive and versatile tool, is used in many fields of science as a mathematical or physical tool to alter a problem into one that can be more easily solved. It is used in linear systems analysis, antenna studies, optics, random process modeling, probability theory, quantum physics, and boundary-value problems and has been successfully applied to restoration of astronomical data. Some scientists understand Fourier theory as a physical phenomenon, not simply as a mathematical tool. In some branches of science, the FT of one function may yield another physical function. The FT, in essence, decomposes or separates a waveform or function into sinusoids of different frequency which sum to the original waveform. It identifies or distinguishes the different frequency sinusoids and their respective amplitudes. There are

functions for which the Fourier transform does not exist; however, most physical functions have a FT, especially if the transform represents a physical quantity. Other functions can be treated with Fourier theory as limiting cases. Many of the common theoretical functions are actually limiting cases in Fourier theory.

Wavelets

Wavelets were developed independently in the fields of mathematics, quantum physics, electrical engineering, and seismic geology. Interchanges between these fields have led to many new wavelet applications including image processing. Wavelets are mathematical functions that cut up data into different frequency components, and then study each component with a resolution matched to its scale. Wavelet transforms comprise an infinite set. The different wavelet families make different trade-offs between how compactly the basis functions are localized in space and how smooth they are. Within each family of wavelets are wavelet subclasses distinguished by the number of coefficients and by the level of iteration.

The wavelet transform (WT), which is also a linear operation, provides the time-frequency representation. Often a particular spectral component occurring at any instant can be of particular interest. In these cases it may be beneficial to know the time intervals at which these particular spectral components occur. WT is capable of providing the time and frequency information simultaneously, hence giving a time-frequency representation of the signal. The WT was developed as an alternative to the short-time FT (STFT). The WT was developed to overcome some resolution related problems of the STFT. The frequency and time information of a signal at some certain point in the time-frequency plane cannot be known. What spectral component exists at any given time instant is a mystery. Therefore, it is best to investigate what spectral components exist at any given interval of time. This is a problem of resolution, and it is the main reason why researchers have switched to WT from STFT. STFT gives a fixed resolution at all times, whereas WT gives a variable resolution as follows: higher frequencies are better resolved in time, and lower frequencies are better resolved in frequency. This means that a certain high frequency component can be located better in time (with less relative error) than a low frequency component. On the contrary, a low frequency component can be located better in frequency, compared to high frequency component.

Wavelet versus Fourier Transforms

Both transforms are linear and the mathematical properties of the matrices involved in the transforms are similar. The inverse transform matrix for both transforms is the transpose of the original. Wavelets have advantages over traditional Fourier methods in analyzing physical situations where the signal contains discontinuities and sharp spikes. The most interesting dissimilarity is that individual wavelet functions are localized in space, Fourier sine and cosine functions are not. This localization feature, along with wavelets localization of frequency, makes many functions and operators using wavelets 'sparse' when transformed into the wavelet domain. This sparseness, in turn, results in a number of useful applications such as data compression, detecting features in images, and removing noise from time series. One way to see the time-frequency resolution differences between the FT and the WT is to look at the basis function coverage of the time-frequency plane. In order to isolate signal discontinuities, some very short basis functions are needed. At the same time, in order to obtain detailed frequency analysis, some very long basis functions are needed. A way to achieve this is to have short high-frequency basis functions and long low-frequency ones. This happy medium is obtained with WT. FT utilizes just the sine and cosine functions (single set of basis functions). Therefore, its new domain contains basis functions that are sines and cosines. On the other hand, WT includes an infinite set of possible basis functions. Hence, its new domain contains more complicated basis functions called wavelets, mother wavelets, or analyzing wavelets. The basis functions are localized in frequency, making mathematical tools such as power spectra and scalegrams useful at picking out frequencies and calculating power distributions. Thus wavelet analysis provides immediate access to information that can be obscured by other time-frequency methods such as Fourier analysis.

Physical Properties and Analog/Digital Mitigation Processing in Nonideal Systems

The weakest link in most imaging systems is time varying distortions, such as the Earth's atmosphere, motion, or vibrations. To obtain clear imaging through time varying distortions, it is useful to characterize the physical degradation phenomena using an OTF. It is often important to use the appropriate filter based on the OTF magnitude, modulation transfer function (MTF), to correct

(restore) the degraded image (using software or hardware). On the other hand, it may be useful to incorporate real-time phase correction into the imaging system such as adaptive optics.

Optical Transfer Function for Incoherent Imaging

In electronics, the transfer function is redefined as the Fourier transform of the impulse response. The OTF is defined similarly, but is normalized to its own maximum value which normally occurs at zero spatial frequency, that is:

$$\begin{aligned}\mathrm{OTF} &= \tau(\omega) = \tau(\omega_x, \omega_y) \\ &= \frac{\int\int_{-\infty}^{\infty} s(x',y')\exp[-j(\omega_x x' + \omega_y y')\mathrm{d}x'\,\mathrm{d}y']}{\int\int_{-\infty}^{\infty} s(x',y')\mathrm{d}x'\,\mathrm{d}y'} \\ &= \frac{S(\omega_x,\omega_y)}{S(0,0)} = \mathrm{MTF}\,\exp(j\mathrm{PTF}) \qquad [1]\end{aligned}$$

where $S(\omega_x, \omega_y)$ is the FT of the spread function or impulse response $s(x', y')$. Ordinarily, for artificial imaging systems, the OTF is maximum at zero frequency. The magnitude of the OTF is called the MTF. The name refers to spatial modulation of light irradiance. If there is no such modulation, irradiance is uniform and there is no image. Thus, spatial modulation is related to image quality and MTF is a measure of the ability of an imaging component or system to transfer such spatial modulation from input (object plane) to output (image plane).

There is also a phase transfer function (PTF) whose importance in resolution is not nearly as widespread as that of MTF but which, nevertheless, cannot be neglected. Spatial phase determines image position and orientation, rather than amount of detail. If a target is displaced bodily in the image plane such that each part of the target image is displaced by the same amount, the target image is not distorted. However, if portions of the target image are displaced more or less than other portions, then the target image is distorted. This information is contained in the PTF.

The physical implications of the OTF are very analogous to those of electronics transfer functions. Both permit determination of output for any given input. In both cases, since the FT of the delta function is a constant (unity) amplitude, a delta function input permits indication of the frequency response of the system, that is, which frequencies pass through the system unattenuated and which are attenuated and by how much. Perfect fidelity or resemblance between input and output requires infinite bandwidth so that an impulse function is obtained at output for impulse function input. In imaging, an impulse formation at output is a point image. This means that, to obtain a point image for a point object, infinite spatial frequency bandwidth is required of the imaging system. Physically, this means that because of diffraction effects optical elements such as lenses, field stops, and mirrors must be of infinite diameter so as to eliminate diffraction at the edges. This, of course, is not attainable.

Pixel Modulation Transfer Function

To measure the point spread function (PSF), it is important to determine which size object can be considered a point object. This is affected primarily by instrumentation pixel size. The pixel is the smallest element recordable in image space. The brightness value represents average irradiance over that small portion of the image scene. Pixel size is often related to detector size. If only a portion of the detector is illuminated, the output current is equivalent to that obtained for the same total radiant power absorbed by the detector but averaged over the entire detector area. No detail smaller than a pixel can be resolved in the image. In practice, dead space between pixels violates isoplanaticism (spatial stationarity), which is a requirement for linear systems. Nevertheless, dead space is small and such effects are often neglected in image system characterization. However, it is possible to overcome distortions in MTF measurements arising from this lack of isoplanaticism by using a 'white' spatial noise random object. This gives rise to a white noise random image. The ratio of the image power spectral density to object power spectral density is equal to the square of the system MTF. In this way the lack of isoplanaticism is overcome by the spatial randomness of the object and image.

Pixel size strongly affects system MTF. If a pixel represents a point image, then pixel size and shape are minimum spread function. A best case OTF for such an imaging system is then a normalized FT of the pixel shape. For example, a square pixel yields a two-dimensional sinc MTF whose width increases as pixel size decreases.

Optical Transfer Functions for Image Motion and Vibration

Image blurring caused by vibrations is a factor whose influence on resolution is often significant in imaging systems that involve mechanical motion. A stabilized system, which obtains image motion corrections by moving optical elements so as to counteract sensor motions, has a residual error typically on the order of 2500 μrad/s involving pitch, roll, yaw, and

forward motion compensation errors. The greatest errors usually result from rotational vibration. A stabilized mount-type system has a combined error typically on the order of 100 μrad/s. Even where no motion is involved, as in large fixed-position astronomical telescopes, vibrations deriving from thermal gradients in the walls and other parts of the telescope can be the limiting factor in image resolution.

As a consequence of such image motion, in many high-resolution systems, despite the use of high-quality sensors, resolution is limited by image motion and, as a result, the high-resolution capability of the sensor may be wasted. It can be a significant waste of means to use an expensive high-resolution sensor in such a situation unless the blur can be corrected with image restoration. In imaging system design, a convenient engineering tool is OTF. The overall system OTF is limited by the OTF of the weakest link. The formulation of such image motion blur into an OTF format is thus very convenient for system design and system analysis purposes, as well as for image restoration.

OTFs can describe image quality for many forms of image motion such as linear (uniform) motion, sinusoidal vibrations at high vibration frequencies, sinusoidal vibrations at low vibration frequencies, acceleration, etc. The OTF for any type of image motion can be calculated numerically in real time provided the motion function is known. This is usually determined easily via a gyroscope or microelectronic accelerometer.

In general, the motion of interest is not the actual relative motion between object and imager, but rather the relative motion between imager and image plane. The latter motion is that observed in the image plane. Both of these motions are related to each other by the image system magnification. Hence, image plane relative motion is usually much less than the actual relative motion. However, any motion during an exposure gives rise to blurring of image plane detail. One question to be considered is how much blur can take place as a result of motion and still not be noticeable because of inherent blur deriving from the PSF of the rest of the imaging system. In other words, assuming that image motion and vibration blur cannot be removed completely, how much is tolerable before resolution and target acquisition capability are affected? This depends on focal length and system zoom.

A general method of OTF calculation is obtained by the line spread function (LSF) derived from image motion transverse to the optical axis. The MTF is derived as the modulus of the MTF or FT of the LSF, and the PTF is derived as the phase of the OTF. The LSF is the probability density function (PDF) of the histogram of the relative transverse displacement between object and sensor beginning at time t_s and ending at time $t_s + t_e$ where t_s is measured from the instant the sensor is first exposed and t_e is exposure time.

Recently a method of calculating motion OTF analytically has been developed for any type of motion. Also, methods to calculate motion OTF without a motion sensor have been derived for a sequence of consecutive images and even from a single motion-blurred image. All three methods have been used successfully in image restoration.

Optical Transfer Functions for the Atmosphere

Many properties of the atmosphere affect the quality of images propagating through it. There are atmospheric phenomena that give rise to attenuation of the irradiance of the propagating image, thus reducing the contrast of the final image. There are also atmospheric phenomena that cause blurring of detail. Both types of phenomena prevent small detail from being resolved in the final image, thus degrading image quality.

Electromagnetic (EM) wave absorption and scattering by the constituent gases and particulates of the atmosphere and airborne particulates give rise to attenuation. Scattering of photons by airborne particulates is manifested as deflections of the photons to directions other than that of the original propagation. If such scattering causes the deflected photons to miss the imaging receiver, then the scattering is manifested as attenuation. The received irradiance of the image propagated through the atmosphere is correspondingly diminished from that in the object plane. However, if the light scattering is at very small angles with respect to the original direction of the propagation, and several such small-angle scattering events take place, then forward-scattered radiation can take round-about paths and still be received by the imaging system together with the unscattered radiation. The net effect is image blurring caused by a multitude of angles of arrival at the imaging receiver of radiation emanating from the same point in the object plane. Many multiple-scattering paths give rise to a relatively large blurred-point image rather than a fine sharp-point image. Adjacent image plane points can then appear for a single object plane point, thus degrading image resolution. Such aerosol scatter blur is known as the adjacency effect.

Another effect of light scattering, particularly at large angles, is increased path radiance. The atmospheric background irradiance at wavelengths less

than 2–4 μm, consists through the day of scattered background light such as sunlight. This atmospheric background radiation is imaged over the same image space as the received irradiance from the target plane. The result is decreased contrast of the target plane scene. At wavelengths larger than 4 μm, most of the path radiance is not scattered sunlight, but rather thermal emission of the atmospheric constituents, gases in particular. This thermal path radiance decreases contrast in thermal imaging systems, particularly in the longwave infrared (8–13 μm).

Turbulence results from variations in the atmospheric refractive index, which are random in both time and space. These refractive index fluctuations are caused by local fluctuations in atmospheric temperatures, pressure, humidity, etc., all of which are affected by wind speed, which in itself is also random in time and space. Generally, the larger the temperature and humidity gradients, the more serious the image resolution degradation caused by turbulence. The lower the wind speed, the stronger the impact of turbulence. Scattering and turbulence are basically two very different physical mechanisms, each exhibiting quite different properties. Time dynamic properties such as scintillations and image dancing derive from turbulence, while aerosol scatter light changes only slowly with time.

A point that must be strongly emphasized is that there is no such thing as a purely turbulent, purely scattering, or purely absorption atmosphere. All three properties occur simultaneously in the real-world atmosphere. Modeling and interpretation of experimental results must relate to all three processes. Any attempt to pretend otherwise is not realistic. In general, blur is caused by turbulence and small-angle scatter of light by aerosols and particles. Attenuation is caused by large-angle scatter and by absorption.

Generally turbulence blur is dominant for images near the ground, where ground heating gives rise to the turbulence. Aerosol blur is usually dominant at higher elevations, even as little as several meters above ground, depending on weather conditions and wavelength.

The product of both aerosol and turbulence MTFs (in the spatial frequency domain, after FT) yields approximately atmospheric MTF. The atmospheric MTF can be predicted according to atmospheric (meteorological) parameters. Aerosol MTF calculation is based on optical depth, which includes parameters such as scattering and absorption coefficients through the atmosphere over the imaging path. Turbulence MTF calculation is based on the refractive index structure coefficient, which includes parameters such as temperature, humidity, wind speed, etc.

By referring to the edge response in a given scene the atmospheric MTF may be calculated. The edge separating the wide white and black bars is imaged from the scene. The image of the edge is not a step function because of atmospheric blur. The gradient of the edge image is the LSF, from which the overall atmospheric MTF can be obtained after the FT of the LSF is divided by the hardware MTF.

Spatial Filtering

Spatial filtering is a process by which we can alter properties of an optical image by selectively removing certain spatial frequencies that make up an object, for example, filtering video data received from satellite and space probes, or removal of raster from a television picture or scanned image. In digital image processing, the term image refers to a two-dimensional light-intensity function, where amplitude at spatial coordinates (x, y) gives the intensity (brightness) of the image at that point.

Digital image processing techniques are oriented to transform, enhance, restore, or encode an image. Digital image restoration is on the basis of the OTF or even MTF alone describing the image degradation. Resolution is limited usually not by electronics or optics, but by image motion and vibration. For long-range imaging, the image quality may be limited by atmospheric effects.

By image restoration filters we refer primarily to spatial frequency filters placed in the spatial frequency plane in the optical data processor. Although data processing is done optically, the same mathematical concept is usually carried out with a digital computer. It is also possible to do restoration in the spatial domain. The simplest image restoration filter is the inverse filter. When noise becomes a problem, there are often used three classes of minimum mean square error estimations (MMSEE), which are the noncausal Wiener filtering, causal Wiener filtering, and Kalman filtering. Kalman and Wiener filters are proposed to obtain the optimum solution for the MMSEE problem in linear systems. Wiener filters are applied in linear time invariant systems, and Kalman filters in linear systems which may be either time invariant or time variant. A novel area of application for Wiener filtering is image restoration. On the other hand, if the estimation processes are partial and an ideal image is not obtainable, a Kalman filter may present better restoration results than a Wiener filter.

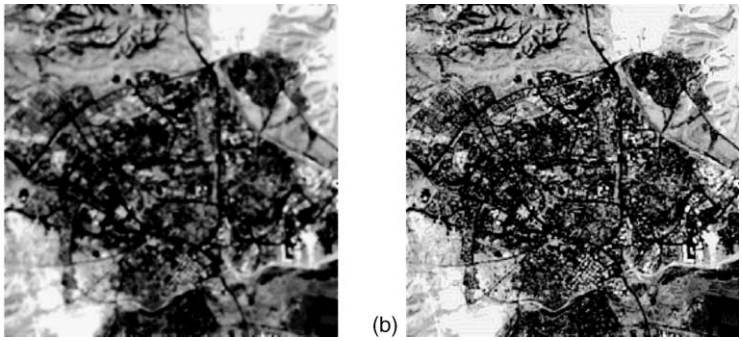

Figure 3 An example for satellite image restoration. (a) Original image of Beer-Sheva, Israel, from Landsat 7 satellite; (b) restored image after Kalman filter using aerosol and turbulence MTFs. Reproduced with permission of the American Society for Photogrammetry and Remote Sensing from Arbel D, Cohen E, Citroen M, Blumberg DG and Kopeika NS (2004) Landsat TM satellite image restoration using Kalman filters. *Photogrammetric Engineering and Remote Sensing* (PE&RS) 70(1): 91–100.

Figure 3 demonstrates the restoration result for a satellite image. Figure 3a presents an original Landsat 7 enhanced thematic mapper plus (ETM+) image of the city of Beer-Sheva, Israel. The image was recorded from 750 km satellite elevation. The image was recorded using an ETM+ sensor with 15 m ground resolution, and its wavelength range is 520–900 nm (Panchromatic band). Figure 3a is of 256×256 pixel size, which is a segment defined as a region of interest (ROI) in the original image. The scene was recorded on August 7, 1999 and was degraded (blurred) as a result of the meteorological conditions, which were measured and recorded (as data) at the same time. Figure 3b shows the restored image using the Kalman filter, which was based on the atmospheric MTF, which is obtained by using aerosol MTF with turbulence MTF. The restored image (Figure 3b) is more detailed. For example, roads and buildings were deblurred and became more accurate than in the original image (Figure 3a).

Introduction

The concept of radiation pressure or pressure from the propagation of light is not new. In the early seventeenth century, Johannes Kepler proposed that radiation pressure from the sun accounted for the fact that tails of comets always point away from the sun. In 1873, James Maxwell, on the basis of electromagnetic theory, showed that pressure should result from the absorption or reflection of a beam of light. However, early studies in the beginning of the twentieth century that attempted to detect and quantify the effects of radiation pressure were unsuccessful, mainly frustrated by thermal forces from temperature gradients that tended to obscure the weak effects of radiation pressure. It was only in the 1960s, that the advent of lasers provided a light source with the power to generate sufficient radiation pressure to overcome forces due to thermal effects.

As lasers became generally available in the early 1970s, Arthur Ashkin from the Bell Labs pioneered the development of optical tweezers. He showed that the forces of radiation pressure from focused laser beams could be used to affect the dynamics of small transparent micrometer-sized particles. According to Ashkin, his early experiments were motivated by simple back of the envelope calculations of the magnitude of the radiation pressure force of light on a totally reflecting mirror. Let us consider such a calculation: a photon of frequency ω has a momentum of $\hbar\omega/c$. For a total power of I, we have a flux of $I/\hbar\omega$ photons per second incident on the mirror. When the photons are reflected, they transfer a momentum of $2I/c$ to the mirror. The force exerted on the mirror for $I = 1$ W, is approximately 10^{-9} N. If the mirror is a 1 μm size particle weighing 10^{-15} kg, this force will induce an acceleration of 10^6 g!

In the following decade, Ashkin demonstrated that by focusing laser light using a high numerical aperture microscope objective, strong intensity gradients could be created to optically trap small dielectric particles such as microspheres. Ashkin named this trapping scheme a 'single-beam gradient force trap', now more commonly called optical tweezers.

Today optical tweezers are well-established and extremely versatile tools for the physical and life sciences. Using optical tweezers, forces up to 200 pN can be applied with a resolution of 100 aN on particles with dimensions on the order of the wavelength of light. Even particles as small as 5 nm can be trapped, rotated, positioned, and arrayed. Optical tweezers have been used in single molecule studies of biopolymers (DNA, RNA), in the manipulation of various types of cells and in cell sorting, in microsurgical procedures, as well as in viscoelastic studies of membranes, and protein. Optical tweezing has also been the key tool in the understanding of the workings of molecular motors such as myosin, kinesin, RNA polymerases, etc.

Theory

Optical tweezers trap dielectric particles using radiation pressure generated by a tightly focused beam of light from a laser. Depending on the size of the particle in relation to the wavelength of the trapping beam, there are two different mechanisms responsible for trapping small particles in a single beam gradient trap. For particles in the Mie regime, where the particle size is large compared to the laser wavelength, a simple geometric-optics model serves best. Figures 1a–c, illustrate possible cases of a Mie particle in an optical trap. Here, the particle is assumed to be a sphere that is transparent with a refractive index higher than that of the surrounding medium. The particle behaves as a convergent lens refracting and deflecting the beam when its center is displaced from the laser focus. In Figure 1a, the sphere is axially displaced from the focus, away from the microscope objective. Ray A is then refracted toward the surface normal as it enters and exits the sphere, causing a change in the momentum of the ray. Due to conservation of momentum, the sphere reacts with a force F_a in the opposite direction. The situation is similar for ray B. The gradient force, F, obtained from the vectorial addition of F_a and F_b, is directed toward the light source. At the same time, the scattering force, arising from back and scattered reflections, is directed away from the light source. It can be seen that above the focal point, the scattering and gradient forces act in the same direction, pushing the particle away from the light source (Figure 1b). For a particle in the focal plane, but transversely displaced from the trap center, the gradient force acts in a restoring direction pushing the bead into the trap focus (Figure 1c). At a location just below the focus, the scattering force balances the gradient force and stable optical trapping is achieved.

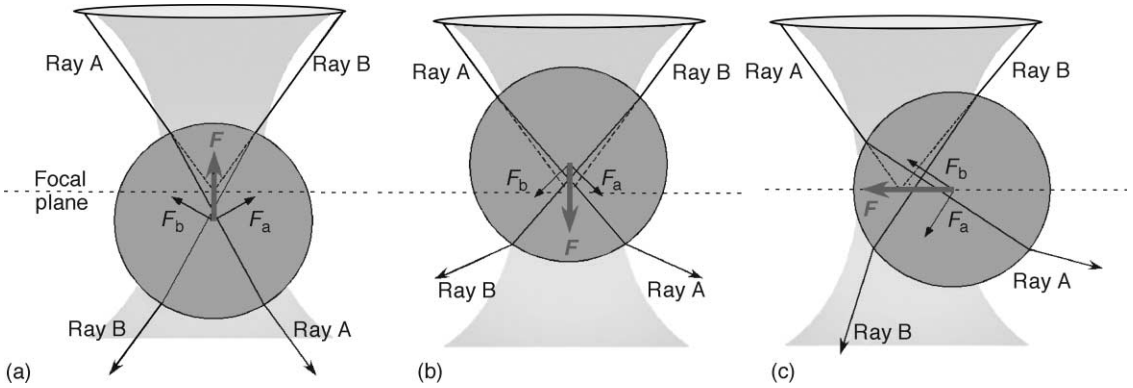

Figure 1 Ray diagram sketches showing three cases of particle trapping in the Mie regime. Rays A and B border the cone of light focused by a high numerical aperture microscope objective. The refraction of these rays gives rise to forces F_a and F_b, the resultant force F tends to restore axial and transverse displacements of the particle from the trap focus (at the intersection of dotted rays A and B).

This simple ray optics model can also be used to estimate the trapping force, an example of such a calculation is shown in **Box 1**.

For dielectric particles in the Rayleigh regime, where the size of the particle is small compared to the wavelength of the incident light, the particle acts as a simple dipole. The electromagnetic light wave polarizes the particle, inducing a set of oscillating dipoles. The dipoles respond to the electric field of the incident light in the direction of the gradient, resulting in the movement of the particle towards the focal point. Additionally, there is also a scattering force, acting in the direction of beam propagation, from light that is scattered or absorbed. While the scattering force is proportional to the electromagnetic field, the gradient force is proportional to the gradient of the electromagnetic field. Therefore, stable optical trapping can be achieved for a field with a gradient large enough to overcome the scattering force. This can be obtained by using a microscope objective with a high numerical aperture.

Stable trapping is achieved when the energy associated with the trapping significantly exceeds the thermal energy of the trapped particle, $\frac{1}{2}k_BT$ per degree of freedom. Since the optical gradient is weakest in the axial direction of the trap, the trap stiffness in this direction limits its stability. Furthermore, the trap is weakened in the axial direction by the scattering force, which pushes the microsphere away from the objective. To overcome this, two counterpropagating laser beams can be used, not only to increase the axial gradient of the trap, but also to provide a compensating scattering force in the opposite direction.

Force Measurement

Optical tweezers can be used as picotensiometers or highly sensitive force sensors. Measuring the displacement of a particle in a trap with known stiffness k, yields the force F given by

$$\mathbf{F} = -k \cdot x \qquad [1]$$

The displacement can be measured in different ways, ranging from video microscopy to light-scattering techniques. Some of these methods are discussed in the instrument design section below.

The trap stiffness is generally not known *a priori* as it depends on the shape and intensity of the trap, as well as the relative refractive index, shape, and position of the object in the trap. Since theoretical approximations are usually not accurate enough, the trap stiffness must be empirically determined and calibrated.

Various force calibration strategies have evolved over the years, however, they can be broadly divided into two types: (i) schemes that rely on the interaction of the optical trap with viscous forces; and (ii) those that exploit the thermal fluctuations of the trapped object.

Force Calibration by Viscous Drag

The conceptual basis for calibration by viscous drag is simple. A known force is exerted on a trapped object and the deviation in its position is measured as a function of the applied force. The trap stiffness can then be calculated from eqn [1]. Force can be exerted by either flowing liquid past the trapped object, translating the microscope stage while keeping the trap fixed, or translating the optical trap while keeping the sample fixed.

In a situation where the Reynolds number is small, inertial forces can be neglected and Stokes' Law gives the viscous drag force on a sphere of known radius r:

$$F_d = (6\pi\eta r)v = \beta v \qquad [2]$$

Box 1

Optical Tweezers in the Ray Optics Model

In a simple ray optics model, the trapped microsphere acts like a small lens on the incident laser beam. If the microsphere is not centered on the beam axis, the beam will be refracted. The corresponding change in the momentum of the laser beam gives rise to a restoring force on the microsphere.

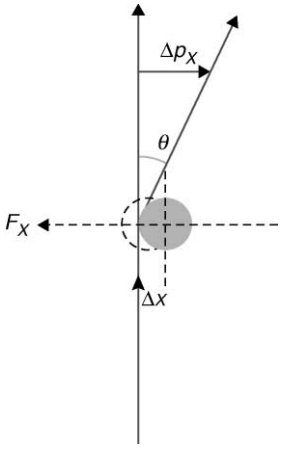

Figure B1

A photon of frequency ω in a medium of refractive index n_1 that is deflected by an angle θ, as shown in Figure B1, acquires a lateral momentum of

$$\Delta p_x = \frac{\hbar \omega n_1}{c} \sin \theta \qquad [B1]$$

Momentum conservation requires a counteracting force on the microsphere, which is for a laser beam of intensity I

$$F_x = \frac{I n_1}{c} \sin \theta \qquad [B2]$$

Assuming that the deflection angle θ is given by the deflection of a beam that is incident on biconvex lens with curvature R and refractive index n_2 at an off-axis displacement Δx, we find for the restoring force on the microsphere:

$$F_x = \frac{2I}{Rc}(n_2 - n_1)\Delta x \qquad [B3]$$

which describes a linear spring with a stiffness of the optical trap of

$$k = \frac{2I}{Rc}(n_2 - n_1) \qquad [B4]$$

Here, η, the viscosity of the sample fluid, is known and immediately allows the determination of the friction coefficient β of the sphere. The fluid velocity, v, can be measured in the case of external fluid flow by either tracking the trapped object when the trap is switched off or measuring the speed of some other marker in the sample. If the stage is moved to generate the fluid flow, the velocity of the fluid surrounding the trapped object can be estimated from the motion of the stage. In either case, the drag coefficient, from eqn [2] may need to be corrected if the trapped object is close to the walls of the sample cell. This correction is well known as Faxen's Law, which accounts for hydrodynamic interactions between the trapped particle and the wall. These effects are particularly significant when the center of the trapped particle is less than a diameter away from the wall. The advantage of these fluid-flow

calibration methods is that the trap stiffness at regions far from the trap center can be measured. The drawback is that, in general, only transverse trapping forces can be measured and the trapped objects have to be approximated as spherical or ellipsoidal.

Thermal Motion Methods

These methods measure the Brownian motion of a trapped particle to deduce the trap stiffness. A trapped particle experiences three forces: (i) the thermal forces due to collisions with surrounding solvent molecules; (ii) forces from viscous drag; and (iii) the restoring force of the trap. For low Reynolds numbers, where the inertial effects can be neglected for the microsphere, the equation of motion is

$$\beta\dot{x} + kx = F(t) \qquad [3]$$

Where β is the viscous drag, k is the trap stiffness, and $F(t)$ is a randomly fluctuating Langevin force due to thermal fluctuations. This motion of the microsphere in the trap at a temperature T is characterized by a Lorentzian power spectrum of the form:

$$x_f^2 = \frac{k_b T}{2\pi^3 \beta(f_0^2 + f^2)} \qquad [4]$$

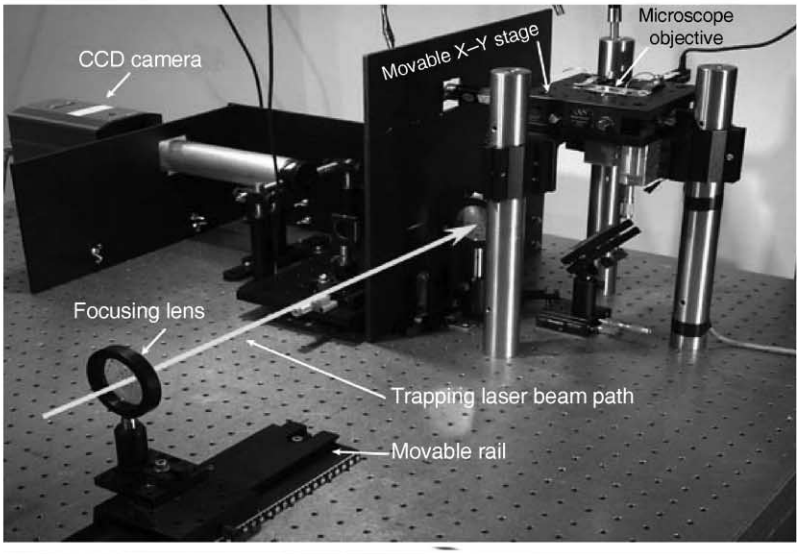
where $f_0 = k/(2\pi\beta)$ is the corner frequency, above which the motion of the particle is Brownian.

To calibrate the optical trap by the corner frequency method, the motion of a trapped particle is observed and its power spectrum, which is the Fourier transform of the autocorrelation function, is calculated. Fitting the power spectrum to a Lorentzian function will yield the corner frequency f_0, which can be directly related to the trap stiffness k, provided that the drag coefficient β can be estimated.

Alternatively, the trap stiffness can be obtained directly from the time constant of the exponential decay of the autocorrelation function of the particle motion. The spring constant is the ratio of the drag coefficient to the time constant of the trap.

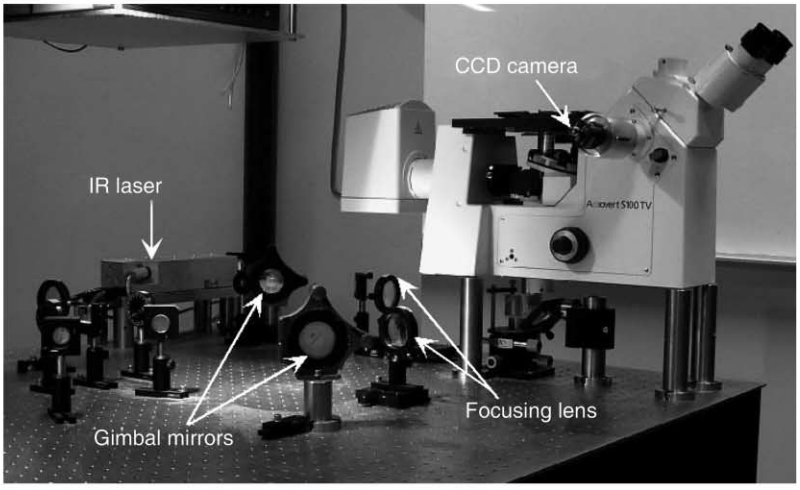
Another approach known as the mean square displacement method does not require the estimation of the drag coefficient but does require a well-calibrated position detector. In this method, the mean square displacement $\langle x^2 \rangle$ of the fluctuations of a trapped particle is computed from position data and then by the Equipartition theorem:

$$\langle x^2 \rangle = k_b T/k \qquad [5]$$



This enables a simple, straightforward calculation of k, the trap stiffness.

Design



Optical tweezing stations broadly fall into three categories: (i) stand-alone systems; (ii) systems incorporating an optical microscope; and (iii) completely configured commercially available systems. Stand-alone systems feature optical tweezers built around a microscope objective and suitable optical components. These systems provide the maximum flexibility and can be easily reconfigured to adapt to different experimental needs. Furthermore, they also tend to provide the best mechanical stability, if configured properly. Figure 2a shows a picture of a stand-alone optical tweezing setup from our laboratory. This system is capable of the basic tasks of trapping, holding, and positioning microscopic objects. The most common optical tweezing stations are integrated into commercial light microscopes as sketched in Figure 3. The advantage of these hybrid systems is that the commercial microscope provides a flexible, optimized optical imaging platform, in which the optical trapping system can be integrated with only moderate difficulty. Figure 2b shows a picture of a typical optical tweezing station built around a commercial inverted microscope and mounted on a vibration–isolation table. This system includes an acousto-optic modulator that enables beam scanning for line-tweezing experiments. At the time of this writing, optical tweezing systems range from less than $10 000 for basic demonstration stations to between $50 000 to $100 000 for more sophisticated hybrid systems.

Commercial fully integrated systems are available from P.A.L.M. Microlaser Technologies AG (Bernried, Germany), Cell Robotics, Inc (Albuquerque, NM, USA), and Arryx (Chicago, IL, USA). Figure 2c shows a commercial optical tweezers set-up available from P.A.L.M. Microlaser Technologies.

When designing an optical tweezing station, the first item to consider is the choice of laser system. A simple single beam tweezing system can be built around a laser with less than 100 mW of power. Even though the minimum power required for trapping is a few milliwatts in the laser focus, there is considerable power loss in the tweezing and microscope optics. Also, the trap stiffness and thus the maximum trapping force decreases linearly with intensity, therefore most optical tweezers typically use lasers with an output power of 1 W. In some special applications, when beam scanning or multiple traps are required, the power requirement can be significantly larger. The wavelength of the laser also affects the capability of the trap in that the optimum wavelength depends on the size of the objects that are to be trapped. In general, the strongest traps occur

for particles of size comparable to the wavelength of the laser. Another important concern in the choice of wavelength is possible damage to the sample from absorption and heating. In general, biological material is more transparent to the longer wavelengths of the IR spectrum. Studies on living cells have shown that generally, a range of wavelengths of 700 nm to 1100 nm, termed 'the optical window' of cells and tissue, is most suitable. Importantly, at higher wavelengths there is a reduced possibility of damage from multiphoton effects. DNA (260 nm) and proteins (280 nm) are strong absorbers in the ultraviolet range. Due to multiphoton effects, wavelengths between 700–800 nm have been seen to affect cell metabolism and lead to cell death within seconds. However, at wavelengths greater than 1000 nm, the simultaneous absorption of four photons required is unlikely at typical laser intensities used in trapping experiments.

The beam quality of the laser also restricts the choice of laser system. Diode lasers, in particular, have poor beam quality since the beam is often elliptical in shape and astigmatic, leading to a larger inefficient trap. Over the years, Nd-YAG lasers, at 1064 nm, have emerged as the lasers of choice, providing the best balance between price, power, and quality.

To achieve stable trapping it is essential to create an optical potential in which the gradient forces dominate the scattering force as discussed in the Theory section above. This suggests that the higher the numerical aperture (NA) of the microscope objective the stronger and more stable the trap will be. Oil or water-immersion microscope objectives with $NA > 1.2$ are commonly used. Further, this requirement also implies that the back aperture (rear entrance) of the microscope objective needs to be completely filled or, in the case of a Gaussian beam, overfilled to a certain degree to achieve optimal trapping efficiency. Since most commercial objectives are corrected for achromatic and spherical aberrations in the visual region of the spectrum, only

Figure 2 (a) A stand-alone tweezing station built around a microscope objective mounted on a vibration isolation table. (b) A typical tweezing station incorporated into a standard commercial microscope. This setup features dual-steerable optical traps and includes a CCD camera. Position detecting instrumentation can be mounted on the existing microscope stage. (c) The commercially available PALM® Combisystem utilizes an IR laser (wavelength 1064 nm) and a UV laser (wavelength 377 nm) coupled via the epi-fluorescence path to a research microscope. The system advertises automated and noncontact laser microdissection as well as trapping, sorting, and positioning. (**Figure 2:** (c), courtesy of P.A.L.M. Microlaser Technologies, Bernried, Germany.)

a small fraction of the working distance is usable for viable trapping. Normally this is limited to within 40 μm of the cover slip.

In addition to providing a beam large enough to overfill the back aperture, there are two other criteria that the external optics have to satisfy: first, the optical trap should be parfocal with the specimen plane. This enables the visualization of trapped objects. Second, the laser beam should be able to pivot around the back aperture without moving laterally to maintain the same degree of overfilling. This allows for a stable two-dimensionally movable trap. In practice, these requirements are fulfilled by using a telescopic system of lenses and Gimbal mounted mirrors. The latter are special mounts that enable a mirror to be tilted around its center position without lateral displacement. The telescope expands the incoming beam to fill the back aperture of the microscope objective and also images the back aperture onto the center of the Gimbal mounted mirror. As seen in Figure 4, since the back aperture of the microscope objective and the Gimbal mounted mirror are in conjugate planes, a small tilting of the mirror will only result in a change in the angle of the laser beam entering the microscope objective. The position of the beam will be unchanged, as will the degree of overfilling.

More sophisticated optical tweezer designs use acousto-optic modulators and galvanometer scanning mirrors to create scanning line tweezers and/or multiple traps. The basic approach is to deflect the laser beam to create multiple traps or to scan a single trap to create a one-dimensional potential well. Additionally, a new generation of holographic optical tweezers, capable of creating three-dimensional arrays of trapped particles, has emerged. Computer generated holograms that modify the phase and amplitude of the trapping laser are reverse engineered from the desired two- or three-dimensional optical trapping patterns. Furthermore, constructing such holograms from liquid crystal light modulators allows for dynamic control of the trapping pattern, yielding a fully computerized reconfigurable trapping system. An interesting example of the application of holographic optical tweezers to colloidal transport is shown in Figure 5, the first demonstration of 'kinetically locked-in states' where particles traveling across a potential mesh display a preference for certain paths.

It is to be noted that the optical tweezer is fundamentally a constant-extension technique, that is, it attempts to maintain the extension of a stretched molecule whereas the force is varied. However, it is of interest to study the action of molecular motors under constant force conditions. A basic optical tweezers setup can be modified to include an electronic feedback loop to provide constant force conditions. More recently, scanning-line optical tweezers have been adapted to implement all-optical constant force schemes that dispense with the need for electronic feedback.

An important aspect of any force measurement is the ability to accurately image and measure the position of a trapped particle. Standard digital video microscopy techniques yield a resolution of ~5 nm but have limited bandwidth and thus cannot be used for systems that employ feedback control of laser intensity or trap position. In these systems, the forward- or back-scattered trapping laser light from the trapped particle can be imaged onto a calibrated quadrant photodiode to provide sensitive position detection at high bandwidths (~1 kHz). If the photodiode is fixed in a plane conjugate to the back focal plane of the microscope objective, the trap can

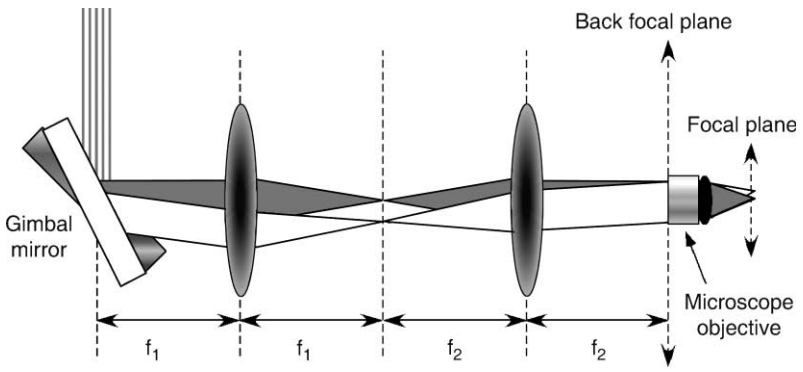

Figure 4 A sketch showing the working of a gimbal mounted mirror in two positions (shown as shaded and as unshaded). For small tilts of the mirror, the beam is seen to 'pivot' about the back aperture of the microscope objective resulting in the displacement of the optical trap in the focal plane. Note that for both beams the degree of overfilling of the back aperture of the microscope objective is unchanged, a crucial requirement for movable traps.

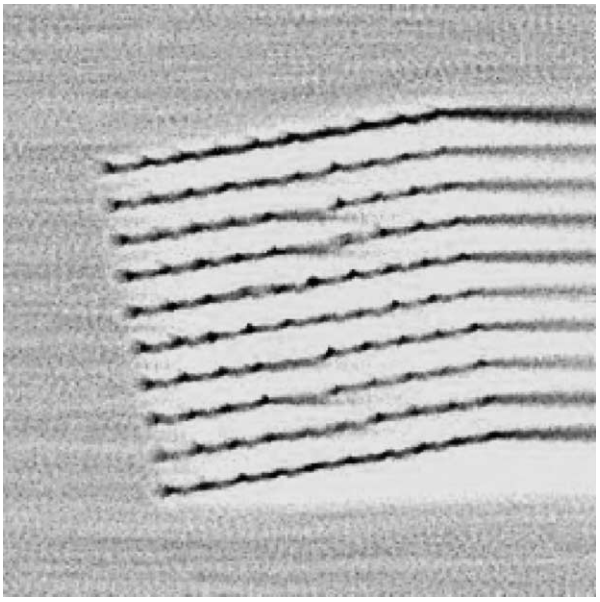

Figure 5 Data showing the superimposed paths of approximately 18 000 micron-sized particles flowing across a 10×10 grid of optical traps created by holographic optical tweezers. The particles are deflected laterally assuming a path dictated by the potential energy landscape and display kinetically locked-in states. This technique can be used to sort particles based on size, refractive index or charge. (Picture courtesy of D. Grier.)

be moved without having to move or recalibrate the photodiode detector. Using the quadrant photodiode method 2- and 3-dimensional position sensing is possible. A further improvement is found in schemes that use an additional laser dedicated to position sensing. The most sensitive method, however, for position sensing is interferometry. In this scheme, the trapping laser beam is split into two orthogonally polarized beams that are recombined after passing through the microscope objective and the sample. For a particle perfectly centered in the trap, the resulting combined beam has a circular polarization. In other cases, the bead displacement is sensitively reflected in the ellipticity of the polarization.

Applications

Colloids

Optical tweezers have been widely used to probe the interaction in colloids and other complex fluids. In fact, an optical tweezer apparatus was included in the instrumentation on the International Space Station for use with colloidal crystallization experiments in space. Various aspects of colloidal interactions have been studied using optical tweezers including mutual- and self-diffusion coefficients, the effects of hydrodynamic and electrostatic interactions, and depletion layer effects. More sophisticated scanning-line tweezing setups have been used to probe entropically driven self-assembly and interactions of colloids in polymer suspensions.

Blinking optical tweezers provide an elegant method for positioning colloidal particles in configurations of interest in a solution. When the tweezers are switched off the colloids respond to their environment, reacting to thermal forces and interacting either with other colloids or interfaces. The trajectories of the released colloids can be tracked and analyzed in 2D using digital video microscopy or 3D if combined with an evanescent illumination scheme. Switching on the tweezers again results in a return to the initial configuration, yielding a reproducible and tightly controlled experiment to examine colloidal behavior.

Biopolymers

The study of biopolymers has benefited from the development of optical tweezers. By chemically attaching a trappable latex microsphere to a biopolymer of interest, the molecule can be stretched, positioned, or moved. Measuring the response of the biopolymer to these external forces yields useful information such as elasticity, rigidity, and domain unfolding characteristics. This information obtained at a single molecule level has provided invaluable insight into the relationships between the structure and function of biopolymers. For example, in an early tweezing experiment, characterizing the intrinsic elasticity of λ-phage DNA, it was discovered that the double-stranded DNA undergoes a reversible structural transition when stretched at forces greater than 65 pN, extending to about 1.7 times its crystallographic contour length. These studies complement well-established structural techniques, such as X-ray crystallography and NMR, which provide information in a force-free environment. Furthermore, by anchoring one strand of DNA to a surface and pulling on the other strand, unzipping forces for DNA have been measured. Optical tweezers have also been combined with other mechanical tools, such as a micropipette, and used as sensitive tensiometers. Protein folding and unfolding experiments are generally harder, as their contour length is shorter than that of typical DNA fragments. Nevertheless, the folding and unfolding behavior of single giant muscle protein, titin has been probed by attaching a different latex bead to either end of the molecule. The first bead is held by a movable micropipette and the second bead is optically trapped. As the micropipette is moved, the position of the optically trapped bead provides information about the forces required to unfold the membrane domains of the protein.

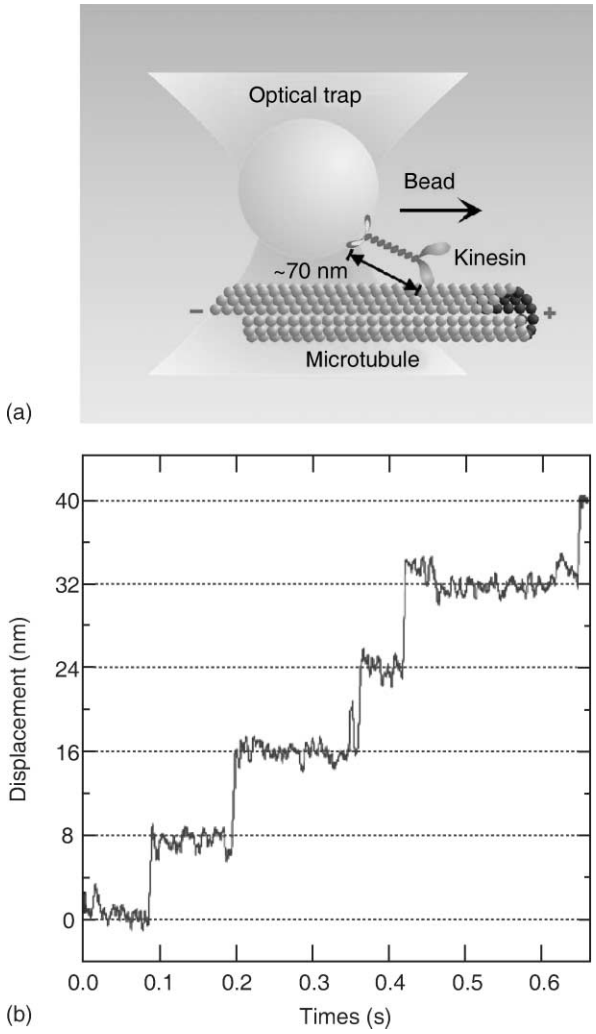

Figure 6 Observation of the stepping motion of the molecular motor kinesin. (a) A microsphere attached to a kinesin molecule is optically trapped; as the kinesin steps along a microtubule track which is immobilized onto a glass substrate, it pulls on the microsphere, whose motion is followed by an electronic feedback mechanism. (b) Motion of a single kinesin motor stepping against a 5 pN force. The data shows the discrete 8 nm steps of kinesin. (Figures courtesy of S. Block.)

Molecular Motors

Molecular motors (proteins that transduce chemical potential energy in to mechanical motion) have been the subject of intense attention since the early 1990s. Optical tweezers have played a crucial role in furthering the understanding of the mechanisms of molecular motors. The characteristics of molecular motor systems that have been studied with optical tweezers include speed, step-size, processivity, ATPs consumed per stroke, stall force, and static force. In fact, many of the advances in optical tweezers technology have been motivated by the study of molecular motors and have lead to spectacular results. An impressive example is the observance of the stepping motion of kinesin, as shown in Figure 6. Other experiments on molecular motors with optical tweezers have measured the stall force of motors as they move along their polymer track, or observed the transcription of DNA and RNA polymers, yielding interesting observations of the pauses during the transcription process.

Cells

The application of optical tweezers to cell biology was first demonstrated by Ashkin and co-workers in the late 1980s, by successfully trapping living objects: large viruses and bacteria. Since then, optical tweezers have been widely used to study various aspects of cellular biology. These include cell reproduction, growth, adhesion, mobility, and membrane elasticity. Additionally, the noninvasive nature of optical tweezers enables manipulations in the interior of an unopened object, allowing for the study of intracellular mechanisms by subcellular manipulations.

Optical tweezers have also been combined with various techniques to yield application-oriented tools for cell biologists. For instance, the combination of optical tweezers and state-of-the-art image recognition algorithms has been used to develop microfluidic cell sorters. In reproductive medicine, two of the major problems are penetration of the egg and sperm motility. A promising new solution combines laser zona drilling to pierce the egg envelope and optical tweezing to transport the sperm cells to the egg.

Phase Conjugation and Image Correction

E N Leith, University of Michigan, Ann Arbor, MI, USA

Introduction

Phase conjugation of a wave is a process that has long been recognized. However, the technique for producing high-quality phase conjugation is relatively new. Also, the principal use of phase conjugation, the correction of phase errors in waves that have propagated through phase-distorting media, is relatively new, having originated in holography in the 1960s. Today, phase conjugation is an important area of modern optics. This article describes the conjugation of a wavefield by the process of holography and the holographic phase conjugation method of removing phase distortions from a wavefield, thereby permitting high-quality images to be produced from phase-distorted waves.

The basic meaning of a conjugated wave is explained with the aid of Figure 1. Figure 1a shows a wavefield propagating to the right. For simplicity, we show only one wavefront, i.e., one contour of constant phase. It is understood that a wavefield consists of a sequence of such wavefronts, with each wavefront differing in phase by 2π from the adjacent one, and separated by the wavelength λ. Of the two points, A and B, on the wavefront, we say that the wavefront at A lags that at B, since when the wavefront crosses a plane normal to the direction of travel, point A of the wavefront crosses that plane behind point B. The wavefield produces, at the plane P, a field $ae^{i\phi}$, where a is the amplitude and ϕ is the phase of the wavefront at the plane P.

We place a phase conjugator in the path of the wave. The wave passes through the conjugator, emerging as a phase conjugated wave, in which the point B, which formerly led point A in phase, now lags behind it by a corresponding amount. This illustrates the basic meaning of the term 'phase conjugation'. This device could be considered as a forward phase conjugator, since the phase conjugated wave travels in the same direction as the original wave.

Next (Figure 1b) we describe a backward phase conjugator. The conjugate wave travels in a direction opposite to that of the incident wave. The conjugate wave emitted by the phase conjugator seems to be

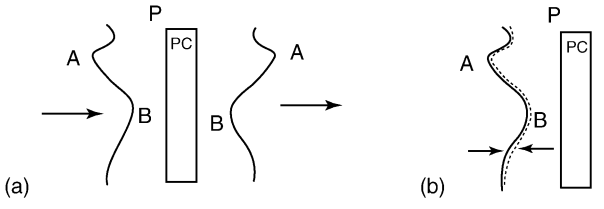

Figure 1 A phase conjugator. (a) shows a forward phase conjugator; (b) shows a backward phase conjugator. For clarity, in (b) the conjugated wave is shown with dotted lines. PC is phase conjugator, and P is the entrance plane of the conjugator.

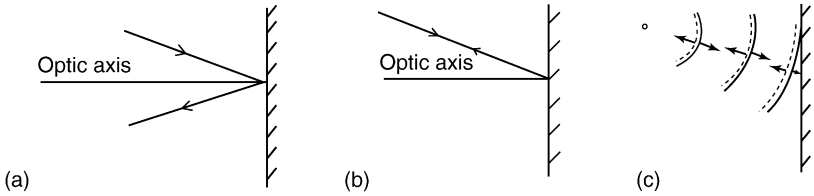

Figure 2 Light reflected from mirrors. (a) Light falling on a conventional mirror and being reflected; (b) light reflected from a conjugating mirror; (c) as in (b), except that illustration is with wavefronts instead of rays.

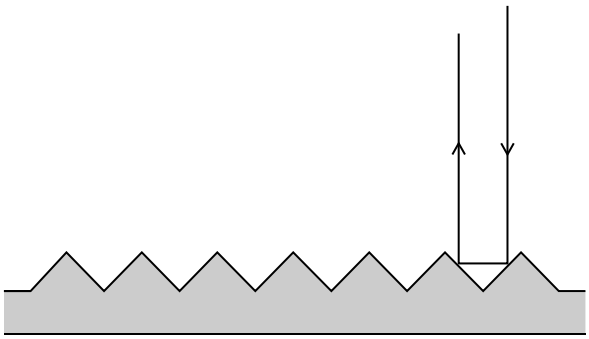

Figure 3 A ray of light reflected from a retroreflector (or corner cube).

identical to the incident wave; we show the two waves to be in coincidence, or more precisely, for purposes of clarity, almost in coincidence. The points A on the two wavefronts coincide, as do the points B. As before, on the incident wave, point A lags behind point B. On the exiting wave, since the wave is traveling in the opposite direction, point B is now lagging point A, i.e., is lagging in phase. In either case, forward or backward conjugation, the wave emerging from the conjugator has the complex amplitude $a(x, y)e^{-i\phi(x,y)}$.

A phase conjugator (backward variety) is like a mirror, in that it obeys the basic mirror law, that the angle of reflection equals the angle of incidence, but in a rather different way, as Figure 2 shows. In fact, the reflected ray travels back on itself. A simple way to generate a conjugate wave, and one that has been known for a very long time, is with the use of an array of retroreflectors, or corner cubes. As shown in Figure 3, each ray undergoes two reflections and emerges traveling in exactly the opposite direction, although with some displacement. If we considered the third dimension, there could be three reflections. The amount of displacement depends on where the ray strikes; if it strikes near the apex of the corner cube, the ray displacement will be slight; if at the edge, the displacement is greatest. Thus, the image formed in reflection is degraded. This geometrical degradation is greater for larger corner cubes. Thus, why not make the cubes very small? Then, however, the image is degraded by diffraction effects, since each corner cube constitutes a small aperture. Thus, there is an optimum size for the cubes; if too large, geometrical factors degrade the image; if too small, diffraction effects degrade the image.

Phase Conjugation by Holography

With holography, however, came a method of conjugating a wavefront that yields high-resolution imagery. The holographic process inherently produces a phase conjugate image, as was noted by Gabor in his early papers on holography. The holographic process is illustrated in Figure 4. For simplicity, we assume the object to be a planar transparency $s(x, y)$. A coherent light wave, generally a plane or spherical wave, passes through the transparency and a diffracted field u is produced at the recording plane P, as in Figure 4a. The field u is typically the Fresnel diffraction pattern of the object s, but if the propagation distance is sufficiently great, u could be the Fraunhofer pattern of s. Of course, lenses can be placed between the object and recording planes, thus modifying the diffraction pattern.

The field u is combined with a reference wave u_o, which is generally an off-axis planar or spherical wave. The two beams produce an interference pattern with intensity

$$I = |u_o + u|^2 = |u_o|^2 + |u|^2 + 2Re\, u_o^* u \qquad [1]$$

where the final term can be written as $u_o^* u + u_o u^*$; the * denotes complex conjugate. The process of forming the interference of the two beams, i.e., forming the intensity of their sum, has generated the conjugate term u^*. When the intensity is recorded, as on photographic film, for example, both terms are stored on the film. Suppose for simplicity that u_o is a plane wave $a_o e^{i2\pi f_o x}$, where a_o is a constant, and $f_o = (\sin\theta)/\lambda$, where θ is the angle that the reference wave makes with the optic axis and λ is the wavelength of the light. Also, u can be

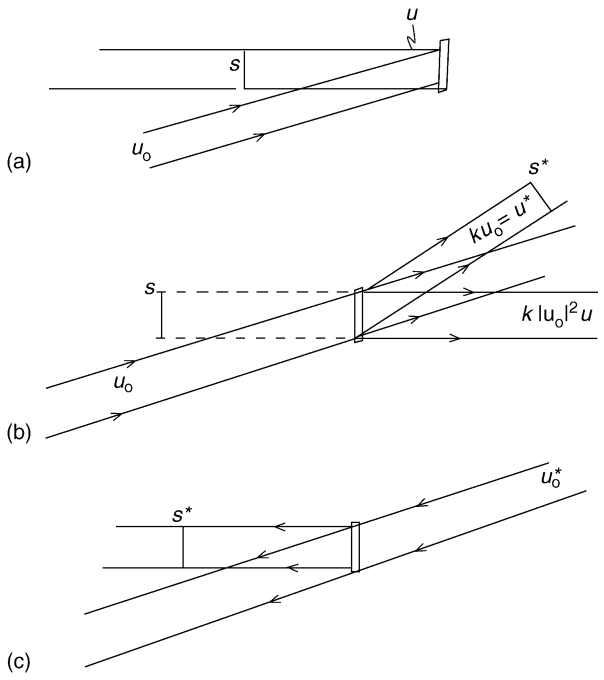

Figure 4 The holographic process. (a) Making the hologram; (b) reading out the hologram, using a readout beam that duplicates reference beam; (c) reading out with reversal of reference beam.

written as a product of an amplitude term a and a phase term $e^{i\phi}$, or $u = ae^{i\phi}$. Let the photographic plate, after exposure and development, have a transmittance t proportional to the intensity I, or $t = kI$, with k a constant; this is an oversimplification of the recording process, but preserves the essence of the holographic process. Now let the photographic plate, which after development becomes a hologram, be illuminated with a readout wave that, for simplicity, we let be u_o, a duplicate of the reference wave. Then, the field emerging from the hologram is

$$u_e = u_o k\left[|u_o|^2 + |u|^2 + u_o^* u + u_o u^*\right] \qquad [2]$$

Only the last two terms are of interest. These can be written as $k|u_o|^2 u$ and $ku_o^2 u^*$, respectively, or alternatively, as $ka_o^2 a e^{i\phi}$ and $ka_o^2 a e^{i(4\pi f_o x - \phi)}$. The term $k|u_o|^2 u$ represents a wave that is, to within a constant, identical to the object wave u; the other term represents a wave that is, to within a constant and a linear phase term, a conjugate of the original wave. The factor $e^{i4\pi f_o x}$ has the physical meaning that the wave is propagating in a direction 2θ given by $\sin 2\theta/\lambda = 2f_o$. The readout waves are shown in Figure 4b.

The so-called true wave u and the conjugate wave u^* thus propagate angularly away from each other and from the direct transmitted beam, which carries the uninteresting components $|u_o|^2$ and $|u|^2$.

However, a more suitable way to form the conjugate wave is to illuminate the hologram with a readout wave that is, again, a duplicate of the original reference wave, but propagating in the opposite direction, as in Figure 4c. The conjugate wave is now propagating along the z axis, along the path of the original object wave. It is readily shown that this counterpropagating wave is identical in shape to the original object wave recorded by the hologram, except that it travels in the opposite direction, exactly the situation portrayed in Figure 2. This wave propagates so as to form an image that is, to within a constant, identical to the original object, except for the counterpropagation, which produces a conjugate image $s^*(x, y)$. The image intensity, however, is $|s|^2$, which is identical to the original image intensity.

This conjugate wave was, in the early days of holography, a detriment, since without the use of the off-axis method (reference wave introduced at an angle to the object wave) the two images were inseparable, and the true image could be observed only against the background of the defocused conjugate image. Thus, an out-of-focus image overlaid the true image, making it noisy.

In 1962, the same year that the off-axis reference wave for separating the two images was introduced, a possible use for the conjugate image was suggested. If the original propagation path of the object wave were aberrated, as would occur if the wave propagated through an irregular medium, then the conjugate wave propagating through the medium would undergo a correction and would arrive at the original object position perfectly corrected, resulting in a sharp image, a process sometimes called wavefront healing. The idea lay dormant for 3 years, until in 1965, experimental demonstration of this idea was reported. In one case, the object was a transparency containing opaque lettering against a transparent background and the inhomogeneity was a piece of frosted glass, which resulted in extremely severe aberrations, so that the object wave, having traversed the diffuser, was no longer capable of forming an image. However, when the distorted wave was recorded holographically, conjugated, and sent back through the same diffuser, the result was a highly legible image.

The principle of wavefront healing is illustrated in Figure 5, when the inhomogeneity is an extended, or three-dimensional, structure. A point object O sends a spherical wave into the inhomogeneity. As the wavefront propagates, it becomes distorted, and loses its sphericity. When it emerges from the inhomogeneity, the wavefront is highly distorted.

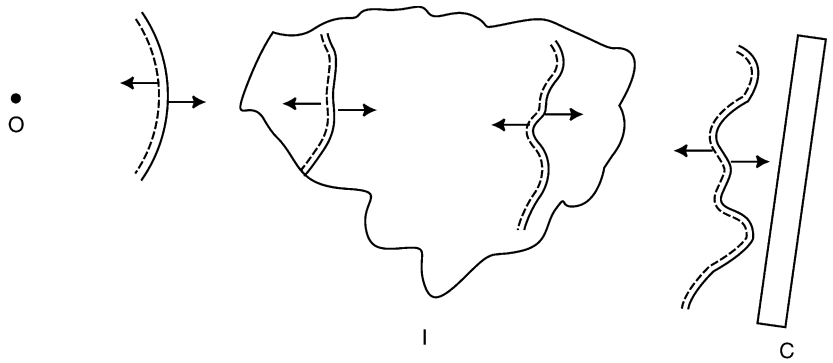

Figure 5 The wavefront healing process. C is the conjugator, I is the inhomogeneity, and O is a point object.

The wave is conjugated at the conjugator C and emerges as a back-propagating wave that retraces the original wave path through the inhomogeneity, gradually losing its aberrations and looking more like a spherical wave. When it emerges from the inhomogeneity, it is a perfect spherical wave that converges to a point image that coincides with the original object. At each plane throughout the inhomogeneity, the back-propagating conjugate wave (dashed lines) has the same shape as did the original wave when it crossed that plane (solid line).

This interesting wavefront healing property of holographic phase conjugation was the beginning of a new branch of optics, called phase conjugation, giving rise to a number of applications. However, the holographic method had the problem that it did not occur instantaneously, but had to await the processing of the photographic film on which the hologram was recorded. This delay limited the range of potential applications. Later, in the 1970s, nonlinear crystals became available that did the equivalent of holography, but in real time, or near real time – a process known as four wave mixing. There are yet other types of real-time phase conjugators with nonlinear devices.

Pseudoscopic Image

As long as the object is only two-dimensional, a function of x and y only, with no extent along the axial dimension, z, the intensity distribution of the true and conjugate images is identical. The conjugateness, being a pure phase phenomenon, disappears when the observable is the image intensity $|s|^2$, and not the complex amplitude s. Since the intensity is always the observable, whether the image is viewed by eye, or with a camera, the conjugateness generally is of no significance.

However, when the object for holography is three-dimensional, the situation is different, and the conjugate image exhibits some strange properties. These arise from conflicting cues pertaining to the three-dimensionality of the image. To explain, we review some basics about how a three-dimensional world is perceived by a viewer. First, there is the stereo effect, resulting from the viewer having two eyes, with each eye seeing an object from slightly different positions, a phenomenon called binocular disparity. The mind uses this stereo effect to perceive three-dimensionality. But there are other cues that also contribute to perception of three-dimensionality. Another is parallax; as the viewer moves his head, objects farther from the observer change their angular position more slowly than objects close by. The observer can sense the three-dimensionality of an object, even with only one eye, by moving the head, thereby inducing parallax. Also, there is interposition, whereby near object portions block the viewing of object portions lying behind them, again giving a sense of depth. There are still other cues, more subjective, such as perspective, parallel lines converging toward infinity, shadowing, etc. With these observations in mind, we consider the hologram under illumination and the two images that it forms (Figure 6). As depicted in Figure 6, these two images lie in mirror symmetrical positions relative to the hologram. Both images have the same side facing the hologram. It must be this way, because when the hologram was recorded, it was side **a** that faced the recording plane. And both images must therefore have side **a** closer to the hologram.

When a viewer observes the true image (a virtual image), he views it looking through the hologram, and he sees the image at the position where the original object was when the hologram was recorded, and it is, in its visual properties, indistinguishable from the actual object; it has all of the three-dimensional and the parallax properties that the original object would exhibit. However, when the viewer observes the conjugate image, he must view it

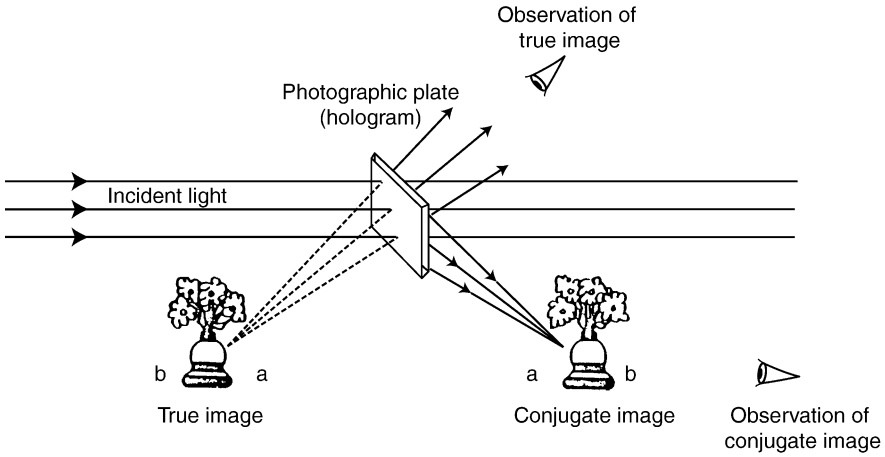

Figure 6 Formation of the true and conjugate images from a hologram.

from the side of the image opposite from the hologram, i.e., he views the image from the back side. When a viewer observes the conjugate image, he sees it from the back side (side **b**). All of the above cited cues are in agreement about the orientation of the image, viz., that side **b** is closer to the observer than is side **a**. That is, all cues but one. The conjugate image is formed as the hologram recording plate saw it, with side **a** being closer. Thus, all interpositions are formed with the same relation that the object had with respect to the recording plate. The side **a** is the part of the object that was closer to the hologram, so that when interpositions occur, side **a** blocks side **b**. Since the observer thus sees side **a** partially obscuring side **b**, he must conclude that side **a** is closer than is side **b**. However, this observation is in direct conflict with the other cues, especially the stereo and the parallax cues, which are themselves strong cues, as is the interposition cue. The conflict of these cues, with two of them interpreting the image as being formed with one depth orientation, the other with the opposite, gives a number of strange effects. For example, as the viewer moves his head so as to induce parallax, the object appears to rotate. If the image is that of a human head, for example, the observed effect is that as the viewer changes his position, the head appears to rotate in synchronism with the observer, as if the image had its gaze fixed on the viewer, an effect that is often perceived as being eerie.

Similarly, if the object were two flat plates, (Figure 7) in the situation depicted, the planes have no overlap, i.e., no interposition, as seen by the observer. And the observer unequivocally perceives plate A as being closer than plate B. However, if the viewer moves his head to a position where

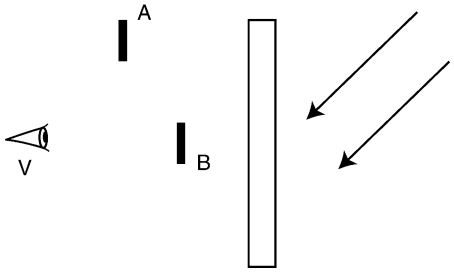

Figure 7 Pseudoscopic conjugate image formed from an object consisting of two plates. The viewer V perceives plate A as being closer than B and there are no conflicting cues, since there is no interposition. However, if the observer moves his head upward, there is partial interposition, thus conflicting cues, and the sense of three-dimensionality is lost.

interposition occurs, the conflict of cues arises, A becomes partially blocked by B, which is quite correct as observed at the position of the hologram, but is quite incorrect from the viewer's vantage point. The result of this conflict is that the viewer, who previously perceived the three-dimensionality, now sees the three-dimensionality perception suddenly collapse, and the sense of three-dimensionality is lost. Other strange perception anomalies can also be produced. Such images, with conflicting depth cues, are called pseudoscopic, as opposed to orthoscopic images, where the cues do not conflict.

One Way Phase Conjugation

A significant limitation of phase conjugation aberration correction is that the image and object are on the same side of the inhomogeneity. One would usually want them to be on opposite sides. In a modified form

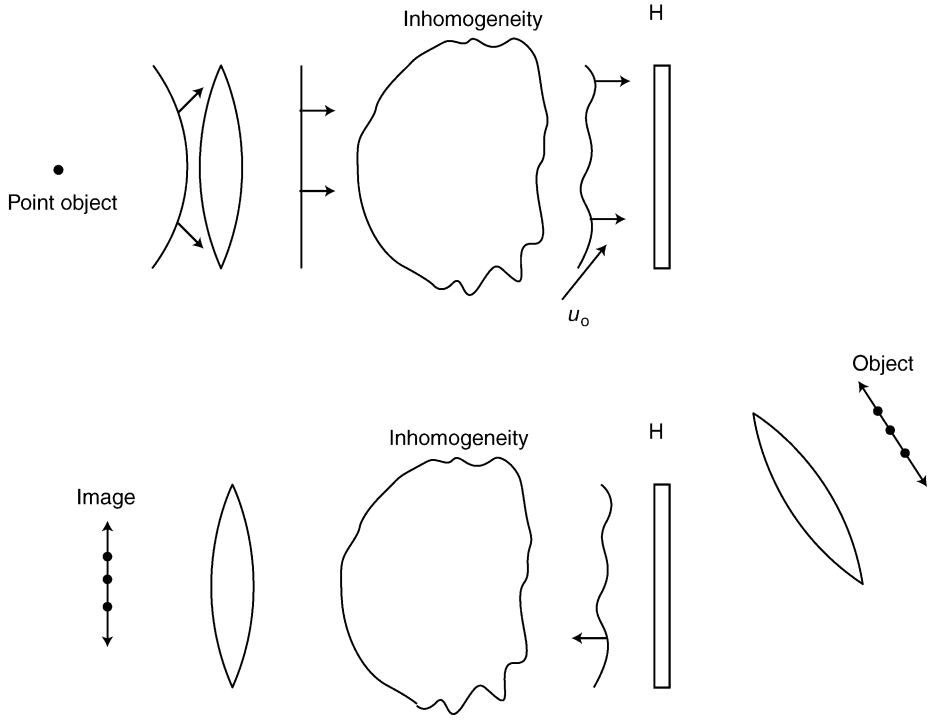

Figure 8 One-way phase conjugation. Top: Making the hologram. Bottom: The viewing process. We show three points on the object. The center point forms a well-corrected image, but the other two points produce imperfectly corrected images.

of the phase conjugation process, shown in Figure 8, this result is achieved. The first step of the process is carried out by passing a plane wave, instead of the object wave, through the inhomogeneity. This plane wave originates from a point source located at the focal plane of a collimating lens. The plane wave thus carries information about the inhomogeneity to the recording plate, where it is combined with a reference wave and a hologram of the distorted plane wave is recorded. Thus, information about the phase defect is stored on the hologram.

Next, the hologram is read out, not with a counterpropagating replica of the reference wave as before, but instead with an object-bearing wave that passes through the hologram. This wave emerges from the hologram and now has on it the recorded aberration information. As it counterpropagates along the path of the original object wave, it passes through the inhomogeneity, whereupon the aberration is cancelled and a corrected image forms at the focal plane of the collimating lens, where previously the point source had originated. The goal is achieved; the object and the corrected image are now on opposite sides of the inhomogeneity.

This correction is only approximate. To explain, we think of the object as being a collection of many points. The radiation from each point is converted into a plane wave by the lens, with different object points producing plane waves propagating at different angles. These plane waves then impinge on the hologram and emerge with each one bearing the aberration stored on the hologram. They continue on their paths and enter the inhomogeneity. The plane wave component, whose path direction matches that of the reference wave used in recording the hologram, will emerge from the inhomogeneity as a perfectly corrected wave, thus forming a well-corrected point image at the position of the original point radiator. However, another plane wave component, traveling in an incorrect direction, will be laterally displaced from the proper position for entering the inhomogeneity, and the aberration correction will be imperfect, the degree of imperfection being in direct relation to this displacement error. The displacement error is the product of the angular error and the propagation distance between hologram and inhomogeneity. If the inhomogeneity is slowly varying as a function of x and y, and if the object does not have a large extent, so that the range of angles is small, the image degradation will be small.

If the last two conditions do not apply, two options are available. First, the distance between inhomogeneity and hologram can be reduced, either

by bringing the hologram closer to the inhomogeneity, or by imaging the hologram onto the inhomogeneity. The correction is now valid over a wider extent of the image, especially if the inhomogeneity can be treated as planar rather than extending over a volume. Alternatively, a scanning process can be carried out on the object beam falling on the hologram, so that in sequence, each plane wave component assumes the proper angle to counterpropagate along the path for perfect correction, and will form a well-corrected image point. This output spot then falls on a pinhole positioned to separate it from other, imperfectly corrected points. Then, over time, all points of the object will form well-corrected image points, and the entire object will thus be well-imaged. The one way phase conjugation method was first used to correct the spherical aberration of a lens, and the result was quite successful.

Phase conjugation has become an important branch of modern optics. The process is often carried out using photographic materials. More often nowadays, it is carried out using nonlinear crystals. Some of the crystal methods are essentially holography in real time, but others, such as phase conjugation by Brillouin scattering, go beyond holography.

Introduction

We describe a new paradigm for designing imaging systems that have performance that is otherwise unobtainable. These are hybrid systems that use the optics of the system to acquire an 'intermediate' image, which is processed to produce the final image. The optical components of the system are designed jointly with signal processing to optimize overall performance. It is possible to extend the depth of field of an imaging system, for example, by a factor of eight to ten. On the other hand, by concentrating on the increase of the depth of focus in the detector plane, it is possible to use that increase in the depth of focus to make the system invariant to focus-related aberrations. By doing this, it becomes possible to design a single-lens imaging system with small f-number and large field of view. Another example of the sort of new imaging system that can be designed is a two-lens zoom lens that images with a large field and a very short overall length.

First, the term 'Wavefront Coding' is defined as employed with imaging systems, and a description is given of how such coding is achieved. Examples of means of applying Wavefront Coding are given along with the analysis and design tools that are useful in designing hybrid optical/digital imaging systems. Finally, some potential future applications of Wavefront Coding in imaging systems are suggested.

Background and Basic Concepts

Some early suggested modifications to imaging systems can be viewed as wavefront modification, even though they were not described in that manner at the time. These include the work of Ojeda-Castañeda that described masks to block portions of the lens to extend the depth of field. In addition, it has long been known that the depth of field is slightly greater in lenses that have spherical aberration. In both of these cases, the wavefront is modified, in one case by changing the wave amplitude, and in the other by a deviation from the traditional ideal phase front. However, in both cases, the increase in the depth of

field was only a few percent. Häusler extended the depth of field by requiring that the focus be continuously changed during the exposure time of the camera. This resulted in a modulation transfer function (MTF) for the imaging system that was the incoherent superposition of a spread of MTFs for the different foci during the exposure. To form an acceptable image, signal processing was used.

The use of Wavefront Coding here refers to new optical systems arrived at by designing the modulation of the wave and signal processing to achieve previously unobtainable imaging modalities. These new imaging systems can have more than an order of magnitude increase in depth of field, for example. The coding of signals so that particular information is optimally conveyed is not new. For example, in radar, coding of the pulses is done to optimally provide information concerning a target's range. At the radar receiver, signal processing is required to extract the range information. In a similar manner, an imaging system can have a coded wavefront in order to provide range or misfocus information in a manner such that signal processing can easily extract the desired information in the scene. Alternatively, the wavefront can be modified so that the imaging system is invariant to object depth or to misfocus of the system, so that, after processing, good resolution can be obtained over a large image depth.

A primary feature of Wavefront Coding in imaging is that the optical image-gathering portion of the system can be designed in combination with the design of the signal processing. This is normally not done in the design of imaging systems. It is done, however, in tomography, coded aperture imaging, and sometimes, interferometric imaging. In 1984, a group pointed out the potential of increasing the performance of imaging systems by jointly designing the optics and the signal processing. Since that time, major advances have been made in doing this. Now, several analysis and design tools are available, and are described in the following section.

Theory and Applications of Wavefront Coding

Wavefront Coding refers to a modification of the imaging system by placing specialized phase plates (or phase and amplitude masks) in the aperture stop, or in an image of the aperture stop, of the imaging system. This could be a phase plate as a separate optical element, or, if a surface of a lens is close to the aperture stop, the Wavefront Coding surface can be superimposed onto the normal lens surface. Processing to decode the image that is formed by the detector array (the intermediate image) is related to the coding that is impressed on the wavefront. The term 'signal processing' also includes the spatial integration provided by the width and height of the pixels. The final image is hence a function of the optics that form the intermediate image and the signal processing that produces the final image.

In the following section, we discuss the Woodward function as used in analysis and design of hybrid imaging systems, and show visualizations of the effect of Wavefront Coding on the image performance of two dramatically different types of systems. Then, other design techniques are discussed for imaging systems using Wavefront Coding and several examples of systems are given where the depth of field of imaging systems is extended by at least an order of magnitude. By concentrating on the increase in the depth of focus, rather than the depth of field, very simple imaging systems can be designed where Wavefront Coding makes the imaging system invariant to focus-related aberrations, and the shape of the lens is used to minimize the other aberrations.

Wavefront Coding Theory

The Woodward function

P. M. Woodward showed that the capability of a radar system to estimate both the range and the velocity of a target can be described by a mathematical function that became known as the Ambiguity Function. The Ambiguity Function shows how well systems that use different types of radar pulses can measure the transit time of the pulse (hence the range to the target) and the Doppler shift in the frequency of the returned pulse (hence the velocity of the target). Because the parameters, range, and Doppler, are measured with different accuracy, there is ambiguity in the measurement, and the Ambiguity Function is a display of the tradeoffs that are possible, Brenner, Lohmann, and Ojeda-Castañeda showed that the same mathematical function, with differently defined variables, can represent the Optical Transfer Function (OTF) of a one-dimensional imaging system.

The Ambiguity Function for a radar system is given by

$$A(u,v) = \int P(x+u/2)P^{*}(x-u/2)\exp(\mathrm{i}2\pi vx)\mathrm{d}x \quad [1]$$

where $\mathrm{i} = \mathrm{sqrt}(-1)$, * denotes complex conjugate, u is time, v is frequency, x is a dummy variable, and $P(x)$ is a complex function representing the transmitted waveform of the radar system. The OTF of a one-dimensional imaging system for different values of

misfocus can be written as

$$H(u,\psi) = \int \left\{P(x+u/2)\exp(j(x+u/2)^2\psi)\right\} \times \left\{P^*(x-u/2)\exp(-j(x-u/2)^2\psi)\right\}\mathrm{d}x \quad [2]$$

where $P(x)$ represents the complex pupil function of the imaging system. The misfocus parameter ψ can be shown to be equal to the physical parameters:

$$\psi = (\pi L^2/(4\lambda))(1/f - 1/d_o - 1/d_i) = 2\pi W_{20}/\lambda = kW_{20} \quad [3]$$

where L is the one-dimensional length of the aperture, and λ is the center wavelength of the narrowband illumination. The distance d_o is measured between the object and the first principal plane of the lens, and d_i is the distance between the second principal plane of the lens and the image plane. The focal length of the lens is given by f. The wavenumber is given by k and the traditional misfocus aberration constant is given by W_{20}. A comparison of the form of the ambiguity function and the OTF shows that:

$$H(u,\psi) = A(u, u\psi/\pi) \quad [4]$$

The mathematics of the Woodward function as used for the Ambiguity Function has been studied extensively. Hence one can apply the theory that was worked out for the Ambiguity Function to the study of imaging systems. This gives a tool that is, in many ways, more powerful than other forms of three-dimensional optical transfer functions. For example, it can be shown that the squared volume under the Woodward function is a constant. This means that whatever one does to modify the Woodward function, there is a constraint on what can be done. Another constant is the power under a vertical cut of the Woodward function at a particular value of spatial frequency. This means that there is constant power for all misfocus values at any given spatial frequency. It can be bunched up about the normal in-focus position, or it can be spread out as shown below, but the squared area does not change.

Examples of the Woodward function for different imaging systems

A display of the Woodward function for a high-quality, one-dimensional lens is shown in Figure 1a. The horizontal line and the slanted line represent in-focus and out-of-focus slices through the Woodward function. A projection onto the horizontal axis gives

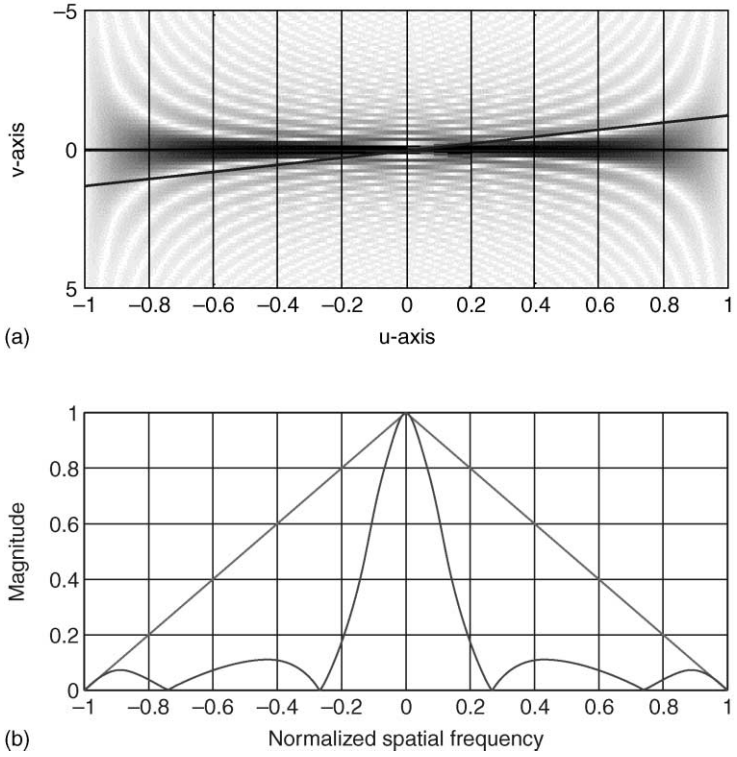

Figure 1 (a) The Woodward function for a high-quality one-dimensional lens with slices that represent in-focus and out-of-focus imaging. (b) The corresponding values of the modulation transfer function for those two cases.

the OTFs for those two focal conditions. The magnitudes of those two OTFs, the MTF, is shown in Figure 1b. Note that the out-of-focus MTF goes through a zero, where there is a phase shift, which gives a contrast reversal in the image.

Extended depth of field. Figure 2a shows the corresponding display of the Woodward function for a one-dimensional lens with a cubic phase function, $\phi = \alpha x^3$ added in the aperture stop. The appearance of the Woodward function immediately shows that this imaging system will have an increased depth of field, because the Woodward function shows that the energy is spread over a larger misfocus region. The slices in the Woodward function are taken for the same misfocus values as were used for the images in Figure 1. Notice that the MTFs of Figure 2b are very similar, and that the MTF for the misfocused case does not go through a zero. This implies that the imaging system will have an extended depth of focus.

The analogy to the Ambiguity Function of radar was key in selection of the cubic function for early demonstrations of extending the depth of field of an imaging system. Work in the radar field had shown that a radar pulse, where the carrier frequency increases quadratically with time, has an Ambiguity Function that is identical to the distribution in Figure 2a. Because a quadratic in time is a cubic in phase, the cubic phase function:

$$\phi = \alpha x^3 \qquad [5]$$

was selected as one that will provide the same Woodward function, and hence an increase in the depth of field. Many families of phase distributions have now been found that extend the depth of focus of an imaging system.

Antialiasing. When the resolution of the optics of an imaging system exceeds the resolution of the image detector array, the high spatial frequencies cannot be detected. They are not lost, however. When a spatial frequency is sampled below the Nyquist sampling rate, the high spatial frequency shows up, or aliases, as a lower spatial frequency. This aliased frequency is equal to the sampling frequency (determined by the pixel spacing) less the difference between the high frequency that has been undersampled and the sampling frequency. This results in an image with broad bands (low spatial frequencies) across the image as is often seen in television images of patterns with high spatial frequency content, such as striped shirts. Because the signal power at a given spatial

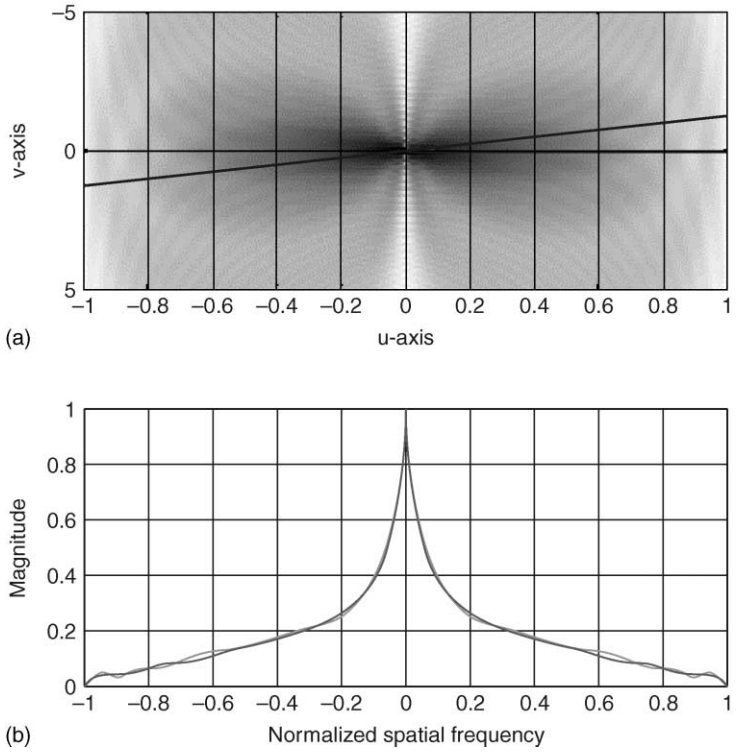

Figure 2 The Woodward function and the modulation transfer functions for a high-quality one-dimensional lens that has a phase plate with a cubic profile in the aperture stop. (a) The Woodward function showing a broadened pattern that is indicative of an increased depth of field. (b) The MTFs that are associated with the slices that represent in focus and out of focus.

frequency over all misfocus (the squared area under a vertical slice of the Woodward function at that spatial frequency) is constant, these frequency components cannot be removed. They can, however, be reduced at a given focus value by spreading the Woodward function vertically. Figure 3 shows a Woodward function that would be ideal. Below the cutoff spatial frequency, all of the signal power is in the focal plane, and beyond the cutoff frequency, the power is spread as much as possible over a large misfocus region. There is no assurance that a phase distribution can be found to give a desired Woodward function, however. Figure 4 shows the effect of one phase function, given by

$$S(r, \theta) = r^3 \cos(3\theta) \qquad [6]$$

upon the MTF of the imaging system. The dashed vertical line shows the cutoff spatial frequency that is due to the sampling rate of the pixels. Note that in Figure 4, the magnitude of the Wavefront Coded spatial frequencies that are aliased have lower values than do those that are passed by a traditional full aperture F/2.5 system. Stopping the traditional system down to F/25 reduces the aliased MTF to an amount close to that obtained with the wide aperture and Wavefront Coding, but it also reduces the amount of light by a factor of 100.

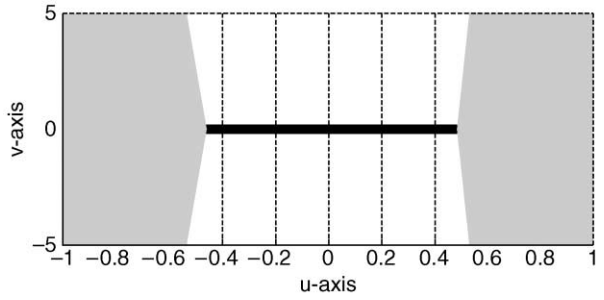

Figure 3 The Woodward function for an ideal antialiasing filter.

Wavefront Coding in Imaging Systems with Extended Depth of Field or Focus

Figure 2 shows the Woodward function for one phase distribution (cubic in x and y for a two-dimensional imaging system) that increases the depth of field of an imaging system. The cubic function was selected by using analogies to the Ambiguity Function of radar. Even though it is doubtful that this phase distribution could have been found by using conventional lens design techniques, it is instructive to show the ray traces and point spread functions that are obtained when this phase distribution is used in the aperture stop.

Ray trace analysis

Figure 5 shows the ray trace from a point object through a conventional (one-dimensional) lens and through a lens that has been modified with the cubic profile of eqn [5]. Figure 5a shows the rays through a conventional lens coming to a focus, and Figure 5b shows the corresponding rays as they go through a lens with a cubic profile added. In the latter case, the

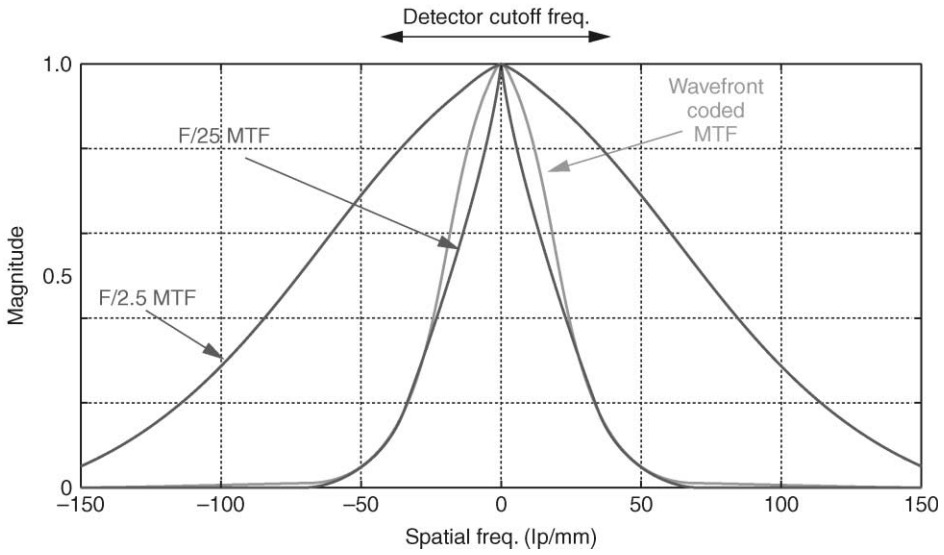

Figure 4 Normalized MTFs for traditional optics and Wavefront Coding. The full aperture F/2.5 system has a large amount of optical power beyond the detector cutoff frequency of 50 lp/mm. With Wavefront Coding the aliased optical power can be greatly reduced. The traditional system aperture needs to be reduced to F/25 to compare to the antialiasing performance of the Wavefront Coded system. This reduction reduces the light level by a factor of 100 in comparison with the F/2.5 system.

rays cross, but have a relatively constant ray density in the region of what was the focal region. Figure 6 shows experimentally acquired point spread functions (PSF) for both cases. Note that the PSF changes very little over the region of misfocus. After signal processing, the PSF can be brought back to that of the conventional imaging system when in focus. Figure 7 illustrates the effect of the signal processing upon the intermediate image that is acquired by the optics. The object is a tilted bar pattern, so that a portion is in focus, and the remainder of the bar pattern is so far out of focus that there is a contrast reversal in the image. With the system that has a coded wavefront to give an extended depth of field, the entire image appears to have the same blur, no matter which part of the tilted bar pattern is observed. This is because the same PSF is convolved with the object distribution for all regions of misfocus. Signal processing removes the effect of the modified PSF, resulting in the image of Figure 7b. Figure 7c shows a trace through the image of Figure 7b. The amount of the misfocus that can be tolerated is a design parameter, and is discussed in the next section.

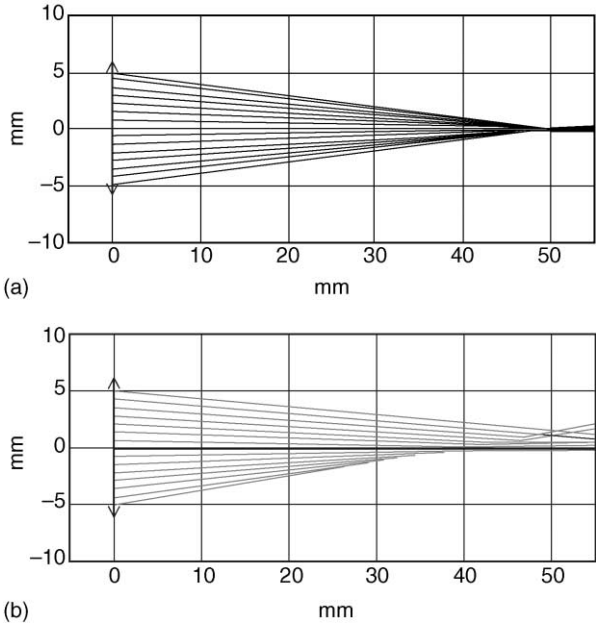

Figure 5 Ray traces from a point object through (a) a conventional one-dimensional lens, and (b) a lens that has been modified to have a cubic profile on the surface.

Signal processing requirements

It is necessary to do signal processing when using an imaging system that employs Wavefront Coding; the signal processing is needed to 'decode' the image that is formed by the detector array. This intermediate image is not a clear image. To obtain an intermediate image, the object distribution is convolved with a PSF, or impulse response, that has a shape similar to that

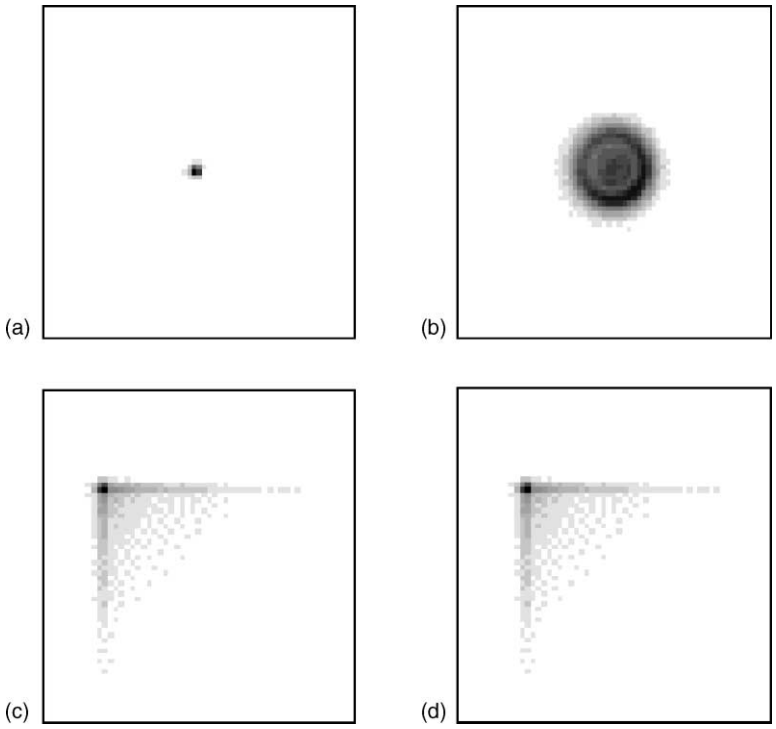

Figure 6 Point spread functions for a conventional lens in focus (a) and with large misfocus (b), and a lens that has been modified to have a cubic profile on the surface when in focus (c) and with a large misfocus (d).

of Figure 6c and d. To obtain the final image, the intermediate image must go through a deconvolution with the PSF. Because of the square law detection that occurs in the detector array, this deconvolution does not simply undo the effects of the convolution with the PSF that describes image formation. A straightforward digital convolution is required in most cases, and has been shown to run at video frame rates in software.

Parameter trade offs in imaging systems with extended depth of field

Depth of field and signal-to-noise ratio. The greater the phase modulation by the phase plate (with a cubic profile in this example), the greater the extension of the depth of field. The greater the phase modulation for extending the depth of field, the larger the PSF, and the greater the drop in the MTF, as seen in Figure 2b, which show the MTF of the imaging system. The use of the phase function to extend the depth of field causes portions of the MTF to sag as compared with the MTF of the in-focus conventional system. This reduces the signal-to-noise ratio. If there is a greater phase alteration, the MTF sags more.

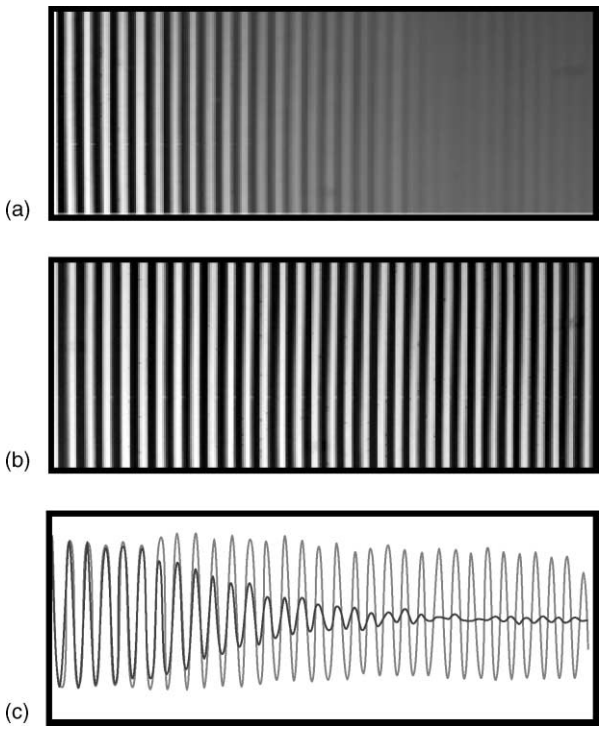

Figure 7 Image of a tilted bar pattern with an extended depth of field imaging system. (a) Image with a conventional imaging system. (b) Final image from the imaging system with Wavefront Coding. (c) Traces through the images to give quantitative comparisons of the image quality.

Focus budget and focus-related aberrations. Another set of trade offs can be seen by considering the imaging systems from the detector plane. Here, we see an increase in the depth of focus of the system. All of this increase in the focal depth can be used to increase the depth of field if the optics of the system are of high quality. Otherwise, the increase in the depth of focus can be used to compensate for focus-related aberrations. For example, chromatic aberration occurs when different colors focus to different planes. Figure 8 shows that if the depth of focus is extended, then there is a region where red, blue, and green, for example, are in focus. Figure 9 shows the red, blue, and green images of a US Air Force test pattern, as formed with a two-element imaging system with severe chromatic aberration, and with the same system when a Wavefront Coding element is used to extend the depth of focus.

Compensation can also be seen for the case of curvature of field, where the image of a plane object falls onto a curved surface. If an extension of the depth of focus causes the focal region to resemble a curved bar instead of a curved line, then it is possible to place a flat detector array in the curved region, and therefore obtain a good image after signal processing. Similar arguments can be made for other focus-related aberrations. This leads to the concept of a focus budget, where a portion of the increased depth of focus can be allocated to extend the depth of field by some amount, and other portions of the depth of focus allocated to provide invariance to focus-related aberrations.

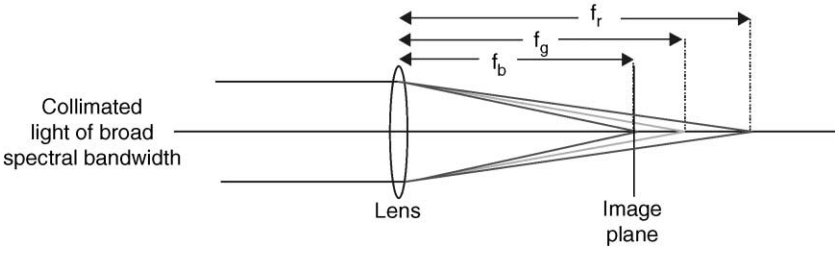

Figure 8 Ray traces showing different focal planes for red, blue, and green, and the effect of extending the depth of focus for each color.

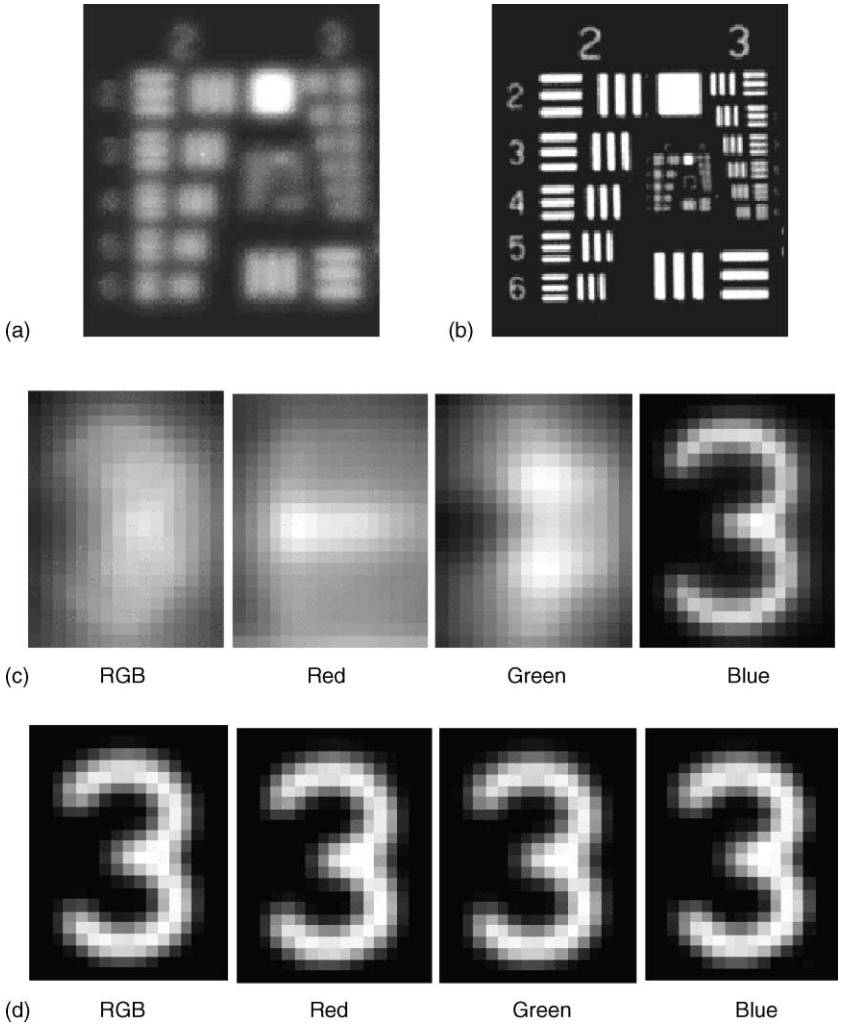

Figure 9 Color images of a US Air Force test pattern. (a) Images from a two-element lens of the center portion of the test pattern. (b) Images from an extended-depth-of-focus imaging system of the center portion of the test pattern. (c) Images from a two-element lens of a small number 'three' on the test pattern. (d) Images from an extended-depth-of-focus imaging system of a small number 'three' on the test pattern. Some residual effects remain due to different magnifications at different wavelengths.

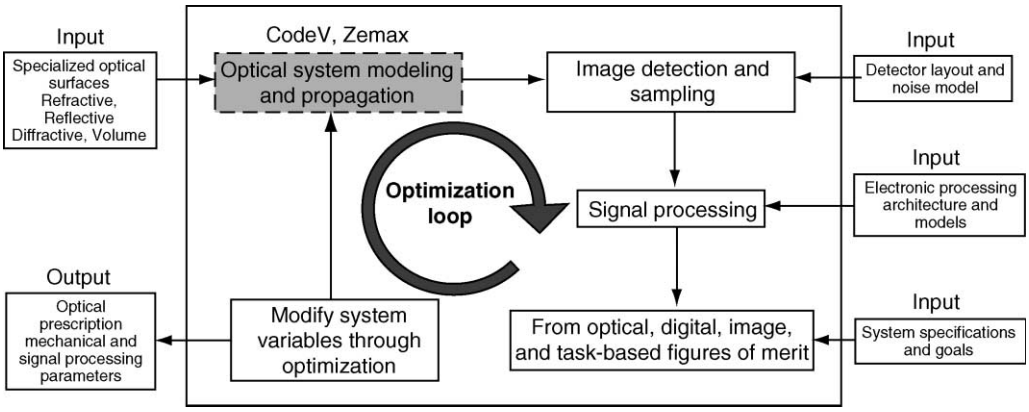

Figure 10 Schematic of a tool for designing imaging systems with Wavefront Coding. A ray trace determines the distribution in the exit aperture, and software determines the effect of the detector array and the signal processing. Then the ray trace and signal processing can be modified to optimize the entire system.

New design tools for imaging systems with wavefront coding

The Woodward function is a very good tool for analyzing imaging systems with a coded wavefront and is a good guide for someone who is expert in designing such systems. However, another approach is better for those designers who are more familiar with conventional lens design tools. If one combines a conventional ray-tracing tool with custom software, it is possible to jointly design the optical and the signal processing portions of the system. A schematic of such a system is shown in Figure 10. The ray-tracing tool is used to trace the rays and determine the distribution in the exit aperture. Various software tools then are used to take into account the effect of pixel size and spacing, and the signal processing. The criteria for optimizing the design can include the size of the digital filter, acceptable noise gain, and other parameters related to signal processing as well as the parameters of the optical elements.

Example applications of hybrid imaging systems with an extended depth of field or focus

Barcode and label readers. The images of Figure 7 show that image-based bar code reading is a good application for imaging systems that are based on Wavefront Coding. A bar code or label reader need not be positioned nearly as accurately as without the

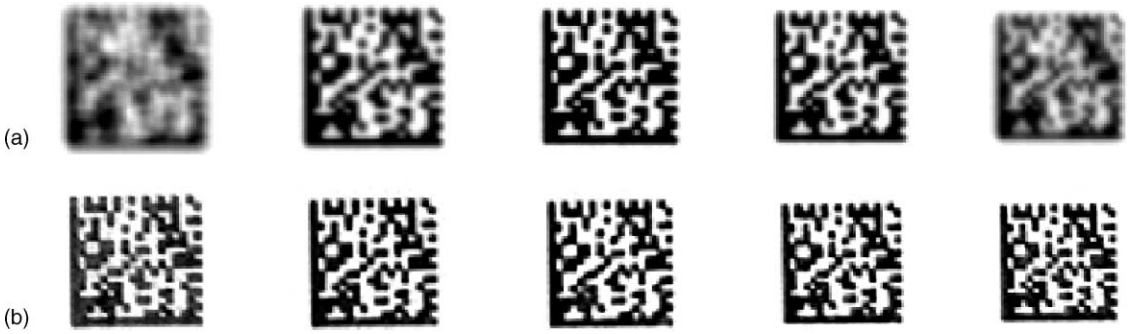

Figure 11 Images of a 2D bar code as the object position is varied for (a) conventional images and (b) Wavefront Coded images after signal processing for the same object positions as in (a).

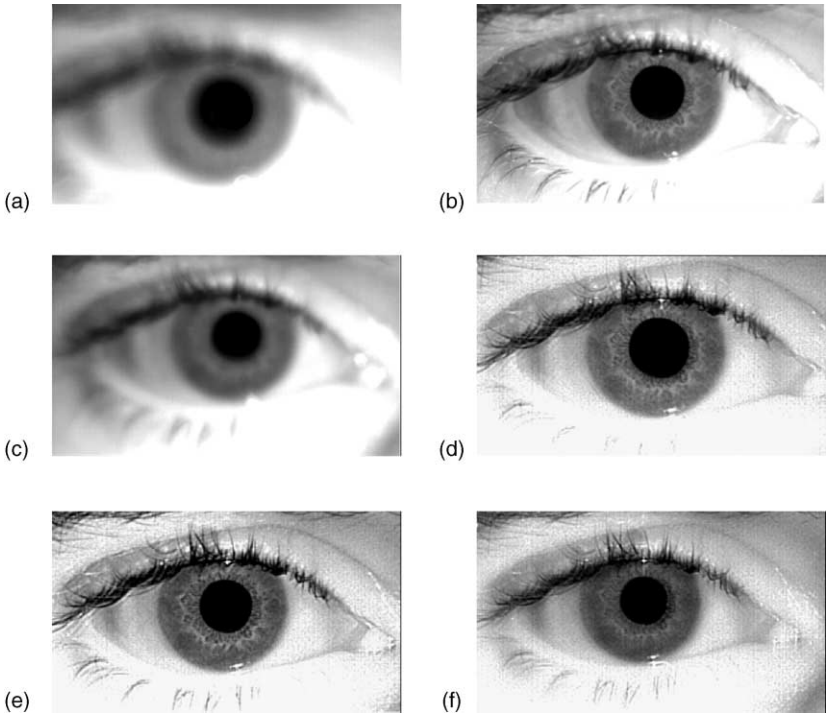

Figure 12 Images of an iris taken with infrared illumination. The top row shows images with a traditional CMOS camera. The lower row is taken with a camera using wavefront coding to extend the depth of field. The misfocus distance in the right and left columns is the same.

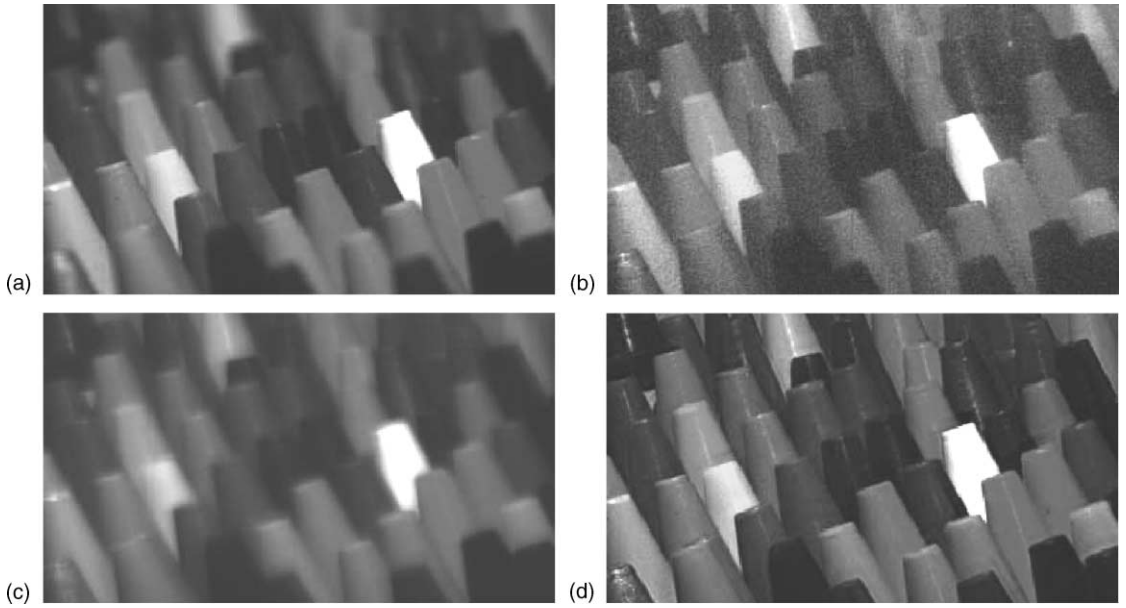

Figure 13 Images from a digital camera (a) Conventional camera with the lens wide open and focused on the white crayon. (b) Conventional camera with the lens stopped down to increase the depth of field, with the resulting increase in noise due to a lower light level. (c) Intermediate image of a camera that was modified with Wavefront Coding to have an extended depth of field. (d) Final image with the modified camera.

extended depth of field. Images of 2D bar codes imaged with and without Wavefront Coding are shown in Figure 11. Images in Figure 11a show the image of a 2D bar code formed by a conventional imaging system as the position of the object is varied. As with most imaging systems with fast optics and moderate magnification, the depth of field of the system is smaller than the application would prefer. Images in Figure 11b show the Wavefront Coded images of a 2D bar code after signal processing for the same object positions as (Figure 11a). These images are sharp and clear over a very large change in the distance to the bar code.

Biometric imaging systems. Biometric imaging applications, such as fingerprint or iris recognition, provide the means to eliminate passwords, secure E-commerce, and securely identify humans or animals. In traditional imaging technology, quite often the trade-off between light throughput and depth of field makes conventional biometric systems difficult to use or not sufficiently reliable. By using Wavefront Coding, the depth of information gathered can greatly increasing the ease of use and possibly reducing the cost of the systems.

Figures 12a,b, and c shows example images of an iris taken with near IR illumination and a traditional CMOS imaging system at three different planes of focus. At best focus (Figure 12b) the detail of the iris is sharp and clear. This iris detail is used by iris recognition algorithms to accept or reject the person.

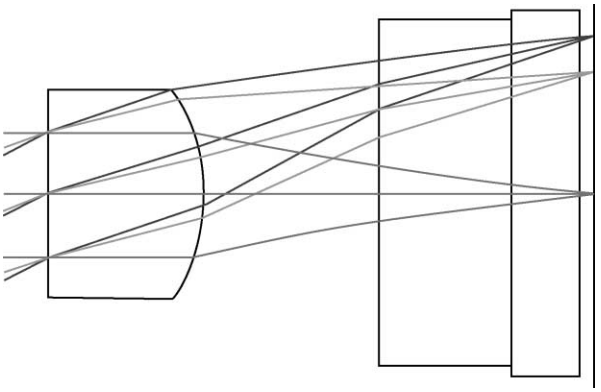

Figure 14 A schematic of a fast single-lens imaging system that has good performance over a wide field of view and the full visible range.

With slight movement towards (Figure 12a) or away (Figure 12c) from the imaging system the detail of the iris is lost. Figures 12d,e, and f show example iris images taken with the same near-IR illumination and a CMOS Wavefront Coded imaging system. At best focus (Figure 12e), the iris detail is as high as that from the traditional system. Movement towards (Figure 12d) or away (Figure 12f) from the imaging system results in images with essentially a constant level of iris detail. The size of the iris changes through magnification change. Increasing the range at which clear images can be made extends the useful image capture volume, enabling a more flexible system that is easier to use.

Color images with digital cameras. A conventional digital camera has a small depth of field as shown in Figure 13a, where the camera was focused on the white crayon. In a conventional imaging system, the only way to increase the depth of field is to stop down the lens. As seen in Figure 13b, this reduces the light that is available, and results in a very noisy image. The intermediate image of an imaging system that has an extended depth of field is shown in Figure 13c, where it is seen that the result of convolving the object distribution with the modified PSF is an intermediate image that appears to have the same blur over the entire image. After signal processing of the intermediate image to obtain the final image, a clear image is seen with good signal-to-noise ratio.

Inexpensive imaging systems with high-quality imaging characteristics. By exploiting the extension of the depth of focus that is made possible with Wavefront Coding techniques, one can design imaging systems that have fewer optical elements than traditional designs that do not use Wavefront Coding. In high-volume applications, reduction in the number of optical elements can lead to greatly reduced costs. Figure 14 shows a schematic of a fast, single-lens Wavefront Coded imaging system that is very compact and has the performance of a longer lens that traditionally requires two or more optical elements. In this example, the entire focus budget was used to compensate for focus-related aberrations, and the shape of the lens was used to compensate for distortion and coma. Even zoom systems can be greatly simplified with the new design techniques. Figure 15 shows a fast two-element Wavefront Coded zoom lens that images over a wide field with performance that is traditionally obtained only with three or more optical elements. Both of these imaging systems use non-rotationally symmetric forms of phase functions and are different from the ones of eqns [5] and [6].

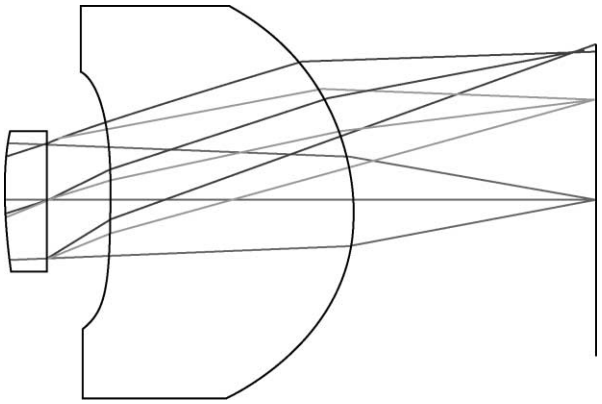

Figure 15 A schematic of a fast two-element zoom system with good performance over a 2.5 × zoom and a wide viewing angle.

Large depth of focus microscopes. A microscope can be modified to employ Wavefront Coding by either modifying the surface of one of the lenses in the objective, or by inserting a phase plate into the system at some appropriate position. One easy means of doing the modification is to place a Wavefront Coding phase plate in the slider position of a microscope, as shown in Figure 16. In this case, the optics is of high quality, and the entire focus budget was allocated to increasing the depth of field. A modified Zeiss microscope was used to obtain the images shown in Figure 17. An image of a diatom in Figure 17 shows the comparison with a conventional microscope in (a) and as with a Wavefront Coded microscope in (b). Notice that the greater depth of field gives more of an appearance of depth in the image.

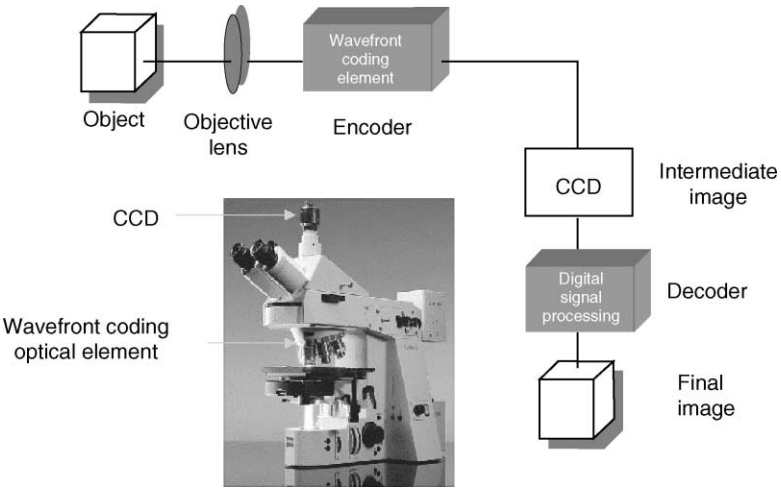

Figure 16 Schematic of a modified Zeiss microscope to employ Wavefront Coding to extend the depth of field.

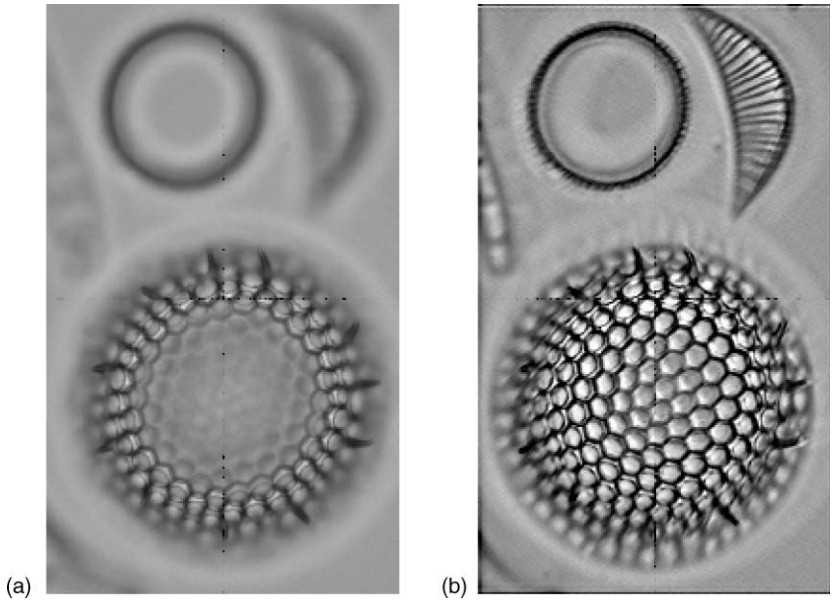

Figure 17 A 100 × image of diatoms made with (a) conventional and (b) modified Zeiss microscope to give an extended depth of field.

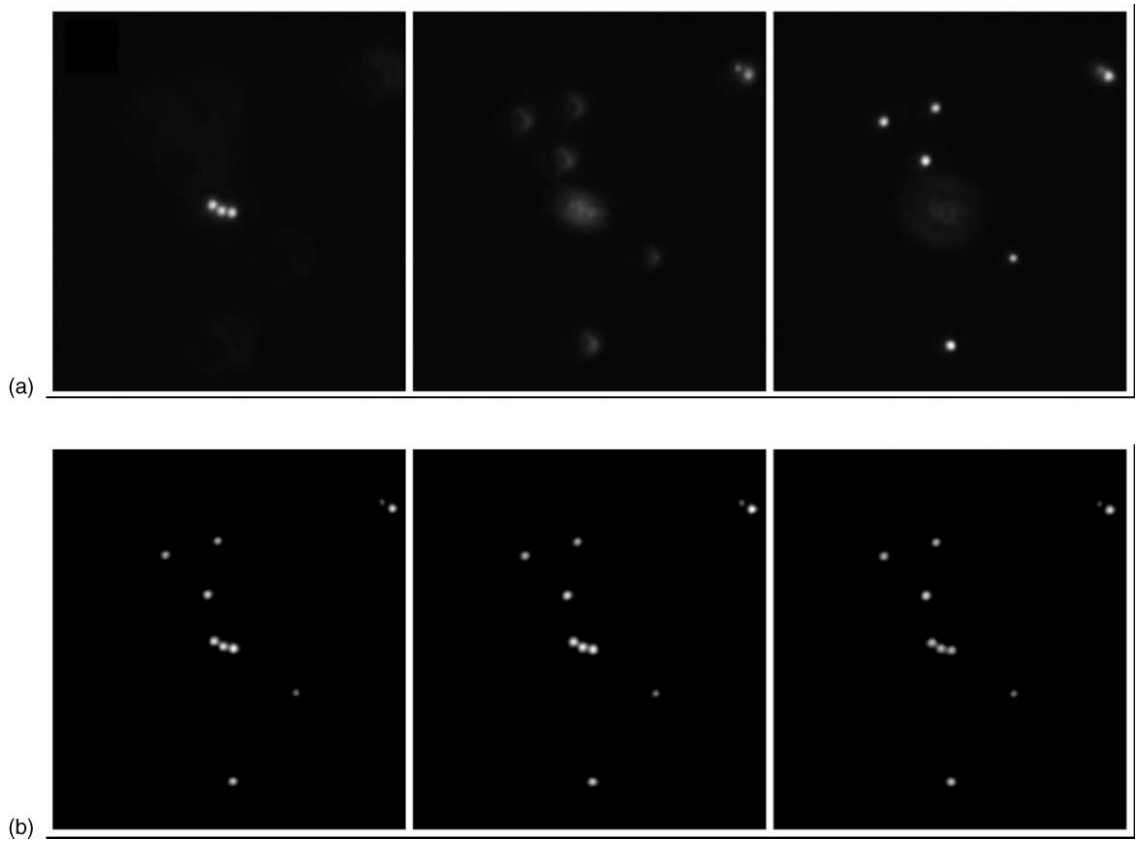

Figure 18 Imaging 0.5 micron diameter fluorescent beads at different sample distances. The images were taken with a 63×, NA = 1.4 imaging system in one micron steps. (a) Three image planes taken using a traditional system. They show that individual beads are sharp only in a single plane. The images in (b), which were taken with a Wavefront Coding system at the same image planes, show all beads are imaged clearly at each plane.

Other modes of microscopy are also possible. In fluorescence microscopy, ultraviolet light illuminates objects that have fluorescing compounds in them. The images are formed using the fluorescence that is excited by the ultraviolet illumination. Figure 18 shows images of fluorescing beads having a 0.5 micron diameter. The beads are at various depths within the sample. The traditional system, operating at 63 × with an immersion objective having a NA of 1.4, has a depth of field that is too small to image all of them. The images in Figure 18a were taken with the same microscope but with a wavefront coding phase element placed in the slider and signal processing of the captured images. All beads are clearly seen at all three of the focus positions.

Potential Future Applications

Wavefront Coding should be useful in many imaging system where signal processing is to be done anyway; in that case, optimizing the optics and the signal processing to the purpose of the imaging system. Examples where an extended depth of field may be desired are endoscopes, video cameras, and lithography. In designing an imaging system to take advantage of a large depth of focus to produce inexpensive digital cameras, high-quality images can be formed with fewer optical elements and much lighter cameras. In lithography, a larger process window is possible.

Because an increase in the depth of focus can permit wide spectral imaging, wide band infrared images can be formed. In systems that are used to provide images for machine interpretation, it is possible to design the optics and signal processing so that the desired process can be optimized globally, with the optics and the signal processing. For example, if the object is to classify cells as cancerous or noncancerous, it may be that the optics should be modified so that the information of primary importance is acquired and transmitted to the detector array. This modification would be done in conjunction with the optimization of the signal processing.

Conclusion

The mathematics and concepts that underlie a new approach to lens design were summarized. The technique has thus far been useful in enhancing the performance of some imaging systems such as microscopes, and in making simpler systems for inexpensive cameras. This new approach requires that some signal processing be done, but in digital cameras, some signal processing is being done already.

List of Units and Nomenclature

Modulation transfer function	The magnitude of the optical transfer function of an imaging system.
Optical transfer function	The response of an imaging system as a function of the spatial frequency of a sinusoidal object distribution.
Spatial frequency	A measure of spatial variation in the form of sinusoids in cycles per millimeter.

Introduction

The photon nature of light is the central topic in the field of quantum optics, which has developed into a leading area of research. The possible technological impacts of this field to many areas, such as imaging, computing, and lithography, have greatly expanded interest into the nature of the photon. A photon description of light goes well beyond the particle nature of light, to include any optical phenomena that cannot be adequately described by classical physical optics. This article will introduce the nature of the photon through a discussion of many such phenomena, covering topics from the beginning of quantum mechanics, including black-body radiation and Compton scattering, to areas of modern interest, such as squeezed light and entangled photons.

The Origins of Quantum Optics

One of the earliest theories in the development of quantum physics was the description of black-body radiation by Max Planck (1858–1947). Using the model of a radiating body as a collection of oscillators, he postulated that the amount of energy emitted or absorbed was proportional to its frequency, ν, and that these oscillators could only have energies corresponding to integer multiples of such a packet of energy, where one unit of energy was given by

$$E = h\nu \qquad [1]$$

where $h = 6.626 \times 10^{-34}$ Js is the universal constant, now known as Planck's constant. He then assumed a Maxwell–Boltzmann distribution to describe the probability of such oscillator states being occupied:

$$P(n) = P_0 e^{-nh\nu/kT} \qquad [2]$$

where $k = 1.381 \times 10^{-23}$ JK^{-1} is Boltzmann's constant and T is the temperature of the blackbody. The energy density in the radiation field, at a given frequency, is given by the oscillator density (at that frequency) times the average energy of the oscillators. Previous models had not only failed to quantize the oscillator energies, but in doing so also assumed equal occupation probabilities that led to a prediction of infinite energy densities at short wavelengths, the so-called ultraviolet catastrophe. The oscillator density is given by

$$n(\nu) = 8\pi\nu^2/c^3 \qquad [3]$$

where $c = 3 \times 10^8$ m s^{-1} is the speed of light. This value can be found by a mode density calculation within a box, as is often done in an introductory electromagnetics text. The average energy of the oscillators is found by calculating the sum of the occupation probability times the state energy and dividing by the sum of the occupation probabilities:

$$E_{\text{av}} = \sum_{n=0}^{\infty} [P(n)h\nu m] \Big/ \sum_{n=0}^{\infty} P(n) \qquad [4]$$

Evaluating the above expression for E_{av} and multiplying by $n(\nu)$, one finds the Planck radiation law:

$$I(\nu) = \frac{8h\pi\nu^3}{c^3(e^{h\nu/kT} - 1)} \qquad [5]$$

The black-body curve described by Planck's law is shown in Figure 1. By introducing quantization to solve a problem that classical physics had failed to explain, Planck paved the way for quantum physics.

Albert Einstein (1879–1955) made use of Planck's quantization for two important results that will be described here. The first is the photoelectric effect, a process by which electrons are released from a metal surface when exposed to light. The process has several traits that could not be explained by

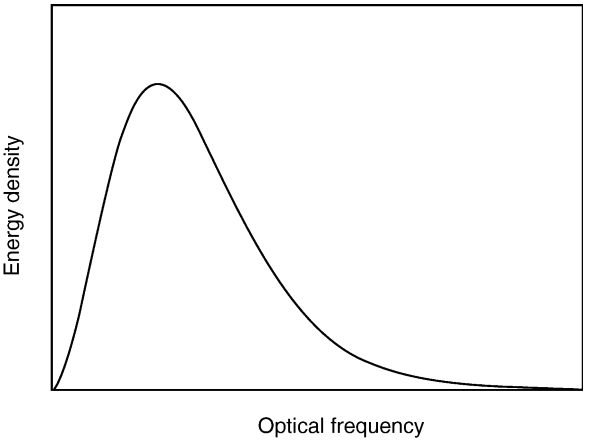

Figure 1 The spectral density emitted by a blackbody at a given temperature as given by Planck's law.

classical physics. A given metal will only release electrons if the incident light is above a certain frequency, regardless of the intensity. However, once sufficient frequency components are present, electrons are immediately released, with their number dependent on the intensity of the light and independent of its frequency. Contrarily, the maximum potential energy of the released electrons depends only on the maximum frequency of light present, independent of intensity. Einstein was able to satisfy all of these conditions by saying that the light energy comes in quantized amounts as described by Planck, and that the electrons in the metal require a minimum energy, or work function W, to be ejected. Then for each quantum of light, which we now call a photon, with energy greater than W that strikes an electron, the electron will be released with kinetic energy given by

$$K = h\nu - W \qquad [6]$$

It is historically important to note that, although Planck introduced the idea of a quantized release of radiation from oscillators, he still believed the light field itself to be continuous and classical. Planck's approach of quantizing energy levels of matter while treating light classically has since become known as the semiclassical method, and is adequate for solving many problems. Thus, it was also in quantizing light itself that Einstein took the next step, and thus can be viewed in many respects as the father of the modern photon, although the term photon was not used until two decades later.

The second area in which Einstein used the idea of energy quantization is in predicting radiative transition probabilities. A radiative transition is a process by which a photon is either absorbed or emitted to satisfy conservation of energy when an atom moves to a higher or lower energy state. Einstein assumed three such processes existed, as shown in Figure 2: absorption of a photon raising the atom to a higher energy level; spontaneous emission of a photon, where the atom emits a photon in going to a lower energy level; and stimulated emission, a process in which a photon interacts with the atom and causes it to emit a second photon (in phase with the first) and thereby go to a lower energy level. For each of these processes he defined a corresponding coefficient, now known as the Einstein A and B coefficients. They are labeled B_{12} for absorption, A_{21} for spontaneous emission, and B_{21} for stimulated emission. Note that there is no A_{12} as absorption by its very nature is a stimulated process. Einstein further stated that the rate of spontaneous emission was only dependent on his material dependent coefficient and the number of

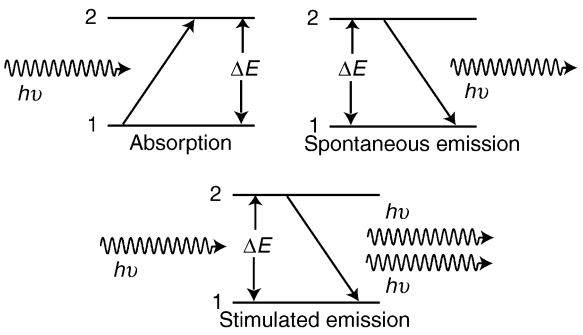

Figure 2 Energy level diagrams representing the processes of absorption, spontaneous emission, and stimulated emission.

atoms in the upper energy state, with the rate given by

$$R_{sp} = A_{21}N_2$$

However, he said that the rates of the stimulated processes were also dependent upon the strength of the optical field seen by the atoms, $I(\nu)$, and were given by

$$R_{ab} = I(\nu)B_{12}N_1 \qquad [7]$$

for absorption and

$$R_{st} = I(\nu)B_{21}N_2 \qquad [8]$$

for stimulated emission. The full absorption rate is given by R_{ab} as defined above, whereas the full emission rate is the sum of the spontaneous and stimulated rates, given by

$$R_{em} = [A_{21} + B_{21}I(\nu)]N_2 \qquad [9]$$

Einstein was primarily interested in a system in equilibrium, for which $R_{ab} = R_{em}$. If one then looks at the limit where the optical field is very large such that spontaneous emission is negligibly small and the population is equally divided between the upper and lower state, the relationship $B_{12} = B_{21}$ is found. Applying the same Maxwell–Boltzmann occupation statistics that Planck used to find his black-body expression, one can find that in thermal equilibrium the ratio of probability of finding an atom in state 1 to finding an atom in state 2 is

$$N_1/N_2 = e^{(E_2-E_1)/kT} = e^{h\nu/kT} \qquad [10]$$

Note that for a two-level system in thermal equilibrium, the population in the upper level can at most equal, never exceed, the population in the lower level, regardless of the strength of the applied field. This is important in showing that the B coefficients are equal, and will also be a crucial point when discussing the theory of the laser later in this article.

Appropriately combining the above expressions leads to

$$I(\nu) = A_{21}/[B_{21}(e^{h\nu/kT} - 1)] \qquad [11]$$

Equating this with Planck's radiation law yields the relation:

$$A_{21}/B_{21} = 8\pi h\nu^3/c^3 \qquad [12]$$

Thus, to fully specify the transition probabilities for a given system, one needs only to find A or B. It is rather straightforward using only atomic quantization to calculate B (such a derivation can be found in many introductory quantum mechanics textbooks). Direct calculation of A is more involved, requiring quantization of both the optical field as well as the atomic system.

Arthur Compton (1892–1962) used the idea of quantized radiation to explain the presence of longer wavelength components present when X-rays are scattered from matter, an effect which now bears his name. The amount of scattering is independent of the scattering material and the wavelength of the source, depending only on the angle of scattering, θ. If the scattering is treated as a collision between a particle-like photon and a massive particle (taken to be initially at rest) as shown in Figure 3, the result can then be found simply by applying conservation of energy and momentum, where the photon energy is as given above and the photon momentum is given by

$$p = E/c = h/\lambda \qquad [13]$$

Recalling that the momentum is a vector quantity, the conservation laws provide a set of three coupled equations. Solving them directly one finds that

$$\Delta\lambda = (h/c)(1 - \cos\theta)(2K)/[p^2 - (K/c)^2] \qquad [14]$$

where K and p correspond to the final kinetic energy and momentum of the massive particle. It is important to allow for the possibility of very high velocities for the massive particle, thus implying that relativistic expressions for K and p are needed. In terms of the kinetic energy, the relativistic expression for momentum is

$$p = \sqrt{2Km + (K/c)^2} \qquad [15]$$

where m is the mass of the scattering particle. Using this relation, the above expression can be simplified, giving the wavelength shift to be

$$\Delta\lambda = (1 - \cos\theta)h/mc \qquad [16]$$

The scaling factor is known as the Compton wavelength:

$$\lambda_c = h/mc \qquad [17]$$

For the case of an electron, the Compton wavelength has the value 0.02426 angstroms. For a massive particle, the Compton wavelength is often used when wanting to discuss and analyze wavelike properties. As a final note on this process, if the calculation would have been done nonrelativistically, there would have been an extra factor of $[1 - 0.25(\nu/c)^2]^{-1}$, where ν is the velocity of the particle. The appearance of the factor (ν/c) in any result implies the need for a relativistic treatment, though often (as in this case) taking the limit of $\nu/c = 0$ yields the proper result.

Another area in which the photon nature of light is revealed is a form of inelastic scattering of light now known as the spontaneous Raman effect. Discovered by CV Raman (1888–1970), this is a process in which a material illuminated by a light source scatters light into frequency components not found in the source. The frequency shift is due to the energy difference, ΔE, between two energy states in the material. There are two possible cases, each of which is represented in Figure 4. In the first, known as Stokes scattering, an atom in the lower state absorbs a source photon, raising it to the upper state via a virtual level, during which it emits a photon at the Stokes frequency, ν_s, as represented by the relation

$$h\nu_i = h\nu_s + \Delta E \qquad [18]$$

where ν_i is the frequency of the incident photon from the source. The second case, anti-Stokes scattering, has an atom in the upper state absorb the source photon and simultaneously fall to the lower state, again through the virtual level during which it emits a photon at the higher anti-Stokes frequency, ν_a,

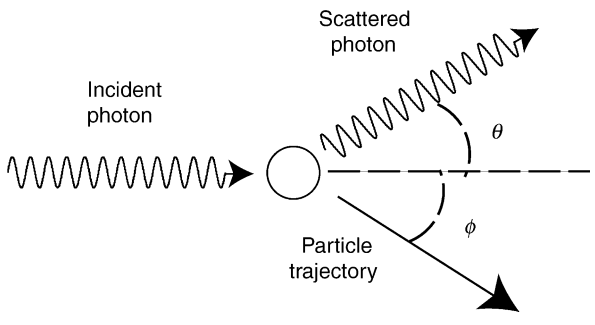

Figure 3 Schematic representation of Compton scattering.

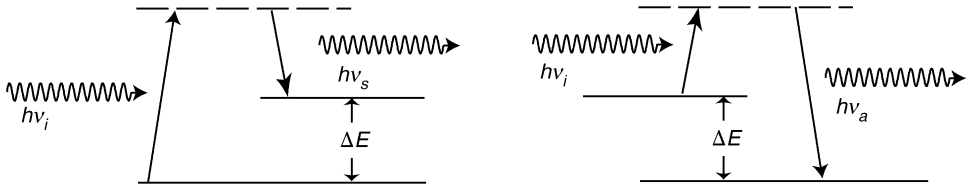

Figure 4 Energy level diagrams for Stokes and anti-Stokes Raman scattering.

given by

$$h\nu_i = h\nu_a - \Delta E \qquad [19]$$

Since the anti-Stokes scattering requires the atom to be initially in the upper state, the probability of such scattering is generally much less than that for Stokes scattering. This can be quantified by the same occupation statistics used above, giving the ratio of probabilities as

$$P_{as}/P_s = e^{-h\Delta E/kT} \qquad [20]$$

It is important to note that the energy difference can either be based on the electronic structure of an atomic system as has been discussed thus far, or other energies such as the vibrational energies in a molecular system. The ability to probe a variety of energy structures without having to tune the source to a particular wavelength has led to wide use of Raman scattering for spectroscopy. A related effect, known as stimulated Raman scattering, will be discussed later.

The Photon in Modern Physics

As an indication of the widespread importance of the results discussed thus far, they led to four Nobel prizes in physics: Planck in 1918; Einstein in 1921; Compton in 1927; and Raman in 1930. Our initial understanding of the photon comes from these results, but it was with the development of modern quantum mechanics by Erwin Schrödinger (1887–1961), Werner Heisenberg (1901–1976), and Paul Dirac (1902–1984); quantum electodynamics by Richard Feynman (1918–1988) and others; and the invention of the laser by Charles Townes (1915–) and others, that the field of quantum optics and our modern view of the photon began to fully take shape. In this section, the basics of modern quantum optics will first be introduced. A brief discussion of the theory of the laser as related to photon transitions will then be given, followed finally by examples of important areas of experimental quantum optics that have been made accessible by the laser.

It is now common to treat the photon with a very similar formalism as that originally created for massive particles in the development of quantum mechanics. That is, one describes the photon by a wave function, $|\Psi\rangle$, which contains all the information about the photon and must satisfy the Schrödinger equation

$$i\hbar\frac{\partial}{\partial t}|\Psi\rangle = H|\Psi\rangle \qquad [21]$$

where $\hbar = h/2\pi = 1.054 \times 10^{-34}$ Js and H is the Hamiltonian for the photon. Just as in classical electromagnetics, the Hamiltonian is related to an electric and magnetic field. Clearly, for this treatment to be in agreement with the well-established classical electromagnetic theory, these fields must satisfy Maxwell's equations. There are several possible representations of the Hamiltonian, but for the purposes of this discussion a convenient choice is

$$H = h\nu(\hat{n} + 0.5) \qquad [22]$$

where $\hat{n}$ is called the number operator as it returns the average number of photons in the state, $\langle\hat{n}\rangle$, represented by the operation

$$\langle\hat{n}\rangle \equiv \langle\Psi|\hat{n}|\Psi\rangle \qquad [23]$$

Explanations of the notation used can be found in any elementary quantum mechanics text. Note that in defining the Hamiltonian, a single frequency ν was used. This implies a single mode field. For a more general case, one would simply sum over the modes corresponding to various frequencies.

In addition to obeying the Schrödinger equation, the photon is also restricted by the Heisenberg uncertainties as for massive matter, given in a general form as

$$\Delta q \Delta p \geq \hbar \qquad [24]$$

where q and p are any set of canonically conjugate variables, such as position and momentum or energy and time. Note that, depending on the exact definitions used for q and p, there can be extra factors such as 0.5, and sometimes normalized

variables are used such that the inequality is with respect to 1. However, it is interesting to note that, unlike for massive particles that were considered well localized in classical theory, the idea of uncertainty for light had been accepted in some form long before the development of quantum mechanics. Neglecting the scaling factor $\hbar$, which is purely quantum in origin, an uncertainty principle can be derived for any wavelike phenomena simply using the relationship between Fourier transform pairs.

Using the basic ideas of a photon state and the uncertainty principle, some important properties of light will now be explored. There are several possible forms the wave function can take. It is often convenient to write the wave function in terms of states containing a certain number of photons. Such states are known as Fock or number states and are represented as $|n\rangle$, with n being the number of photons in the state and are said to be eigenstates of the number operator. The energy of a Fock state is given by

$$E_n = h\nu(n + 0.5) \qquad [25]$$

Notice that this predicts a background, or vacuum, energy for the electromagnetic field, even when the average number of photons in the field is zero. This vacuum energy is given by $0.5\,h\nu$. Correspondingly, due to the uncertainty principle, there must be some uncertainty in this energy as well as with any energy. The fluctuations in the vacuum energy are known as vacuum fluctuations. Many processes, such as spontaneous emission that cannot be adequately described by a simple semiclassical approach, where matter is treated quantum mechanically and light is treated classically, can be treated by the addition of vacuum fluctuations, without requiring a full quantum mechanical treatment of the electromagnetic field. Such an approach is used in many texts, but there are several important physical phenomena that do require the fully quantized approach discussed here.

The state most resembling a classical field is known as the coherent state, represented here as a sum of Fock states:

$$|\Psi\rangle = |\alpha\rangle = e^{-|\alpha|^2/2} \sum_{n=0}^{\infty} \frac{\alpha^n}{\sqrt{n!}} |n\rangle \qquad [26]$$

where α is a parameter describing the field, with the average number of photons in the field given by

$$\langle \hat{n} \rangle = |\alpha|^2 \qquad [27]$$

One key property of coherent states is that they exhibit minimal uncertainty. That is, the uncertainty relations become equalities. Also, the uncertainty is equally divided between quadrature components.

Before applying the above principles to explore some of the dramatic results of quantum optics, a brief discussion of the laser will be given due to its importance in the field. The theory of operation of the laser is based directly on Einstein's transition probabilities. For the transition of interest, one wants to generate a large number of coherent photons (that is, photons in phase with one another). Recall that in the process of stimulated emission, one photon leads to two coherent photons, whereas spontaneous emission leads to photons which are not phase referenced to anything else in the system. Also, if a significant number of the photons are to escape the region where they are generated, it is important to minimize the absorption. Thus, a laser requires that the stimulated emission rate exceed both the spontaneous emission rate and the absorption rate. The first condition places a lower limit on the optical field density present at the lasing frequency. This density can be reasonably large, but presents no fundamental difficulties. In practice, mirrors are placed around the emission region to confine the photons and counteract losses, thereby building up the energy density until the above condition is satisfied. The second condition, however, can be written as

$$N_2 > N_1 \qquad [28]$$

and is the more restrictive requirement. Such a condition is referred to as inversion and, as was previously mentioned, cannot be sustained in a two-level system once equilibrium is reached. Therefore, to be able to maintain lasing, additional levels are needed. Two typical laser energy diagrams are shown in **Figure 5**. In such multilevel systems, it is possible to create an inversion in the levels of interest and thus allow lasing. Further details on lasers (both in theory and practice) are widely available, though it should be noted that the output of a laser is a good approximation of a coherent state described above.

The invention of the laser revolutionized optics, as well as the whole of modern physics, by making readily available electromagnetic fields of a vastly different nature than that from any previous source of light. This quickly led to the birth of a new field known as nonlinear optics. Nonlinear optics describes interactions between light and matter which have properties dependent on the field strength. Although some nonlinear processes can be described adequately without the use of a photon picture, most nonlinear process can be best described as some combination of annihilation (absorption) and creation (emission) of photons. Two such

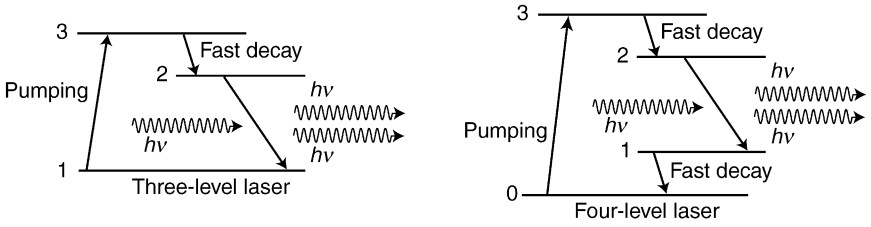

Figure 5 Energy level diagrams for three-level and four-level lasers.

processes, that are of great interest in quantum optics, are stimulated scattering and parametric down conversion.

Earlier, the process of spontaneous Raman scattering was discussed. For such a process, it is assumed that the incident field driving the process is relatively weak such that the scattering process generates very low photon densities in the various modes of the electromagnetic field. However, just as there are both stimulated and spontaneous emission processes in the radiative transitions discussed previously, in the presence of strong fields there can also be stimulated scattering. The total Raman scattering rate can be expressed as

$$R = \eta I_i(I_R + 1) \qquad [29]$$

where η is a scaling factor, including the gain of the process for a given material, I_i is the strength of the incident optical field (generally a laser field to be sufficiently strong to cause stimulated scattering), and I_R is the Raman field strength. Note that for I_R, the rate is just linear with the applied field, representing the spontaneous process. However, with a strong pump, the generated field will quickly become large enough such that the stimulated process will dominate. The spontaneous scattering is not directional dependent, but since the stimulated process grows along the length of the scattering material in the path of the incident beam, it will tend to be generated along the path of the incident laser. Due to linear and nonlinear dispersion effects, however, the light will form in a narrow cone about the pumping laser rather than exactly collinear. Unlike the spontaneous scattering, a significant percentage of the incident photons can be converted to the Raman frequencies, making stimulated Raman scattering an extremely powerful spectroscopic tool.

Possibly the most important nonlinear optical process for quantum optics is parametric down conversion. This process is interesting both in the nature of the process itself, as well in the properties of the generated light. In parametric down conversion, shown schematically in Figure 6, one photon (known as a pump photon) of frequency ν_p is annihilated

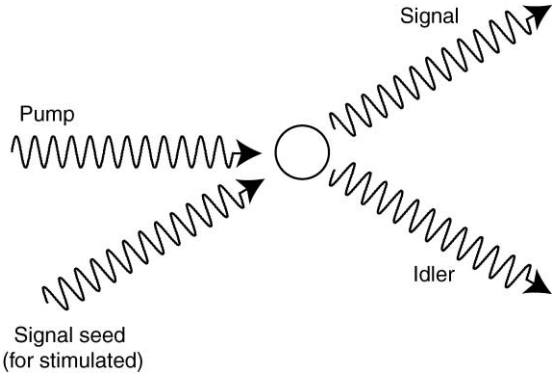

Figure 6 Schematic representation of parametric down conversion.

and two new photons (generally referred to as signal and idler) are created with frequencies ν_s and ν_i respectively, given by the conservation of energy relationship:

$$h\nu_p = h\nu_s + h\nu_i \qquad [30]$$

In the case where $\nu_s = \nu_i$, the process is referred to as degenerate. Down conversion can either be spontaneous, in which only pump photons are externally applied, or stimulated, in which both pump photons and signal photons are applied. In the stimulated case, the signal is amplified and idler photons are generated as a byproduct. Parametric down conversion is one of the leading sources of nonclassical states of light. The term nonclassical is used rather than quantum, because all states of light can be accurately described by a quantum picture, but while most can also be described very well with a classical picture the states referred to as nonclassical cannot. Two of the most common nonclassical states of light are entangled states and squeezed states.

Entangled states are multiphoton states in which the state cannot be written as a product of the states of the individual photons. For simplicity, only two-photon entangled states (commonly referred to as EPR states for Einstein, Podolsky, and Rosen) will be discussed. More extensive and general material, including discussions of higher-order entanglement,

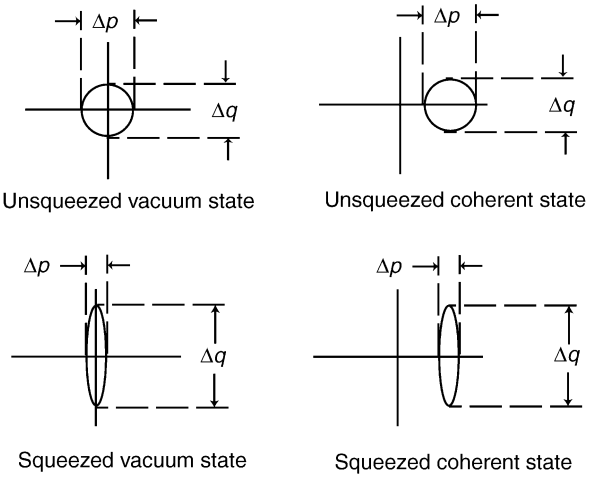

Figure 7 Uncertainty diagrams for squeezed and unsqueezed vacuum and coherent states.

such as the three-photon entangled states (commonly referred to as GHZ states for Greenberger, Horne, and Zeilinger), can be found in a variety of textbooks on modern quantum optics. One of the simplest ways to generate a two-photon entangled state is by the process of spontaneous parametric down conversion described above. If the product of the pumping intensity, generation length, and generation gain is of an appropriate level, individual pairs of photons are emitted. The states of these photon pairs are entangled, with the position, momentum, wavelength, polarization, and all other properties of the photons completely correlated and inseparable. Such states have been a powerful tool for the experimental verification of many of the predictions of quantum mechanics and quantum optics. Entangled states can also act as a source for many of the newer technologies in quantum optics, including cryptography and teleportation.

Another important form of nonclassical light is known as squeezed light. The principle behind squeezed light is that, unlike for coherent states where the uncertainty is equally distributed, the uncertainty in one quadrature can be reduced at the expense of increased uncertainty in the other quadrature. This is shown schematically in Figure 7. As opposed to entangled states which tend to be very weak, containing only a few photons, squeezed states of light can be quite intense. This makes squeezed light more desirable for many applications.

In conclusion, it should be noted that while the photon description of light can explain a wide variety of physical processes and is now leading to many exciting technological developments, much is still unknown about the photon at the fundamental level. Any accurate description of the photon must be in agreement with experimental evidence, including that discussed in this article, but one should be aware that the accepted picture of the photon nature of light is still constantly evolving and growing.

Introduction

The fabrication and study of dielectric structures whose refractive index is periodically modulated on a micron or submicron scale, known as photonic crystals (PCs), are attracting considerable interest at present. One-, two-, or three-dimensional (1D-, 2D-, or 3D-) periodic PCs exhibit photonic band gaps (PBGs), analogously to electronic band gaps in ordinary crystals, and can incorporate defects, designed to form localized narrow-linewidth (high-Q) modes at PBG frequencies. The advent of such structures opens up new perspectives in atomic physics and quantum optics, since they are expected to allow an unprecedented control over the spectral density of modes (DOM) and the spatial modulation of narrow-linewidth (high-Q) modes, in the microwave, infrared, and optical domains. An interesting situation arises when foreign atoms or ions – dopants – with transition frequencies within the PBG, are implanted in the PC. Then light near one of these frequencies resonantly interacts with the dopants and is concurrently affected by the PBG dispersion. Consequently, highly nonlinear processes with a rich variety of unusual PC-related features are anticipated. Such nonlinear optical processes, involving near-resonant transitions in PCs, undergo basic modifications as compared to the corresponding processes in free space, which are attributed to the strong suppression of the DOM within PBGs, to sharp bandedges and to intra-gap narrow lines associated with high-Q defect modes.

Results are detailed below for spontaneous emission of radiation in PCs and for the resonant interaction of atoms with the field of a single high-Q defect mode. These results stem from the failure of perturbation theory and the onset of strong field-atom coupling near sharp bandedges or narrow defect-mode lines in 2D and 3D PCs. 3D-PBGs are needed, in order to extinguish spontaneous emission in all possible directions of propagation and dipole orientations. If only one polarized atomic transition is involved in the spontaneous emission, 2D-PCs suffice for its suppression. For controlling strictly unidirectional field propagation, it is sufficient to resort to PBGs in 1D-periodic structures (Bragg reflectors or dielectric multi-layer mirrors).

As a further example of field–atom interactions in doped PCs, we will show that two ultraweak electromagnetic fields (or photons), coupled to appropriate transitions of the dopants in a PC, can mutually induce large phase shifts or drastic changes in absorption. Appreciable photon–photon correlations can then be established, which can be utilized in both classical and quantum optical communications.

Radiative Decay and Photon–Atom Binding in a PC

The interaction of a two-level atom with an arbitrary field-mode continuum can be described by the following second-quantized Hamiltonian in the

rotating-wave approximation (RWA)

$$H = \hbar\omega_a|e\rangle\langle e| + \hbar\sum_{\vec{k}}\omega_{\vec{k}}a^{\dagger}_{\vec{k}}a_{\vec{k}} + \hbar\sum_{\vec{k}}[\kappa(\omega_{\vec{k}})a^{\dagger}_{\vec{k}}|g\rangle\langle e| + \text{hermitian constant}] \quad [1]$$

Here $|e\rangle$ and $|g\rangle$ are the excited and ground atomic states, respectively, ω_a is the atomic transition frequency, $a^{\dagger}_{\vec{k}}$ and $a_{\vec{k}}$ are the creation and annihilation operators of a field mode with wavevector $\vec{k}$, and frequency $\omega_{\vec{k}}$, and $\hbar\kappa(\omega_{\vec{k}})$ is the resonant coupling energy of this mode with the atomic dipole. The $\vec{k}$-summation can be replaced by an integral over the continuum DOM in the frequency domain, $\sum_{\vec{k}} \rightarrow \int_0^{\infty} d\omega\rho(\omega)$, avoiding, for the sake of simplicity, the study of direction-(angle-)dependent DOM effects.

We consider a two-level atom that is excited at time $t = 0$ in an empty, periodic dielectric structure. The wavefunction of the combined system field + atom can be cast in the general form:

$$|\Psi(t)\rangle = \alpha(t)|e, \{0_\omega\}\rangle + \int \beta_\omega(t)|g, 1_\omega\rangle\rho(\omega)d\omega \quad [2]$$

where $\{0_\omega\}$ signifies the completeness of field modes in the vacuum state and $|1_\omega\rangle$ denotes single-photon occupation of the ω-mode. The corresponding Schrödinger equation can be solved with the initial condition $|\Psi(0)\rangle = |e, \{0_\omega\}\rangle$ by means of the continuum spectral response:

$$G(\omega) = |\kappa(\omega)|^2\rho(\omega) \quad [3]$$

The analysis of eqn [2], with $G(\omega)$ appropriate for photonic bandstructures, is aimed at revealing the prominent features of the atomic excitation decay $\alpha(t)$ and the corresponding emission spectrum.

In what follows, we consider a photonic bandstructure with several PBGs, separated by allowed bands. Each PBG is labeled by index i and has lower and upper cutoff frequencies ω_{Li} and ω_{Ui}, respectively. Then $G(\omega) = 0$ for $\omega_{Li} < \omega < \omega_{Ui}$. Naively, one might expect that an excited atom would either be stable against single-photon decay, if ω_a is within a PBG, or decay completely at $t \rightarrow \infty$, if ω_a is anywhere in an allowed band. However, both statements turn out to be inaccurate.

Incomplete decay of $\alpha(t \rightarrow \infty)$ occurs if there is a stable eigenvalue (energy level) $\hbar\omega_i$ of the total (field-atom) Hamiltonian eqn [1]. Such an energy level is possible only if $G(\omega_i) = 0$, i.e., for ω_i in a PBG. It must satisfy:

$$\omega_i = \omega_a + \Delta(\omega_i) \quad [4]$$

$$\Delta(\omega_i) = \int_0^{\omega_{Li}} \frac{G(\omega')}{\omega_i - \omega'}d\omega' + \int_{\omega_{Li}}^{\infty} \frac{G(\omega')}{\omega_i - \omega'}d\omega' \quad [5]$$

Here the integrals are the frequency shifts of the atomic resonance $\hbar\omega_a$ induced by the spectral parts of the reservoir situated, respectively, below and above the ith PBG (Figure 1). If eqn [4] holds, then the corresponding term in $\alpha(t)$ is proportional to $\exp(-i\omega_i t)$, and does not decay. Physically, such a stable level can be interpreted as representing the binding of the photon to the atom (photon-dressed atom), without the ability to leave the atomic vicinity, due to Bragg reflection in the PBG.

Assuming that ω_i occurs in the ith PBG, we observe that the first shift is positive whereas the second shift is negative, i.e., each part of the continuum repels the atomic level from its PBG edge. Equation [4] has a solution if ω_a falls between the minimum and maximum values assumed by its left-hand side in the ith PBG, i.e., if

$$\omega_{Li} - \Delta(\omega_{Li}) < \omega_a < \omega_{Ui} - \Delta(\omega_{Ui}) \quad [6]$$

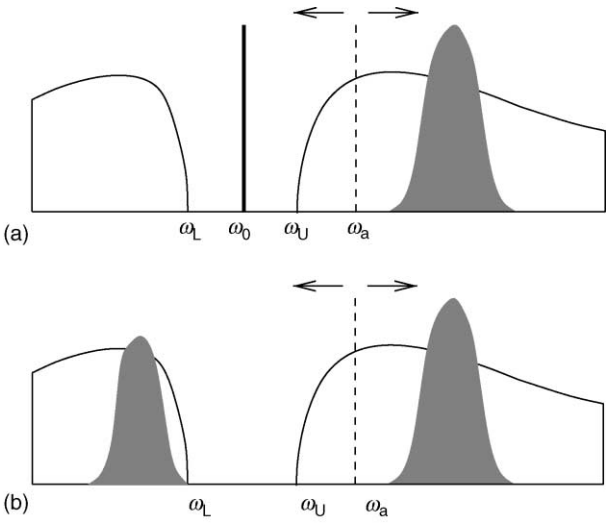

Figure 1 Frequency shifts of the atomic resonance ω_a (dashed line) due to 'repulsion' (arrows) by asymmetric spectral parts of the continuum below and above the PBG: (a) Incomplete decay for ω_a in allowed band. The interaction with the continuum splits the state into a superposition of a stable part in the PBG (solid line) and a decaying part above ω_a (shaded peak). (b) Complete decay for same ω_a, due to larger shifts that split the state into decaying parts in two allowed bands.

Incomplete decay occurs if this condition holds at least for one PBG. There may be, at most, one stable state in a single PBG (Figure 1). However, a two-level atom in a periodic structure can have several stable dressed states simultaneously, when conditions hold for several PBGs. It is quite extraordinary that the conditions (eqn [6]) for incomplete decay can be fulfilled with ω_a, not only in a PBG, but even in an allowed band, e.g., when $\Delta(\omega_{Ui})$ is negative or when $\Delta(\omega_{Li})$ is positive (Figure 1a,b).

Equally counterintuitive is the converse possibility, of complete decay for ω_a within a PBG. When there is a single PBG and one of the inequalities in eqn [6] is violated, complete decay will occur for $\omega_{Li} < \omega_a < \omega_{Li} - \Delta(\omega_{Li})$, if $\Delta(\omega_{Li}) < 0$, or $\omega_{Ui} - \Delta(\omega_{Ui}) < \omega_a < \omega_{Ui}$, if $\Delta(\omega_{Ui}) > 0$.

The possibility that one or several discrete, stable, states exist yields the corresponding wavefunction in the form:

$$|\Psi(t)\rangle = \sum_i \sqrt{c_i}|\psi_i\rangle e^{-i\omega_i t} + |\Psi_c(t)\rangle \qquad [7]$$

Here the summation is over all discrete atomic photon-dressed states with energies $\hbar\omega_i$, $|\psi_i\rangle$ is a discrete-(dressed-)state eigenfunction of the Hamiltonian (eqn [1]) normalized to unity, and weighted by the amplitude $\sqrt{c_i} = [1 + \int_0^\infty d\omega G(\omega)/(\omega - \omega_i)^2]^{-1/2}$. The dressed state $|\psi_i\rangle$ consists of an excited-state component and a photon-bound ground-state component.

The population of the excited state for long times:

$$|\alpha(t)|^2 = \sum_{i,i'} c_i c_{i'} \cos(\omega_i - \omega_{i'})t \quad \text{for} \quad t \to \infty \qquad [8]$$

is a nonzero time-constant if there is one discrete stable state, whereas in the case of several such states, it undergoes beats at the frequencies corresponding to their energy differences. The splitting of an excited state $|e\rangle$ into superposed stable states, oscillating at bandgap frequencies ω_i, whose amplitudes c_i, and eigenfrequencies ω_i are controllable by the atomic transition detuning from cutoff, constitutes spontaneous coherence control.

If, however, ω_a is far from the cutoff, then eqn [2] results in an exponentially decaying amplitude:

$$\alpha(t) \approx e^{-(\gamma_a + i\tilde{\omega}_a)t} \qquad [9]$$

where $\tilde{\omega}_a = \omega_a + \Delta_a$, Δ_a, and γ_a being the effective spectral shift and width of the decaying atom. This regime holds for a locally smooth $G(\omega \approx \omega_a)$ such that

$$|\gamma_a'|, |\Delta_a'| \ll 1; \; |\gamma_a'\Delta_a| \ll \gamma_a; \; \gamma_a, |\Delta_a| \ll |\omega_a - \omega_g| \qquad [10]$$

where ω_g is the bandedge frequency nearest to ω_a and the primes denote differentiation with respect to ω_a.

We now apply the foregoing general results to a model DOM distribution. This distribution is derived on keeping the lowest term in the Taylor expansion of the dispersion relation $\omega(\vec{k})$ near a photonic bandedge ω_U (the effects of the further PBG edge are neglected). This yields the effective mass approximation:

$$\omega \approx \omega_U + \sum_{i=x,y,z} (k - k_U)_i^2/m_i \qquad [11]$$

with $1/m_i = (1/2)(\partial^2\omega/\partial k_i^2)|_{\omega=\omega_U}$. In a structure with period L, k_U satisfies the Bragg condition $k_U = \pi/L$. The corresponding DOM in a 3D-periodic structure with an allowed symmetry may be approximated as

$$\rho(\omega) \sim (\omega - \omega_U)^{(1-D)/2}\theta(\omega - \omega_U) \qquad [12]$$

where θ is the step function and D is the dimension of the Brillouin-zone surface spanned by bandedge modes with vanishing group velocity. In realistic photonic structures $D \leq 2$, $D = 2$ corresponding to completely isotropic dispersion (spherical Brillouin-zone surface) and $D = 0$ corresponding to an anisotropic three-dimensional Brillouin zone. Both cases can be represented, respectively, as the limits $\varepsilon \to 0$ and $\varepsilon \to \infty$ of the function:

$$G(\omega) = \frac{C}{\pi}\frac{\sqrt{\omega - \omega_U}}{\omega - \omega_U + \varepsilon}\theta(\omega - \omega_U) \qquad [13]$$

where ε is the 'cutoff-smoothing' parameter and C is the continuum coupling constant. Depending on whether $C^{2/3}/\varepsilon$ is greater or less than one, the continuum is close to the case $\varepsilon = 0$ ($D = 2$) or $\varepsilon \to \infty$ ($D = 0$), respectively.

Using the properties of the model DOM (eqn [13]), we can infer the criteria for the two regimes discussed above:

(i) The conditions for incomplete decay, eqn [6], are now (Figure 2) $\Delta_c \equiv \omega_a - \omega_U < C\varepsilon^{-1/2}$. Hence, the abrupt, singular cutoff of the DOM with $D = 2$ ($\varepsilon \to 0$) implies the existence of a discrete state for any ω_a, either inside or outside the PBG. The energy of the discrete state, $\hbar\omega_0$, which must lie in the PBG, is found to be a real and positive root of the equation $\omega_a - \omega_0 = C/(\sqrt{\omega_U - \omega_0} + \sqrt{\varepsilon})$.

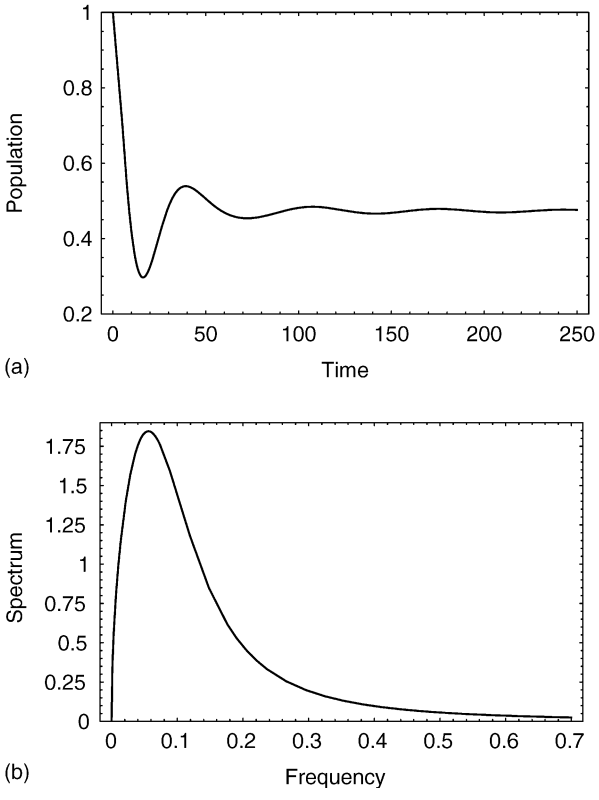

Figure 2 (a) Incomplete decay of the excited state population as a function of $\gamma_c t$, where $\gamma_c = C\varepsilon^{-1/2}$, for $\varepsilon = 10^{-3}$, at cutoff $\Delta_c = 0$. The beat period is $2\pi/(\omega_U - \omega_0)$ and the nondecaying probability is $c_0^2 = 4/9$. (b) The corresponding spectrum. The frequency is normalized to γ_c.

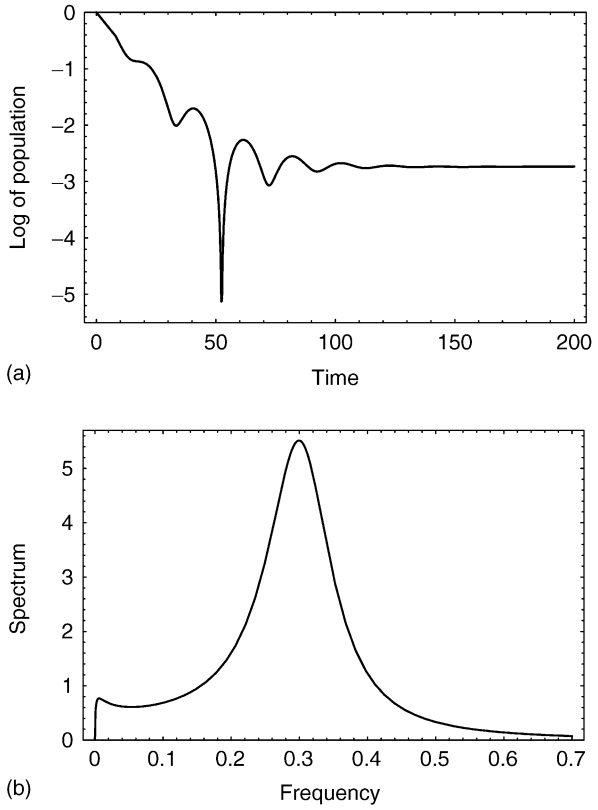

Figure 3 As in Figure 2, for a large detuning from the sharp cutoff, $\varepsilon = 10^{-3}$, $\Delta_c = 0.3$. (a) $\log_{10}|\alpha|t|^2$ is plotted as a function of *i*. The nearly complete decay ($c_0^2 \sim 10^{-3}$) is modulated by beats with frequency Δ_c. A power tail obtains for $t \gg \gamma_a^{-1} \approx \Delta_c^{1/2}/C$, decreasing as $t^{-1/2}$ for $t \ll \Delta_c^2/C^2$ and as $t^{-3/2}$ for $t \gg \Delta_c^2/C^2$. (b) The nearly Lorentzian spectrum, w(ω), has a small peak near ω_U, due to the sharply peaked DOM near the cutoff.

(ii) The conditions for nearly exponential decay, eqn [10], can be shown to reduce now to the requirement that ω_a be in the allowed zone sufficiently far from cutoff, $\Delta_c \gg \min\{C^{2/3}, C\varepsilon^{-1/2}\}$. Under this condition, the intermediate-time exponential decay of the excited state (Figure 3) is given to first approximation by eqn [9], with $\gamma_a = C\sqrt{\Delta_c}/(\varepsilon + \Delta_c)$ and $\Delta_a = -C\sqrt{\varepsilon}/(\varepsilon + \Delta_c)$.

The resulting atomic frequency shift Δ_a is negative in the present model, vanishing for $\varepsilon \to 0$ ($D = 2$). The long-time behavior of $\alpha(t)$ can be shown to exhibit a tail decaying as $t^{-3/2}$ (or $t^{-1/2}$ at $\Delta_c = C\varepsilon^{-1/2}$) and oscillating at the cutoff frequency ω_U (Figure 3).

With the increase of ε, the smoothing inhibits the decay more strongly for ω_a at cutoff, $\Delta_c = 0$, because $G(\omega_a \simeq \omega_U)$ is now weaker and the stable-state probability c_0 (eqn [7]) is correspondingly larger. By contrast, at a large detuning from cutoff Δ_c, the large-ε smoothing allows the decay to become complete, and the corresponding spectrum is entirely Lorentzian.

A defect in the periodic structure can produce a narrow-linewidth local mode in the PBG, whose spectral response is describable by a Lorentzian:

$$G_d(\omega) = \frac{\gamma_d}{\pi} \frac{\Gamma_d^2}{\Gamma_d^2 + (\omega - \omega_d)^2} \qquad [14]$$

where γ_d characterizes the coupling strength of the atomic dipole with the defect field, whereas ω_d and Γ_d stand for the line center and width, respectively. The presence of a nonvanishing DOM in the PBG, due to a defect, causes spontaneous emission in the PBG spectral range. This broadens the discrete state ω_0, which becomes metastable (see Figure 4). The oscillator strength of the line at ω_0 is then proportional to c_0.

EIT and Cross-Coupling of Photons in Doped PCs

Nonlinear effects, whereby one light beam influences another, require strong fields or else light confinement

in a high-Q cavity. The analysis above has shown that by choosing an appropriate detuning of an atomic transition from the PBG cutoff, the spontaneous coherence is established between the states of an initially excited atom. The ability to control this coherence, by varying the detuning, opens interesting perspectives for optical processes in PCs containing multilevel atoms with a resonant transition near a bandedge. From among such processes, we discuss here electromagnetically induced transparency (EIT) and its applicability to nonlinear photon switching or giant cross-phase modulation.

Let us examine the nonlinear coupling of two weak (single-photon) optical fields E_a and E_b with the frequencies ω_a and ω_b, respectively, propagating along the z-axis in a PC dilutely doped with identical four-level atoms (Figure 5a). These fields interact with the atoms via the transitions $|1\rangle \rightarrow |2\rangle$ and $|3\rangle \rightarrow |4\rangle$, respectively, while the transition $|2\rangle \rightarrow |3\rangle$ is coupled to the structured mode-continuum $\rho(\omega)$ in the PC (Figure 5b). Initially the atoms are in the ground state $|1\rangle$ and the continuum is in the vacuum state $\{0_\omega\}$. Then the wavefunction of the system at the position z_l of the lth atom reads:

$$|\Psi(z_l, t)\rangle = \alpha_1 |1, \{0_\omega\}\rangle + \alpha_2 |2, \{0_\omega\}\rangle + \int \beta_{3,\omega} |3, 1_\omega\rangle \rho(\omega) \mathrm{d}\omega + \int \beta_{4,\omega} |4, 1_\omega\rangle \rho(\omega) \mathrm{d}\omega \qquad [15]$$

The consecutive terms in eqn [15] denote the atom being in states $|1\rangle$, $|2\rangle$, $|3\rangle$, or $|4\rangle$, with zero $\{0_\omega\}$ or one $|1_\omega\rangle$ photon in mode ω whose DOM is $\rho(\omega)$, and α_1, α_2, $\beta_{3,\omega}$, or $\beta_{4,\omega}$ are the corresponding probability amplitudes. Upon making the weak-field linear-response approximation, we can set $\alpha_1 \simeq 1$ and solve the set of equations for the slowly varying (compared to an optical cycle) probability amplitudes α and β, using the perturbation theory. Under these conditions, we effectively obtain a free-space propagation of the E_b field. By contrast, the evolution of the E_a field in the slowly varying envelope approximation, is given by $E_a(z,t) = E_a(0, t - z/v_g)\exp(ipz)$. We thus see that the real part of the macroscopic complex polarizability p is responsible for the phase shift ϕ_a of the E_a field, $\phi_a = \mathrm{Re}(p)z$, while the probability of the absorption $\mathscr{A}$ of the field depends on the imaginary part of p, $\mathscr{A} = 1 - \exp[-2\mathrm{Im}(p)z]$. The polarizability is expressed by

$$p = a_0 \frac{i\gamma_2/2}{\gamma_2/2 - i\Delta_a + I(\Delta_a)} \qquad [16]$$

where $a_0 \equiv \sigma_0 N$ is the linear resonant absorption coefficient on the atomic transition $|1\rangle \rightarrow |2\rangle$, with σ_0 the resonant absorption cross-section and N the density of doping atoms, γ_2 is the radiative width of

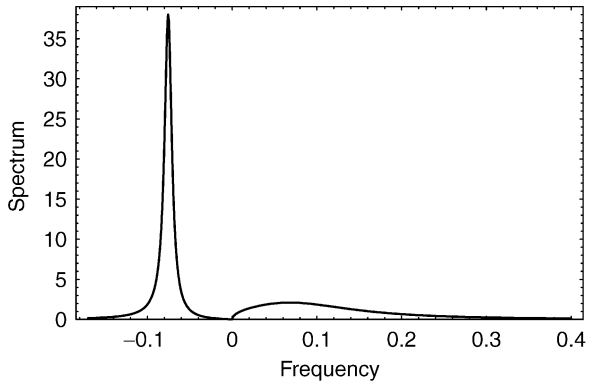

Figure 4 Spectrum w(ω)(same units as in Figures 2 and 3) for ω_a at cutoff, $\Delta_c = 0$, in the presence of a defect in the PBG, $\omega_d = -10$, $\gamma = 0.1$, $\Gamma_d = 3$, $\varepsilon = 10^{-3}$. The oscillator strength is now roughly equally shared between the distribution above cutoff (same as in Figure 2b) and the defect peak at ω_0.

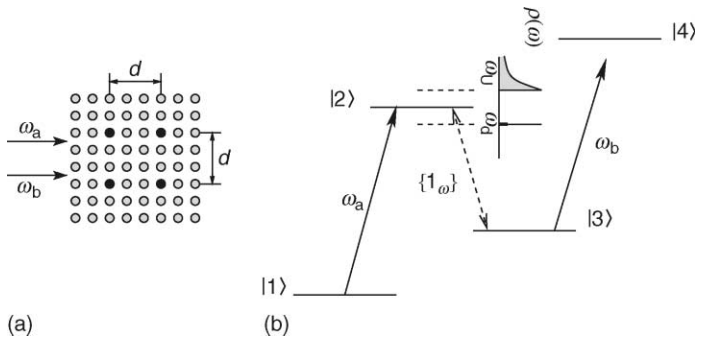

Figure 5 (a) Photonic crystal dilutely doped with atoms located at black dots. (b) Four-level atom coupled to a structured continuum $\rho(\omega)$ near the band-edge or defect mode frequencies (DOM plotted) via the intermediate transition $|2\rangle \rightarrow |3\rangle$ and interacting with two weak fields E_a and E_b at the sideband transitions $|1\rangle \rightarrow |2\rangle$ and $|3\rangle \rightarrow |4\rangle$, respectively.

state $|2\rangle$, $\Delta_a = \omega_a - \omega_{21}$ is the detuning from the atomic resonance ω_{21}, and $I(\Delta_a)$ is the integral of the saturation factor over the structured DOM. The group velocity v_g is expressed as $v_g = \partial_{k_a}\omega_a = [n_a/c + \partial_{\omega_a}\mathrm{Re}(p)]^{-1}$, where n_a is the (averaged) refraction index at the frequency ω_a.

To calculate $I(\Delta_a)$, we assume the isotropic PBG model, eqn [13] with $\varepsilon \to 0$, with the atoms doped at the positions of the local defects in the PC separated by a distance d from each other. These defect modes in the PBG are localized around each atomic site in a volume $V_d \simeq (rL)^3$ of several $(r)^3$ lattice cells L^3, with $L \simeq \pi c/\omega_{23}$, and serve as effective high-Q cavities, eqn [14] with $\Gamma_d \ll 1$. Assuming $|\Delta_b| \gg |\Delta|$, $|\Delta_a|$, γ_4, where $\Delta_b = \omega_b - \omega_{43}$ and $\Delta = \omega - \omega_{23}$, the integration leads to

$$I(\Delta_a) = \frac{B_d^2}{\gamma_{31} - i(\Delta_a - \Delta_d - s_3)} - \frac{B_U^{3/2}}{\sqrt{i\gamma_{31} + (\Delta_a - \Delta_U - s_3)}} \qquad [17]$$

where $\Delta_{d,U} = \omega_{d,U} - \omega_{23} \ll \omega_{23}$ are the detunings of the defect-mode and PBG-edge frequencies from the atomic resonance ω_{23}, γ_{31} the $|1\rangle \leftrightarrow |3\rangle$ decoherence rate, $s_3 = (\mu_{34}^2/\hbar^2\Delta_b)|E_b|^2$ is the E_b field-induced ac Stark shift of level $|3\rangle$ (μ_{ij} is the atomic dipole matrix element on the transition $|i\rangle \to |j\rangle$), and B_d and B_U are the coupling constants of the atom with the structured reservoir, whose main contributions are near ω_d and ω_U.

To illustrate the results of the foregoing analysis, we plot in Figure 6 the imaginary and real parts of the polarizability (eqn [16]). Consider first the case of one incident field $E_a(E_b = 0)$. Clearly, two frequency regions, $\Delta_a \sim \Delta_d$ and $\Delta_a \sim \Delta_U$, where the absorption vanishes and, at the same time, the dispersion slope is steep, are of particular interest. One can see that there is, however, a substantial difference between the spectra in the foregoing frequency regions, for the following physical reasons. First, in the vicinity of Δ_d, the atom interacts with the defect mode as in a high-Q cavity. This strong interaction 'dresses' the atomic states $|2\rangle$ and $|3\rangle$, thereby splitting the spectrum around $\Delta_a \simeq \Delta_d$ by the amount equal roughly to $2B_d$. Near the two-photon Raman resonance $\Delta_a = \Delta_d$, the two alternative transition paths $|1\rangle \to |2\rangle$ (the direct transition) and $|1\rangle \to |2\rangle \to |3\rangle \to |2\rangle$ (transition via state $|3\rangle$) interfere distractively with each other, cancelling thus the absorption of the E_a field and the medium becomes transparent to the radiation. This effect has been widely studied in atomic vapors, where the transition $|2\rangle \to |3\rangle$ is strongly driven by a coherent laser field, and is called electromagnetically induced transparency (EIT). The transparency window is rather broad and is given by the inverse Lorentzian (see the first term on the right-hand side of eqn [17]). Due to the steepness of the dispersion curve, the corresponding group velocity is much smaller than the speed of light, $v_g \simeq 2B_d^2/(\gamma_2 a_0) \ll c$, which leads to a large delay time $T_{del} = \zeta/v_g$ at the exit $z = \zeta$ from the medium. One has to keep in mind, however, that the absorption-free propagation time is limited by the EIT decoherence time $T_{del} < \gamma_{31}^{-1}$, which imposes a limitation on the length ζ of the active PC medium. Second, in the vicinity of Δ_U, the strong interaction of the atom with the continuum near the bandedge ω_U causes the Autler–Townes splitting of level $|2\rangle$ into a doublet with a separation equal roughly to B_U. One component of this doublet is shifted out of the PBG, while the other one remains

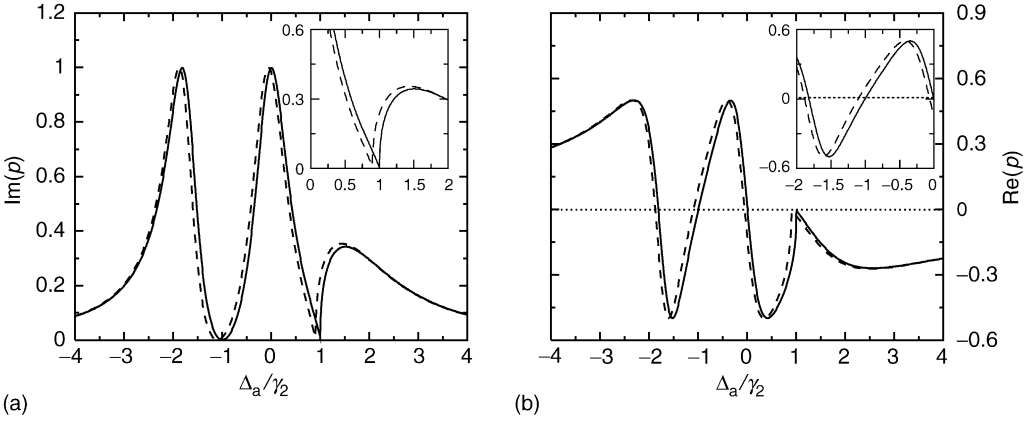

Figure 6 (a) Imaginary and (b) real part of the complex polarizability p as a function of the detuning Δ_a for the case $E_b = 0$ (solid lines) and $E_b \neq 0$ (dashed lines). The parameters (normalized by γ_2) are: $\Delta_d = -1$, $\Delta_U = 1$, $\gamma_{31} = 0.001$, $B_d = B_U = 1$, $s_3 = -0.1$, and $a_0 = 1\ \mathrm{cm}^{-1}$. The insets magnify the important frequency regions.

within the gap and forms the photon–atom bound state. Consequently, there is vanishing absorption and rapid variation of the dispersion at $\Delta_a \simeq \Delta_U$. Since the transparency region is very narrow with a width $\delta\omega \sim \gamma_{31}(\ll \gamma_2, B_U)$, for an absorption-free propagation of the E_a pulse, its temporal width τ_a should satisfy the condition $\tau_a > \pi/\delta\omega$. Simultaneously, a small deviation from the condition $\Delta_a = \Delta_U$ will lead to a strong increase in the absorption of the E_a field.

Let us now switch on the E_b field. As seen from eqn [17], its effect is merely to shift the spectrum by the amount equal to s_3 (Figure 6). This shift, however, will have different implications in the two frequency regions distinguished above: if $s_3 \ll B_d$, i.e., the Stark shift is smaller than the width of the EIT window at Δ_d, the medium will still remain transparent for an E_a field with the detuning $\Delta_a = \Delta_d$, but its phase will experience an appreciable nonlinear shift ϕ_a, given by $\phi_a = Re(p)z \simeq -\gamma_2 a_0 s_3 z/(2B_d^2)$. On the other hand, for an E_a field with the detuning $\Delta_a = \Delta_U$, the medium, which is transparent for $E_b = 0$, $\mathrm{Im}(p) \ll a_0$, will become highly absorptive (opaque) even for such a small frequency shift as s_3 (provided $s_3 < 0$ and $|s_3| > \Delta\omega$), $\mathrm{Im}(p) \simeq \gamma_2 a_0 \sqrt{|s_3|}/(2B_U^{3/2})$ and thus acting as an ultrasensitive, effective switch.

The remaining question is how to maximize the interaction between the E_a pulse, which propagates with a small group velocity, and the E_b pulse, which propagates with a velocity close to the speed of light. The interaction between the fields is maximized if: they enter the medium simultaneously; the transverse shapes of their envelopes overlap completely; and the pulse length l_b of the E_b field satisfies the condition $(l_b + \zeta)/c \leq \zeta/v_g$. Then the E_b pulse leaves the medium not later than the E_a pulse. The effective interaction length between the two pulses is, therefore, $z_{eff} \sim l_b v_g/c \leq \zeta$, after which the two pulses slip apart. Thus, the presence of the E_b (control) field induces either strong absorption or a large phase shift of the E_a (signal) field, depending on the frequency region employed.

The effects surveyed above reveal unusual features of spontaneous emission and photon–atom binding in PCs, atomic interaction with the field of a high-Q defect mode, and nonlinear coupling of two fields via four-level dopant atoms in PCs. These effects are of fundamental interest. In addition, they can serve as the basis for highly efficient optical communications and data processing, in either the classical or the quantum domain, by providing two key elements: ultrasensitive nonlinear phase-shifters and photon switches.

List of Units and Nomenclature

Atomic or photonic eigenstates [dimensionless]	$\|\ldots\rangle$
Complex polarizability [cm^{-1}]	p
Coupling constant [s^{-1}]	κ, $C^{2/3}$, B
Decay rate [s^{-1}]	γ
Density of modes [s]	ρ

Introduction

Photonic crystals are periodically structured electromagnetic media, generally possessing photonic bandgaps: ranges of frequency in which light cannot propagate through the structure. This periodicity, whose lengthscale is proportional to the wavelength of light in the bandgap, is the electromagnetic analog of a crystalline atomic lattice, where the latter acts on the electron wavefunction to produce the familiar band gaps, semiconductors, etc., of solid-state physics. The study of photonic crystals is likewise governed by the Bloch–Floquet theorem, and intentionally introduced defects in the crystal (analogous to electronic dopants) give rise to localized electromagnetic states: linear waveguides and point-like cavities. The crystal can thus form a kind of perfect optical 'insulator', which can confine light around sharp bends, in lower-index media, and within wavelength-scale cavities, among other novel possibilities for control of electromagnetic phenomena. Below is introduced the basic theoretical background of photonic crystals in one, two, and three dimensions (schematically depicted in Figure 1), as well as hybrid structures that combine photonic-crystal effects in some directions with more-conventional index guiding in other directions. (Line and point defects in photonic crystals are discussed in another article.)

Electromagnetic wave propagation in periodic media was first studied by Lord Rayleigh in 1887, in connection with the peculiar reflective properties of a crystalline mineral with periodic 'twinning' planes (across which the dielectric tensor undergoes a mirror flip). These correspond to one-dimensional photonic crystals, and he identified the fact that they have a narrow bandgap prohibiting light propagation through the planes. This bandgap is angle-dependent, due to the differing periodicities experienced by light propagating at non-normal incidences, producing a reflected color that varies sharply with angle. (A similar effect is responsible for many other iridescent colors in nature, such as those of butterfly wings and abalone shells.) Although multilayer films received intensive study over the following century, it was not until 100 years later, when Yablonovitch and John, in 1987, joined the tools of classical electromagnetism and solid-state physics, that the concepts of omnidirectional photonic bandgaps in two and three dimensions was introduced. This generalization, which inspired the name 'photonic crystal', led to many subsequent developments in their fabrication, theory, and application, from integrated optics to negative refraction to optical fibers that guide light in air.

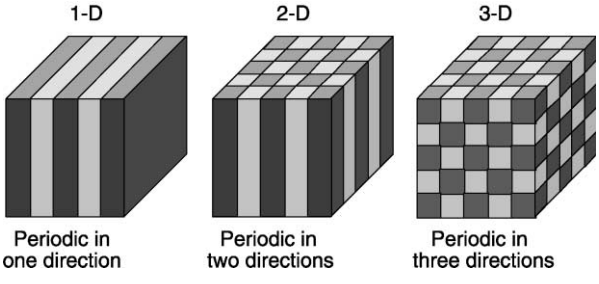

Figure 1 Schematic depiction of photonic crystals periodic in one, two, and three directions, where the periodicity is in the material (typically dielectric) structure of the crystal. Only a 3d periodicity, with a more complex topology than is shown here, can support an omnidirectional photonic bandgap.

Maxwell's Equations in Periodic Media

The study of wave propagation in three-dimensionally periodic media was pioneered by Felix Bloch in 1928, unknowingly extending an 1883 theorem in one dimension by Gaston Floquet. Bloch proved that waves in such a medium can propagate without scattering, their behavior described by a periodic envelope function multiplied by a planewave. Although Bloch studied quantum mechanics, leading to the surprising result that electrons in a conductor scatter only from imperfections and not from the periodic ions, the same techniques can be applied to electromagnetism by casting Maxwell's equations as an eigenproblem in analog with Schrödinger's equation. By combining the source-free Faraday's and Ampere's laws at a fixed (angular) frequency ω, i.e., time dependence $e^{-i\omega t}$, one can obtain an equation in only the magnetic field $\vec{H}$:

$$\vec{\nabla} \times \frac{1}{\varepsilon} \vec{\nabla} \times \vec{H} = \left(\frac{\omega}{c}\right)^2 \vec{H} \qquad [1]$$

where ε is the dielectric function $\varepsilon(x, y, z)$ and c is the speed of light. This is an eigenvalue equation, with eigenvalue $(\omega/c)^2$ and an eigen-operator $\vec{\nabla} \times (1/\varepsilon)\vec{\nabla} \times$ that is Hermitian (acts the same to the left and right)

under the inner product $\int \vec{H}^* \cdot \vec{H}'$ between two fields $\vec{H}$ and $\vec{H}'$. (The two curls correspond roughly to the 'kinetic energy' and $1/\varepsilon$ to the 'potential' compared to the Schrödinger Hamiltonian $\nabla^2 + V$.) It is sometimes more convenient to write a generalized Hermitian eigenproblem in the electric field $\vec{E}$, $\vec{\nabla} \times \vec{\nabla} \times \vec{E} = (\omega/c)^2 \varepsilon \vec{E}$, which separates the kinetic and potential terms. Electric fields that lie in higher ε, i.e., lower potential, will have lower ω; this is discussed further in the context of the variational theorem of eqn [3].

Thus, the same linear-algebraic theorems as those in quantum mechanics can be applied to the electromagnetic wave solutions. The fact that the eigen-operator is Hermitian and positive-definite (for real $\varepsilon > 0$) implies that the eigenfrequencies ω are real, for example, and also leads to orthogonality, variational formulations, and perturbation–theory relations that are discussed further below. An important difference compared to quantum mechanics is that there is a transversality constraint: one typically excludes $\vec{\nabla} \cdot \vec{H} \neq 0$ (or $\vec{\nabla} \cdot \varepsilon \vec{E} \neq 0$) eigensolutions, which lie at $\omega = 0$; i.e., static-field solutions with free magnetic (or electric) charge are forbidden.

Bloch Waves and Brillouin Zones

A photonic crystal corresponds to a periodic dielectric function $\varepsilon(\vec{x}) = \varepsilon(\vec{x} + \vec{R}_i)$ for some primitive lattice vectors $\vec{R}_i$ ($i = 1, 2, 3$ for a crystal periodic in all three dimensions). In this case, the Bloch–Floquet theorem for periodic eigenproblems states that the solutions to eqn [1] can be chosen of the form $\vec{H}(\vec{x}) = e^{i\vec{k}\cdot\vec{x}} \vec{H}_{n,\vec{k}}(\vec{x})$ with eigenvalues $\omega_n(\vec{k})$, where $\vec{H}_{n,\vec{k}}$ is a periodic envelope function satisfying

$$\left(\vec{\nabla} + i\vec{k}\right) \times \frac{1}{\varepsilon}\left(\vec{\nabla} + i\vec{k}\right) \times \vec{H}_{n,\vec{k}} = \frac{\omega_n(\vec{k})}{c}^2 \vec{H}_{n,\vec{k}} \qquad [2]$$

yielding a different Hermitian eigenproblem over the primitive cell of the lattice at each Bloch wavevector $\vec{k}$. This primitive cell is a finite domain if the structure is periodic in all directions, leading to discrete eigenvalues labeled by $n = 1, 2, \ldots$. These eigenvalues $\omega_n(\vec{k})$ are continuous functions of $\vec{k}$, forming discrete 'bands' when plotted versus the latter, in a 'band structure' or dispersion diagram – both ω and $\vec{k}$ are conserved quantities, meaning that a band diagram maps out all possible interactions in the system. (Note also that $\vec{k}$ is not required to be real; complex $\vec{k}$ gives evanescent modes that can exponentially decay from the boundaries of a finite crystal, but which cannot exist in the bulk.)

Moreover, the eigensolutions are periodic functions of $\vec{k}$ as well: the solution at $\vec{k}$ is the same as the solution at $\vec{k} + \vec{G}_j$, where $\vec{G}_j$ is a primitive reciprocal lattice vector defined by $\vec{R}_i \cdot \vec{G}_j = 2\pi\delta_{i,j}$. Thanks to this periodicity, one need only compute the eigensolutions for $\vec{k}$ within the primitive cell of this reciprocal lattice – or, more conventionally, one considers the set of inequivalent wavevectors closest to the $\vec{k} = 0$ origin, a region called the first Brillouin zone. For example, in a one-dimensional system, where $R_1 = a$ for some periodicity a and $G_1 = 2\pi/a$, the first Brillouin zone is the region $k = -\pi/a \ldots \pi/a$; all other wavevectors are equivalent to some point in this zone under translation by a multiple of G_1. Furthermore, the first Brillouin zone may itself be redundant if the crystal possesses additional symmetries such as mirror planes; by eliminating these redundant regions, one obtains the irreducible Brillouin zone, a convex polyhedron that can be found tabulated for most crystalline structures. In the preceding one-dimensional example, since most systems will have time-reversal symmetry ($k \to -k$), the irreducible Brillouin zone would be $k = 0 \ldots \pi/a$.

The familar dispersion relations of uniform waveguides arise as a special case of the Bloch formalism: such translational symmetry corresponds to a period $a \to 0$. In this case, the Brillouin zone of the wavevector k (also called β) is unbounded, and the envelope function $\vec{H}_{n,k}$ is a function only of the transverse coordinates.

The Origin of the Photonic Bandgap

A complete photonic bandgap is a range of ω in which there are no propagating (real $\vec{k}$) solutions of Maxwell's eqn [2] for any $\vec{k}$, surrounded by propagating states above and below the gap. There are also incomplete gaps, which only exist over a subset of all possible wavevectors, polarizations, and/or symmetries. Both sorts of gaps are discussed in the subsequent sections, but in either case, their origins are the same and can be understood by examining the consequences of periodicity for a simple one-dimensional system.

Consider a one-dimensional system with uniform $\varepsilon = \bar{\varepsilon}$, which has planewave eigensolutions $\omega(k) = ck$, as depicted in Figure 2(left). This ε has trivial periodicity a for any $a \geq 0$, with $a = 0$ giving the usual unbounded dispersion relation. One is free, however, to label the states in terms of Bloch envelope functions and wavevectors for some $a \neq 0$, in which case the bands for $|k| > \pi/a$ are translated (folded) into the first Brillouin zone, as shown by the dashed lines in Figure 2(left). In particular, the $k = -\pi/a$ mode in this description now lies at an equivalent wavevector to the $k = \pi/a$ mode, and at the same frequency; this accidental degeneracy is an artifact of

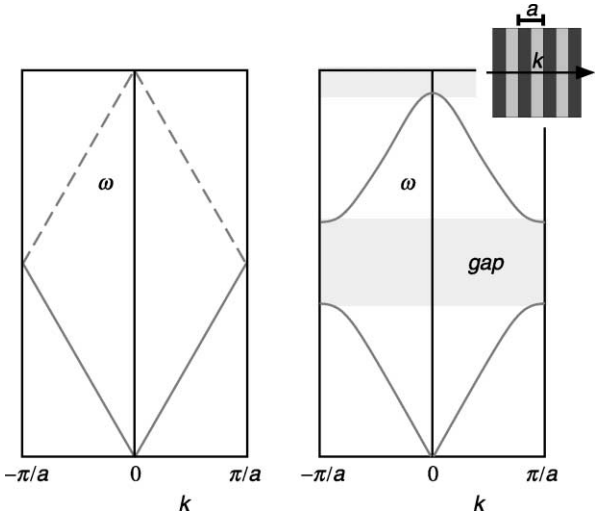

Figure 2 Left: Dispersion relation (band diagram), frequency ω versus wavenumber k, of a uniform one-dimensional medium, where the dashed lines show the 'folding' effect of applying Bloch's theorem with an artificial periodicity a. Right: Schematic effect on the bands of a physical periodic dielectric variation (inset), where a gap has been opened by splitting the degeneracy at the $k = \pm\pi/a$ Brillouin-zone boundaries (as well as a higher-order gap at $k = 0$).

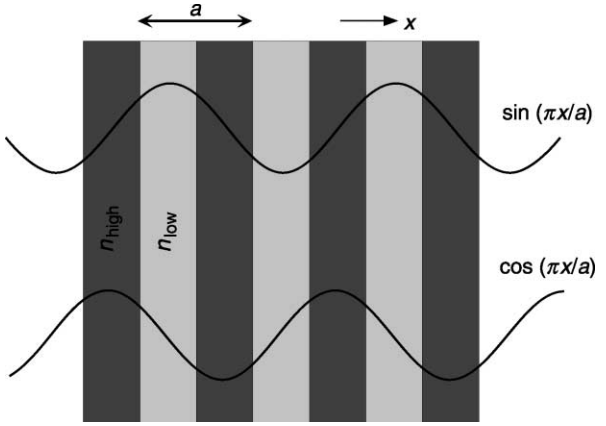

Figure 3 Schematic origin of the band gap in one dimension. The degenerate $ka = \pm\pi/a$ planewaves of a uniform medium are split into $\cos(\pi x/a)$ and $\sin(\pi x/a)$ standing waves by a dielectric periodicity, forming the lower and upper edges of the bandgap, respectively – the former has electric-field peaks in the high dielectric (n_{high}) and so will lie at a lower frequency than the latter (which peaks in the low dielectric).

the 'artificial' period that has been chosen. Instead of writing these wave solutions with electric fields $\vec{E}(x) \sim e^{\pm i\pi x/a}$, one can equivalently write linear combinations $e(x) = \cos(\pi x/a)$ and $o(x) = \sin(\pi x/a)$ as shown in Figure 3, both at $\omega = c\pi/a\sqrt{\bar{\varepsilon}}$. Now, however, suppose that one perturbs ε so that it is nontrivially periodic with period a; for example, a sinusoid $\varepsilon(x) = \bar{\varepsilon}\cdot[1 + \Delta\cdot\cos(2\pi x/a)]$, or a square wave as in the inset of Figure 2(right). In the presence of such an oscillating 'potential', the accidental degeneracy between $e(x)$ and $o(x)$ is broken: supposing $\Delta > 0$, then the field $e(x)$ is more concentrated in the higher-ε regions than $o(x)$, and so lies at a lower frequency. This opposite shifting of the bands away from the mid-gap frequency $\omega \cong c\pi/a\sqrt{\bar{\varepsilon}}$ creates a bandgap, as depicted in Figure 2(right). (In fact, from the perturbation theory described subsequently, one can show that for $\Delta \ll 1$ the bandgap, as a fraction of mid-gap frequency, is $\Delta\omega/\omega \cong \Delta/2$.) By the same arguments, it follows that any periodic dielectric variation in one dimension will lead to a bandgap, albeit a small gap for a small variation; a similar result was identified by Lord Rayleigh in 1887.

More generally, it follows immediately from the properties of Hermitian eigensystems that the eigenvalues minimize a variational problem:

$$\omega^2_{n,\vec{k}} = \min_{\vec{E}_{n,\vec{k}}} \frac{\int \left|\left(\vec{\nabla} + i\vec{k}\right)\times \vec{E}_{n,\vec{k}}\right|^2}{\int \varepsilon |\vec{E}_{n,\vec{k}}|^2} c^2 \qquad [3]$$

in terms of the periodic electric field envelope $\vec{E}_{n,\vec{k}}$, where the numerator minimizes the 'kinetic energy' and the denominator minimizes the 'potential energy' Here, the $n > 1$ bands are additionally constrained to be orthogonal to the lower bands:

$$\int \vec{H}^*_{m,\vec{k}} \cdot \vec{H}_{n,\vec{k}} = \int \varepsilon \vec{E}^*_{m,\vec{k}} \cdot \vec{E}_{n,\vec{k}} = 0 \qquad [4]$$

for $m < n$. Thus, at each $\vec{k}$, there will be a gap between the lower 'dielectric' bands concentrated in the high dielectric (low potential) and the upper 'air' bands that are less concentrated in the high dielectric: the air bands are forced out by the orthogonality condition, or otherwise must have fast oscillations that increase their kinetic energy. (The dielectric/air bands are analogous to the valence/conduction bands in a semiconductor.)

In order for a complete bandgap to arise in two or three dimensions, two additional hurdles must be overcome. First, although in each symmetry direction of the crystal (and each $\vec{k}$ point) there will be a bandgap by the one-dimensional argument, these bandgaps will not necessarily overlap in frequency (or even lie between the same bands). In order that they overlap, the gaps must be sufficiently large, which implies a minimum ε contrast (typically at least 4/1 in 3d). Since the 1d mid-gap frequency $\sim c\pi/a\sqrt{\bar{\varepsilon}}$ varies inversely with the period a, it is also helpful if the periodicity is nearly the same in different directions – thus, the largest gaps typically arise for hexagonal lattices in 2d and fcc lattices in 3d, which have the most nearly circular/spherical Brillouin zones. Second, one must take into account

the vectorial boundary conditions on the electric field: moving across a dielectric boundary from ε to some $\varepsilon' < \varepsilon$, the inverse 'potential' $\varepsilon|\vec{E}|^2$ will decrease discontinuously if $\vec{E}$ is parallel to the interface ($\vec{E}_\parallel$ is continuous) and will increase discontinuously if $\vec{E}$ is perpendicular to the interface ($\varepsilon\vec{E}_\perp$ is continuous). This means that, whenever the electric field lines cross a dielectric boundary, it is much harder to strongly contain the field energy within the high dielectric, and the converse is true when the field lines are parallel to a boundary. Thus, in order to obtain a large bandgap, a dielectric structure should consist of thin, continuous veins/membranes along which the electric field lines can run – this way, the lowest band(s) can be strongly confined, while the upper bands are forced to a much higher frequency because the thin veins cannot support multiple modes (except for two orthogonal polarizations). The veins must also run in all directions, so that this confinement can occur for all $\vec{k}$ and polarizations, necessitating a complex topology in the crystal.

Ultimately, however, in two or three dimensions there are only rules of thumb for the existence of a bandgap in a periodic structure, since no rigorous criteria have yet been determined. This made the design of 3d photonic crystals a trial and error process, with the first example by Ho *et al.* of a complete 3d gap coming three years after the initial 1987 concept. As is discussed by the final section below, a small number of families of 3d photonic crystals have since been identified, with many variations thereof explored for fabrication.

Computational Techniques

Because photonic crystals are generally complex, high index-contrast, two- and three-dimensional vectorial systems, numerical computations are a crucial part of most theoretical analyses. Such computations typically fall into three categories: time-domain 'numerical experiments' that model the time-evolution of the fields with arbitrary starting conditions in a discretized system (e.g., finite-difference); definite-frequency transfer matrices wherein the scattering matrices are computed in some basis to extract transmission/reflection through the structure; and frequency-domain methods to directly extract the Bloch fields and frequencies by diagonalizing the eigenoperator. The first two categories intuitively correspond to directly measurable quantities such as transmission (although they can also be used to compute e.g., eigenvalues), whereas the third is more abstract, yielding the band diagrams that provide a guide to interpretation of measurements as well as a starting-point for device design and semi-analytical methods. Moreover, several band diagrams are included in the following sections, and so the frequency-domain method used to compute them is briefly outlined here.

Any frequency–domain method begins by expanding the fields in some complete basis, $\vec{H}_{\vec{k}}(\vec{x}) = \sum_n h_n \vec{b}_n(\vec{x})$, transforming the partial differential eqn [2] into a discrete matrix eigenvalue problem for the coefficients h_n. Truncating the basis to N elements leads to $N \times N$ matrices, which could be diagonalized in $O(N^3)$ time by standard methods. This is impractical for large 3d systems, however, and is also unnecessary – typically, one only wants the few lowest eigenfrequencies, in which case one can use iterative eigensolver methods requiring only $\sim O(N)$ time. Perhaps the simplest such method is based directly on the variational theorem eqn [3]: given some starting coefficients h_n, one iteratively minimizes the variational 'Rayleigh' quotient using e.g., preconditioned conjugate–gradient descent. This yields the lowest band's eigenvalue and field, and upper bands are found by the same minimization while orthogonalizing against the lower bands ('deflation'). There is one additional difficulty, however, and that is that one must at the same time enforce the $(\vec{\nabla} + i\vec{k}) \cdot \vec{H}_{\vec{k}} = 0$ transversality constraint, which is nontrivial in three dimensions. The simplest way to maintain this constraint is to employ a basis that is already transverse, for example planewaves $\vec{h}_{\vec{G}} e^{i\vec{G}\cdot\vec{x}}$ with transverse amplitudes $\vec{h}_{\vec{G}} \cdot (\vec{G} + \vec{k}) = 0$. (In such a planewave basis, the action of the eigen-operator can be computed via a fast Fourier transform in $O(N \log N)$ time.)

Semi-analytical Methods: Perturbation Theory

As in quantum mechanics, the eigenstates can be the starting point for many analytical and semi-analytical studies. One common technique is perturbation theory, applied to small deviations from an ideal system – closely related to the variational eqn [3], perturbation theory can be exploited to consider effects such as nonlinearities, material absorption, fabrication disorder, and external tunability. Not only is perturbation theory useful in its own right, but it also illustrates both old and peculiarly new features that arise in such analyses of electromagnetism compared to scalar problems such as quantum mechanics.

Given an unperturbed eigenfield $\vec{E}_{n,\vec{k}}$ for a structure ε, the lowest-order correction $\Delta\omega_n^{(1)}$ to the eigenfrequency from a small perturbation $\Delta\varepsilon$ is given by

$$\Delta\omega_n^{(1)} = -\frac{\omega_n(\vec{k})}{2} \frac{\int \Delta\varepsilon \left|\vec{E}_{n,\vec{k}}\right|^2}{\int \varepsilon \left|\vec{E}_{n,\vec{k}}\right|^2} \qquad [5]$$

where the integral is over the primitive cell of the lattice. A Kerr nonlinearity would give $\Delta\varepsilon \sim |\vec{E}|^2$, material absorption would produce an imaginary frequency correction (decay coefficient) from a small imaginary $\Delta\varepsilon$, and so on. Similarly, one can compute the shift in frequency from a small $\Delta\vec{k}$ in order to determine the group velocity $d\omega/dk$; this variation of perturbation theory is also called $k \cdot p$ theory. All such first-order perturbation corrections are well known from quantum mechanics, and in the limit of infinitesimal perturbations give the exact Hellman–Feynman expression for the derivative of the eigenvalue. However, in the limit where $\Delta\varepsilon$ is a small shift Δh of a dielectric boundary between some ε_1 and ε_2, an important class of geometric perturbation, eqn [5] gives a surface integral of $|\vec{E}|^2$ on the interface, but this is ill-defined because the field there is discontinous. The proper derivation of perturbation theory in the face of such discontinuity requires a more careful limiting process from an anisotropically smoothed system, yielding the surface integral:

$$\Delta\omega_n^{(1)} = -\frac{\omega_n(\vec{k})}{2} \frac{\int\int \Delta h \left(\Delta\varepsilon_{12}|\vec{E}_{\parallel}|^2 - \Delta\varepsilon_{12}^{-1}|D_{\perp}|^2\right)}{\int \varepsilon |\vec{E}_{n,\vec{k}}|^2}$$

where $\Delta\varepsilon_{12} = \varepsilon_1 - \varepsilon_2, \Delta\varepsilon_{12}^{-1} = \varepsilon_1^{-1} - \varepsilon_2^{-1}$, and $\vec{E}_{\parallel}/D_{\perp}$ denotes the (continuous) interface parallel/perpendicular components of the unperturbed electric/displacement eigenfield. A similar expression is required in high index-contrast systems to employ, e.g., coupled-mode theory for slowly-varying waveguides or Green's functions for interface roughness.

Standard perturbation–theory techniques also provide expressions for higher-order corrections to the eigenvalue and eigenfield, based on an expansion in the basis of the unperturbed eigenfields. This approach, however, runs into immediate difficulty because the eigenfields are also subject to the transversality constraint, $(\vec{\nabla} + i\vec{k}) \cdot \varepsilon \vec{E}_{\vec{k}} = 0$, and this constraint varies with ε and $\vec{k}$ – the eigenfields $\vec{E}_{\vec{k}}$ are not a complete basis for the eigenfields constrained at a different ε or $\vec{k}$. For ε perturbations, this problem can be eliminated by using the $\vec{H}$ or $\vec{D}$ eigenproblems, whose constraints are independent of ε. For $\vec{k}$ perturbations, one can employ a transformation by Sipe to derive a corrected higher-order perturbation theory (for e.g., the group-velocity dispersion), based on the fact that all of the non-transverse fields lie at $\omega = 0$. Such completeness issues also arise applying the variational eqn [3], as was noted in the previous section: in order for a useful variational bound to apply, one must operate in the constrained (transverse) subspace.

Two-Dimensional Photonic Crystals

After the identification of one-dimensional bandgaps, it took a full century to add a second dimension, and three years to add the third. It should therefore come as no surprise that 2d systems exhibit most of the important characteristics of photonic crystals, from nontrivial Brillouin zones to topological sensitivity to a minimum index contrast, and can also be used to demonstrate most proposed photonic–crystal devices. The key to understanding photonic crystals in two dimensions is to realize that the fields in 2d can be divided into two polarizations by symmetry: *TM* (transverse magnetic), in which the magnetic field is in the (xy) plane and the electric field is perpendicular (z); and *TE* (transverse electric), in which the electric field is in the plane and the magnetic field is perpendicular.

Corresponding to the polarizations, there are two basic topologies for 2d photonic crystals, as depicted in Figure 4(top): high index rods surrounded by low index (top) and low-index holes in high index (bottom). Here, a hexagonal lattice is used because, as noted earlier, it gives the largest gaps. Recall that a photonic band gap requires that the electric field lines run along thin veins: thus, the rods are best suited to TM light ($\vec{E}$ parallel to the rods), and the holes are best suited to TE light ($\vec{E}$ running around the holes). This preference is reflected in the band diagrams, shown in Figure 4, in which the rods/holes (top/bottom) have a strong TM/TE band gap. For these diagrams, the rod/hole radius is chosen to be $0.2a/0.3a$, where a is the lattice constant (the nearest-neighbor periodicity) and the high/low ε is 12/1. The TM/TE bandgaps are then 47%/28% as a fraction of mid-gap frequency, but these bandgaps require a minimum ε contrast of 1.7/1 and 1.9/1, respectively. Moreover, it is conventional to give the frequencies ω in units of $2\pi c/a$, which is equivalent to a/λ (λ being the vacuum wavelength) – Maxwell's equations are scale-invariant, and the same solutions can be applied to any wavelength simply by choosing the appropriate a. For example, the TM mid-gap ω in these units is 0.36, so if one wanted this to correspond to $\lambda = 1.55\ \mu m$ one would use $a = 0.36 \cdot 1.55\ \mu m = 0.56\ \mu m$.

The Brillouin zone (a hexagon) is shown at left-center, with the irreducible Brillouin zone shaded (following the sixfold symmetry of the crystal); the corners (high symmetry points) of this zone are given canonical names, where Γ always denotes the origin $\vec{k} = 0$, K is the nearest-neighbor direction,

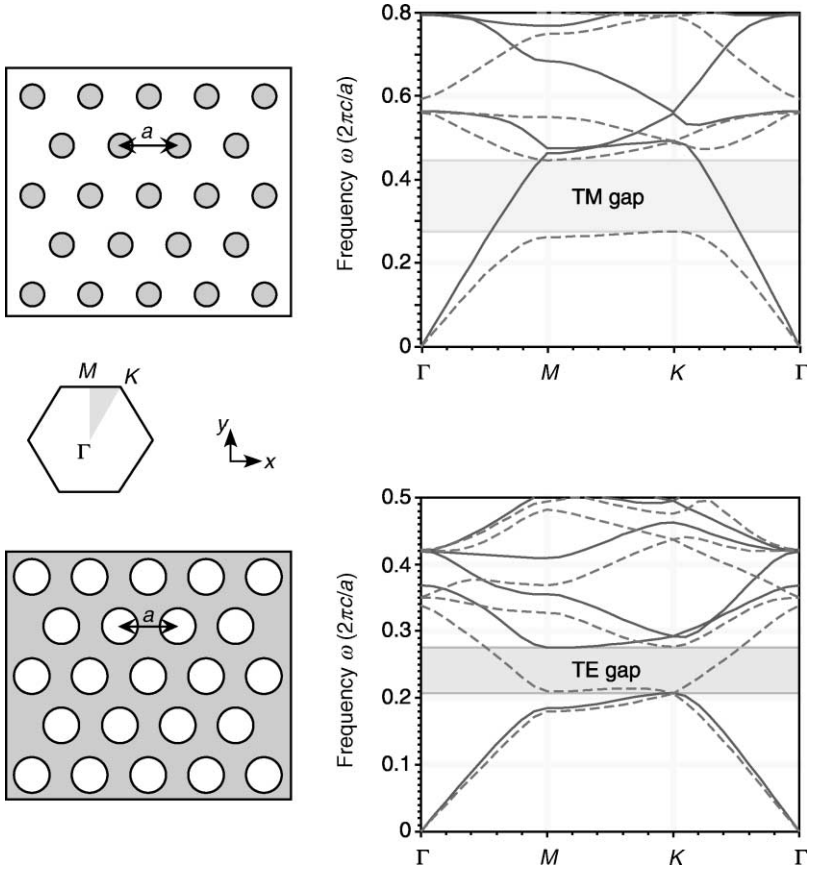

Figure 4 Band diagrams and photonic band gaps for hexagonal lattices of high dielectric rods ($\varepsilon = 12$, $r = 0.2a$) in air (top), and air holes ($r = 0.3a$) in dielectric (bottom), where a is the center–center periodicity. The frequencies are plotted around the boundary of the irreducible Brillouin zone (shaded triangle, left center), with solid/dashed lines denoting TE/TM polarization (electric field parallel/perpendicular to plane of periodicity). The rods/holes have a gap in the TM/TE bands.

and M is the next-nearest-neighbor direction. The Brillouin zone is a two-dimensional region of wavevectors, so the bands $\omega_n(\vec{k})$ are actually surfaces, but in practice the band extrema almost always occur along the boundaries of the irreducible zone (i.e., the high-symmetry directions). So, it is conventional to plot the bands only along these zone boundaries in order to identify the bandgap, as is done in Figure 4.

Actually, the hole lattice can display not only a TE gap, but a complete photonic bandgap (for both polarizations) if the holes are sufficiently large (nearly touching). In this case, the thin veins between nearest-neighbor holes induce a TE gap, while the interstices between triplets of holes form 'rod-like' regions that support a TM gap overlapping the TE gap.

Photonic-Crystal Slabs

In order to realize 2d photonic-crystal phenomena in three dimensions, the most straightforward design is to simply fabricate a 2d-periodic crystal with a finite height: a photonic-crystal slab, as depicted in Figure 5. Such a structure can confine light vertically within the slab via index guiding, a generalization of total internal reflection – this mechanism is the source of several new tradeoffs and behaviors of slab systems compared to their 2d analogs.

The key to index guiding is the fact that the 2d periodicity implies that the 2d Bloch wavevector $\vec{k}_{\|}$ is a conserved quantity, so the projected band structure – all states in the bulk substrate/superstrate (the uniform regions far below/above the slab) versus their in-plane wavevector component (projected wavevector) – creates a map of which states can radiate vertically. If the slab is suspended in air, for example, then the eigensolutions of the bulk air are $\omega = c\sqrt{|\vec{k}_{\|}|^2 + k_{\perp}^2}$, which when plotted versus $\vec{k}_{\|}$ forms the continuous light cone $\omega \geq c|\vec{k}_{\|}|$, shown as a shaded region in Figure 5. Because the slab has a higher ε (12) than the air (1), and frequency goes as $1/\sqrt{\varepsilon}$, discrete guided bands are 'pulled down' in frequency from this continuum – these bands, lying beneath the light cone, cannot couple to any vertically

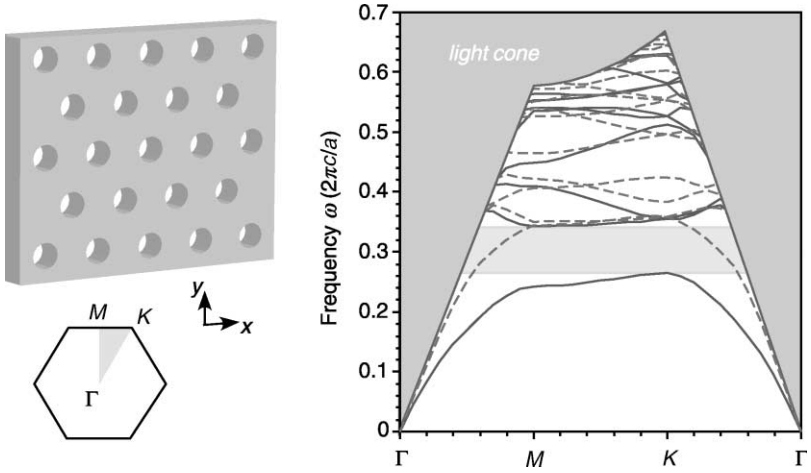

Figure 5 Projected band diagram for a finite-thickness (0.5*a*) slab of air holes in dielectric (cross section as in **Figure 4** bottom), with the irreducible Brillouin zone at lower left. The shaded region is the light cone: the projection of all states that can radiate in the air. Solid/dashed lines denote guided modes (confined to the slab) that are even/odd with respect to the horizontal mirror plane of the slab, whose polarization is TE-like/TM-like, respectively. There is a 'bandgap' (region without guided modes) in the TE-like guided modes only.

radiating mode by the conservation law and so are confined to the slab (exponentially decaying away from it). If the horizontal mid-plane of the slab is a mirror symmetry plane, then just as there were TM and TE states in 2d, here there are two categories of modes: even (TE-like) and odd (TM-like) modes under reflections through the mirror plane (which are purely TE/TM in the mirror plane itself). Because the slab here is based on the 2d hole crystal, which had a TE gap, here there is a 26% 'bandgap' in the even modes: a range of frequencies in which there are no guided modes. It is not a complete photonic bandgap, not only because of the odd modes, but also because there are radiating (light cone) modes at every ω. The presence of these radiating modes means that if all in-plane translational symmetry is broken by a localized change in the structure, say a waveguide bend or a resonant cavity, then vertical radiation losses are inevitable; there are various strategies to minimize the losses to tolerable levels, however. On the other hand, if only one direction of translational symmetry is broken, as in a linear-defect waveguide, ideally lossless guiding can be maintained.

Photonic-crystal slabs have two new critical parameters that influence the existence of a gap. First, it must have vertical mirror symmetry in order that the gaps in the even and odd modes be treatable separately – such symmetry is broken by the presence of a substrate that is not the mirror image of the superstrate, but in practice the symmetry breaking can be weak if the index contrast is sufficiently high (so that the modes are strongly confined in the slab). Second, the height of the slab must not be too small (or the modes will be weakly confined) or too large (or higher-order modes will fill the gap); the optimum height is around half a wavelength λ/n_{eff} (relative to an average/effective index n_{eff} that depends on the polarization). In **Figure 5**, a height of $0.5a$ is used, which is near the optimum (with holes of radius $0.3a$ and $\varepsilon = 12$ as in the previous section).

Three-Dimensional Photonic Crystals

Photonic-crystal slabs are one way of realizing 2d photonic-crystal effects in three dimensions; an example of another way, lifting the sacrifices imposed by the light cone, is depicted in **Figure 6**. This is a 3d-periodic crystal, formed by an alternating hole-slab/rod-slab sequence in an ABCABC stacking of bilayers – equivalently, it is an fcc (face-centered cubic) lattice of air cylinders in dielectric, stacked and oriented in the 111 direction, where each overlapping layer of cylinders forms a rod/hole bilayer simultaneously. Its band diagram is shown in **Figure 6** along the boundaries of its irreducible Brillouin zone (from a truncated octahedron, inset), and this structure has a >21% complete gap ($\Delta\omega$ as a fraction of mid-gap frequency) for $\varepsilon = 12/1$, forbidding light propagation for all wavevectors (directions) and all polarizations. Not only can this crystal confine light perfectly in 3d, but because its layers resemble 2d rod/hole crystals, it turns out that the confined modes created by defects in these layers strongly resemble the TM/TE states created by corresponding defects in two dimensions. One can therefore use this crystal to directly transfer designs from two to three dimensions while retaining omnidirectional confinement. Its fabrication, of

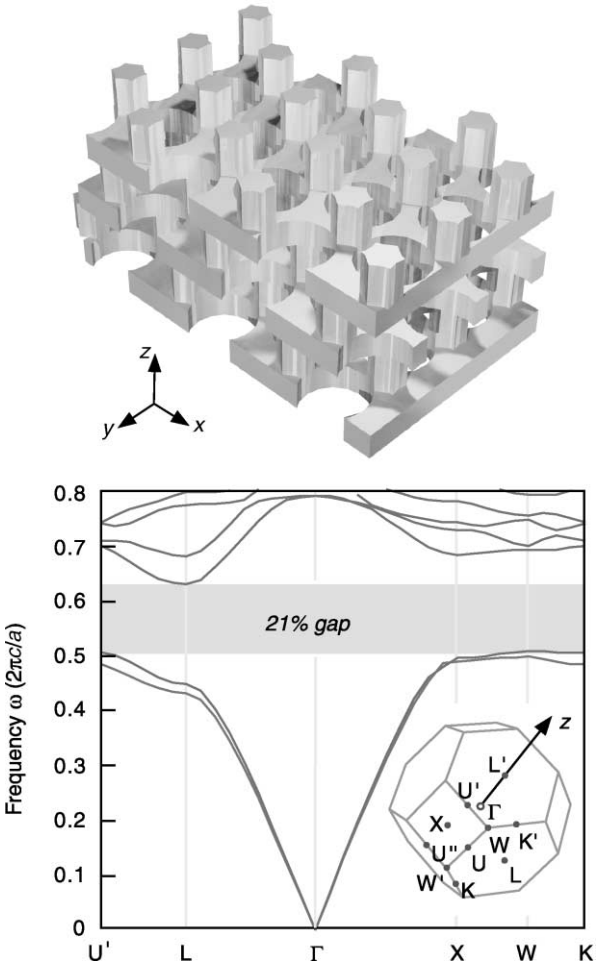

Figure 6 Band diagram (bottom) for 3d-periodic photonic crystal (top) consisting of an alternating stack of rod and hole 2d-periodic slabs (similar to **Figure 4**), with the corners of the irreducible Brillouin zone labeled in the inset. This structure exhibits a $\Delta\omega/\omega_{\text{midgap}} = 21\%$ omnidirectional bandgap.

course, is more complex than that of photonic-crystal slabs (with a minimum ε contrast of 4/1), but this and other 3d photonic crystal structures have been constructed even at micron (infrared) lengthscales, as described below.

There are three general dielectric topologies that have been identified to support complete 3d gaps for $\varepsilon = 12/1$ (e.g., Si:air) contrast: diamond-like arrangements of high dielectric 'atoms' surrounded by low dielectric, which can lead to $>20\%$ gaps between the 2nd and 3rd bands; fcc 'inverse opal' lattices of nearly-touching low dielectric spheres (or similar) surrounded by high dielectric, giving gaps around 10% between the 9th and 10th bands; and cubic 'scaffold' lattices of rods along the cube edges, giving $\sim$7% gaps between the 2nd and 3rd bands. It is notable that the first two topologies correspond to fcc lattices, which have the most nearly spherical Brillouin zones in accordance with the rules of thumb given above. Many variations on these topologies continue to be proposed – for example, the structure of **Figure 6** is diamond/graphite-like – mainly in conjunction with different fabrication strategies, such as the following three successful approaches. First, layer-by-layer fabrication, in which individual crystal layers (typically of constant cross-section) are deposited one-by-one and etched with a 2d pattern via standard lithographic methods (giving fine control over placement of defects, etc.); **Figure 6** can be constructed in this fashion (as well as other diamond-like structures with large gaps). Second, colloidal self-assembly, in which small dielectric spheres in a fluid automatically arrange themselves into close-packed (fcc) crystals by surface forces – these crystals can be back-filled with a high-index material, out of which the original spheres are dissolved in order to form inverse–opal crystals with a complete gap. Third, holographic lithography, in which a variety of 3d crystals can be formed by an interference pattern of four laser beams to harden a light-sensitive resin (which is then back-filled and dissolved, as with colloids, to achieve the requisite index contrast). The second and third techniques are notable for their ability to construct large-scale 3d crystals (thousands of periods) in a short time.

Photonic Crystals

Photonic crystals are materials that have a periodically varying dielectric constant that results in a bandgap, or range of frequencies where electromagnetic waves are unable to propagate. A simple one-dimensional example is the Bragg mirror, or quarter-wave stack, in which periodic layers of alternating dielectrics reflect photons within a frequency band determined by the thickness and refractive index of the layers. Photonic crystals are the extension of this concept into two or three dimensions. They are constructed as a lattice of two different dielectrics, and examples include a triangular lattice of circular rods, or a diamond lattice of spheres. Certain geometries will produce a bandgap, within which propagation is impossible in any direction. These materials are the photonic analog of semiconductors, in that their periodic dielectric function provides a bandgap for photons in much the same way that the periodic atomic potential of a crystal lattice can provide a bandgap for electrons.

While most photonic crystal research has focused on optical wavelength structures, many of the first experimental studies were performed on scale models at microwave frequencies, where fabrication and measurements were simpler. Operating at microwave frequencies also allowed a new class of materials to emerge, based on metals and lumped circuit elements. The nearly infinite dielectric contrast provided by the use of metals, and the ability to make complex subwavelength scale structures at radio frequencies, allows photonic crystals with ultra-wide bandgaps to be produced. Furthermore, the use of lumped circuit elements allows the electromagnetic properties to be easily tuned, resulting in unique microwave structures.

Wire Mesh Photonic Crystals

At optical frequencies, conductive losses preclude the use of metals for many applications. However, at microwave frequencies, metals are nearly ideal materials, since they have low loss and are easily formed into complicated geometries. The simplest metallic photonic crystal is a three-dimensional wire mesh, shown in Figure 1. This example resembles a diamond crystal lattice, in which metal wires have been substituted for atomic bonds. It can be constructed using zig-zag-shaped metal strips that fit together to form a continuous conductive network.

The electromagnetic properties of this wire mesh can be understood by considering a traditional microwave analog: an array of metal waveguides. Open tunnels permeate the mesh in various directions, and it behaves as an interpenetrating fabric of waveguides, whose walls are defined by the wires. Shorter wavelengths, that fit between the wires, can propagate through the crystal, while longer waves see the mesh as a continuous metal surface, and are reflected. As for a conventional waveguide, the cutoff frequency occurs approximately where one half wavelength fits between the rows of wires. Similarly, for a diamond lattice of wires, the cutoff frequency is

$$\omega_{\text{cutoff}} = \frac{\pi c}{na} \qquad [1]$$

where n is the refractive index of the material between the wires, and a is the length of the unit cube of the diamond lattice. Because the cutoff frequency is primarily determined by the diameter of the open tunnels, and it is largely independent of the detailed arrangement of the wires, other mesh geometries can

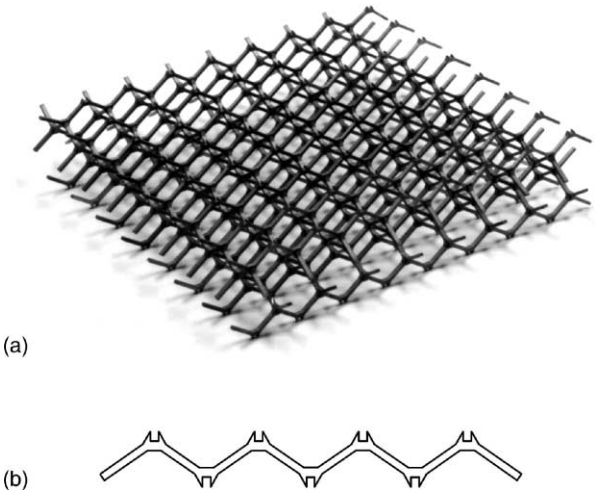

Figure 1 A wire mesh photonic crystal with diamond geometry. (a) The mesh forms continuous conductive structure that is permeated with open tunnels. Figure 2 The transmission magnitude through a conductive wire mesh photonic crystal as a function of frequency, ω. Shorter wavelengths can propagate through the open tunnels, while longer wavelengths see the mesh as a continuous block of metal. The cutoff frequency is determined largely by the lattice constant, a, and the refractive index, n, of the material between the wires. A cut wire forms a defect state within the band gap.

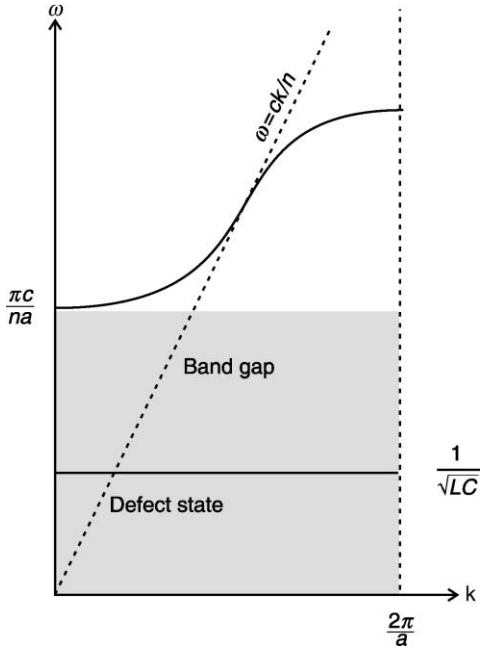

Figure 3 The dispersion diagram for a wire mesh photonic crystal, plotted as frequency, ω, versus wave vector k. The bandgap extends to zero frequency. The lower bandedge of the allowed band is determined largely by the lattice constant. Like other photonic crystals, the wire mesh also supports higher frequency bands, which are not shown. A point defect such as a cut wire creates a mode at a single frequency, which contains all wave vectors.

be expected to give similar results. However, the cutoff frequency can vary by a constant of order unity, depending on the lattice and the unit cell chosen.

The transmission magnitude, as a function of frequency for such a mesh, is depicted in Figure 2. Experimentally, it is found that a typical wire mesh structure attenuates roughly 6 dB per layer for frequencies below cutoff. However, because the exact transmission magnitude above cutoff depends on details of the measurement, such as impedance matching at the crystal boundary, the vertical scale shown here is arbitrary, and the intent is simply to give the qualitative behavior of these and similar crystal structures. Waves just below the cutoff frequency can penetrate a crystal with finite thickness, as depicted by the finite slope of the transmission edge.

We can better understand the behavior of waves within the crystal by examining the dispersion diagram, shown in Figure 3, in which we plot the allowed frequencies as a function of wave vector $k = 2\pi/\lambda$, the spatial frequency of waves inside the material. A band of allowed frequencies is bounded by upper and lower band edges, corresponding to high and low cutoff frequencies, beyond which propagation is forbidden. The reflective nature of the crystal below cutoff is shown as a bandgap that extends down to zero frequency. The slope of the dispersion curve corresponds to the group velocity of waves within the allowed band, and states at the bandedges represent standing waves. The upper edge of this band occurs where the wavelength matches the periodicity of the crystal, and for a diamond mesh, it is approximately

$$\omega_{\text{lattice}} = \frac{2\pi c}{na} \qquad [2]$$

Like traditional dielectric photonic crystals, these wire mesh structures also have higher order bands and gaps that occur at higher frequencies. The nature of the higher band structure depends on the detailed geometry of the mesh to a much greater extent than the lowest order gap, which is our primary interest for radio frequency materials.

Defect States

As in semiconductor crystals, we can alter the behavior of photonic crystals by adding defects to create localized states within the bandgap. For the wire mesh photonic crystal, a defect may be a cut wire, or a lumped circuit element inserted into the mesh. For example, replacing one of the wires with a capacitor creates a parallel resonant circuit, which acts as a small electromagnetic cavity within the mesh. Its resonance frequency is given by

$$\omega_{\text{defect}} = \frac{1}{\sqrt{LC}} \qquad [3]$$

where C is the capacitance of the defect, and L is the inductance of the surrounding wires. The inductance depends logarithmically on the wire diameter, so it is largely fixed for a given mesh lattice. However, the capacitance can be easily changed, since it is a simple lumped circuit element. Thus, by adding capacitive defects we can create tunable local states within the bandgap. The presence of a defect is seen as a narrow transmission band within the bandgap, shown in Figure 2. Because a point defect contains all wave vectors, it is shown as a horizontal line in the dispersion diagram in Figure 3.

If two defects are located in close proximity, their modes overlap, and they interact with each other. For example, two neighboring defects with identical capacitance will exhibit a split pair of resonances, corresponding to a lower frequency symmetric mode, and a higher frequency anti-symmetric mode. The modes are highly localized at the defects, and this interaction is limited to defects that are within one or two lattice constants of each other. If one member of a pair of nearby defects is tuned with respect to the other, the frequencies the two modes exhibit are an avoided crossing behavior, as is typical in many systems of coupled oscillators. The resonance frequencies for more complex arrangements of defects can be calculated by assigning an interaction energy to each neighboring pair, and solving the resulting Hamiltonian matrix to find the energy levels of the complete system. In this way, the interaction among defects in small clusters is analogous to atoms in simple molecules, and the resulting energy level structure is similar.

As more defects are added periodically throughout the mesh, they form a superlattice, and their states merge into an additional band within the original bandgap. The upper frequency of this band depends on the LC resonance frequency of the defects. The lower frequency depends on the density of the remaining wires, since waves at the lower bandedge must be able to fit through the open regions in the mesh. In the extreme case, where every wire is cut and replaced by a capacitor, the mesh is no longer a continuous conductive network. These structures have an allowed band that extends to zero frequency, and they will be explored in greater detail in the next section. Not every wire must be cut to reach this limit, and the conditions for this to occur are the subject of percolation theory.

Capacitive Mesh Photonic Crystals

In a capacitive mesh photonic crystal, small isolated metal islands are distributed on a lattice, and they are capacitively coupled to their neighbors. This represents the extreme case of the wire mesh photonic crystal, where every wire has been cut, and replaced by a capacitor. An example of such a structure, built as a stack of printed circuit boards, is shown in Figure 4. A diamond lattice can be approximated using planar circuit boards, with printed tetrapodal structures consisting of two orthogonal metal strips connected by a metal plated via. Each metallic island couples to its four nearest neighbors through their overlapping capacitor plates.

The capacitive mesh photonic crystal is transmissive at low frequencies because it is not traversed by conducting paths, like the continuous wire mesh version. The crystal supports a lower band that extends from zero frequency, up to an LC resonance frequency:

$$\omega_{\text{lower}} = \frac{1}{\sqrt{LC}} \qquad [4]$$

which marks the lower edge of the bandgap. This is determined by the capacitance between the metal islands, and the inductance associated with each island. At higher frequencies, the capacitors appear as shorts, and the crystal behaves similarly to the conductive wire mesh structure described previously, with an upper edge given by

$$\omega_{\text{upper}} = \frac{\pi c}{na} \qquad [5]$$

At this frequency, the waves can again fit through the open areas between the metallic islands. The transmission magnitude, as a function of frequency for the capacitive mesh photonic crystal, is shown in Figure 5, and the additional band is illustrated in the dispersion diagram in Figure 6. Like the conductive wire mesh, the capacitive mesh also has a rich upper band structure, that is outside the scope of this article.

With these capacitive mesh structures, it is possible to create materials with finite, but arbitrarily large bandgaps, because the upper and lower edges of the bandgap are controlled independently by the lattice constant and the capacitance, respectively. In conventional dielectric photonic crystals, the width of the bandgap depends on the dielectric contrast between the constituent materials. Waves at the upper edge primarily reside in the lower dielectric material, and waves at the lower edge inhabit the higher dielectric material. This reasoning can also be applied to capacitive mesh structures. The lower dielectric is the substrate material that fills the open spaces between the metal islands, and modes at the upper edge of the gap primarily fill these open spaces. However, for modes at the lower edge of the gap, the electric field is primarily concentrated within the capacitors. The metal regions and the capacitors can

The crystal is transparent at low frequencies, because the conducting paths are broken by capacitors. At higher frequencies, the capacitors appear as shorts, and crystal behaves like a solid wire mesh.

be considered as an effective medium, or artificial dielectric whose properties depend on the density, arrangement, and values of the capacitors. By using large capacitors, the dielectric contrast can be made arbitrarily large, and the bandgap arbitrarily wide.

Within the bandgap, these materials can support surface waves, which are modes that are bound to the interface between the crystal and free space. Surface waves propagate along the crystal surface, and they have their own band structure. In the following sections, we examine these waves, and we will introduce periodically textured surfaces that suppress them, much like three-dimensional photonic crystals suppress internal plane waves.

Surface Waves

Electromagnetic waves that are bound to the interface between two materials are known as surface waves. They exist on ordinary metals, and at optical frequencies they are often called surface plasmons. They also exist on photonic crystals within the

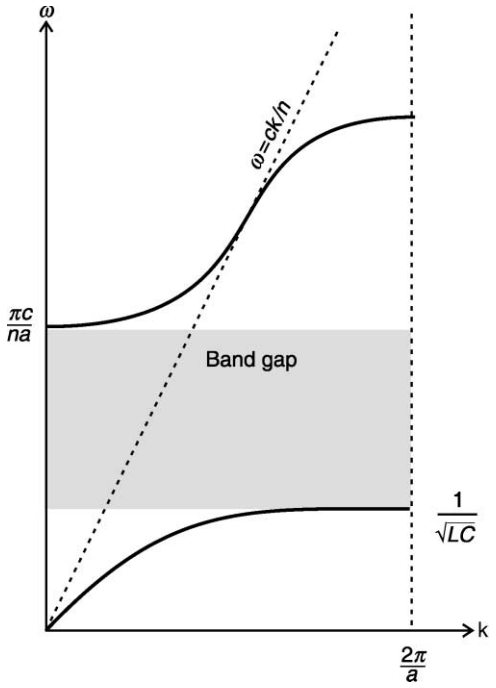

Figure 6 The dispersion diagram of the capacitive mesh photonic crystal. The two edges of the bandgap can be adjusted independently by varying the lattice constant and the capacitance.

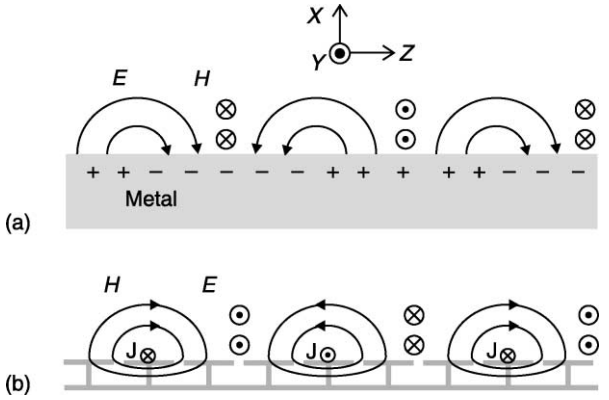

Figure 7 Surface waves can be classified into two polarizations. (a) A TM wave, shown on a metal surface; (b) A TE wave, shown on a textured surface. TM waves consist of electric charges on the metal surface that oscillate along the direction of propagation. They have nonzero electric field components both perpendicular to the surface, and parallel to the direction of propagation. TE waves are associated with transverse currents in the surface. They are similar to TM waves, but with the electric and magnetic fields exchanged.

bandgap region, as well as on other impenetrable materials. They cannot propagate into the crystal because of Bragg reflection, yet they are prevented from escaping into free space by total internal reflection. They typically interact strongly with the top layer of the crystal, and they can often be manipulated or suppressed by adjusting the geometry of that layer. At radio and microwave frequencies, these waves are usually called surface currents, because the associated fields are only loosely bound to the surface, and extend a great distance into free space. Their presence can be seen in antenna radiation patterns and other phenomena, and by suppressing them we can make a variety of unique radio frequency devices. However, we must first understand the nature of these waves.

To understand the nature of these surface currents, we begin by examining surface waves on metals, where we assume a wave confined to a dielectric interface, and then insert the complex dielectric constant of a metal. Consider a surface in the YZ plane, where $X < 0$ is filled with dielectric ε, and $X > 0$ is filled with vacuum. A wave propagates in the Z direction with propagation constant k. For transverse magnetic (TM) polarized waves, which are illustrated in Figure 7, the transverse electric field $E_y = 0$. The electric field has the form

$$E_1 = (\hat{x}E_{1x} + \hat{z}E_{1z})e^{i\omega x - ikz - \alpha x} \qquad [6]$$

for $X > 0$ and

$$E_2 = (\hat{x}E_{2x} + \hat{z}E_{2z})e^{i\omega x - ikz + \gamma x} \qquad [7]$$

for $X < 0$, where α and γ are the attenuation constants into free space and dielectric, respectively. The fields of such a wave are shown in Figure 7. We can solve the wave equation for the electric field:

$$\nabla \times \nabla \times \vec{E} = \varepsilon_r \frac{\omega^2}{c^2} \frac{\partial^2 \vec{E}}{\partial t^2} \qquad [8]$$

by matching E_x and $\varepsilon_r E_z$, at the interface to yield

$$k = \sqrt{\frac{\varepsilon}{1+\varepsilon}} \frac{\omega}{c} \qquad [9]$$

$$\alpha = \sqrt{\frac{-1}{1+\varepsilon}} \frac{\omega}{c} \qquad [10]$$

$$\gamma = \sqrt{\frac{-\varepsilon^2}{1+\varepsilon}} \frac{\omega}{c} \qquad [11]$$

A solution for transverse electric (TE) waves, where $H_y = 0$, can be found by applying the principle of duality, by exchanging the electric and magnetic fields, and substituting μ for ε.

For surface waves on a metal surface, we insert the dielectric constant of a metal, which is

$$\varepsilon = 1 - \frac{i\sigma}{\omega\varepsilon_0} \qquad [12]$$

The conductivity, λ, is

$$\sigma = \frac{nq^2\tau/m}{1 + i\omega\tau} \qquad [13]$$

where τ is the mean electron collision time, q is the electron charge, m and n are the effective mass and the density, respectively, of the conduction electrons. For frequencies much lower than $1/\tau$, which includes microwave and radio frequencies, we can substitute eqns [12] and [13] into eqn [9] to find

$$k \approx \frac{\omega}{c} \qquad [14]$$

Thus, surface waves on metals propagate at nearly the speed of light in vacuum, and they travel for many wavelengths with little attenuation. We can also solve for the decay constants into free space using eqn [10]:

$$\alpha = (1 - i)\frac{\omega}{c}\sqrt{\frac{\omega\varepsilon_0}{2\sigma}} \qquad [15]$$

and into the metal using eqn [11]:

$$\gamma \approx (1 + i)\sqrt{\frac{\omega\mu_0\sigma}{2}} = \frac{(1 + i)}{\delta} \qquad [16]$$

where δ is recognized as the skin depth. Thus, we have derived the skin depth of a metal from the penetration depth of surface waves.

From the skin depth, we can derive the impedance of a metal sheet. Assuming that E_0 is the electric field at the surface, the surface current is given by

$$J_z(x) = \sigma E_z(x) = \sigma E_0 e^{-x(1+i)/\delta} \qquad [17]$$

The magnetic field at the surface is found by integrating along a path that surrounds the surface current:

$$H_0 = \int_0^{-\infty} J_z(x)\mathrm{d}x = \frac{\sigma\delta}{1 + i}E_0 \qquad [18]$$

The surface impedance of the metal is therefore

$$Z_s = \frac{E_z}{H_y} = \frac{1 + i}{\sigma\delta} \qquad [19]$$

We can see that the resistance of a metal surface is accompanied by an equal amount of inductance, because the real and imaginary parts of the surface impedance are equal, and have the same sign.

The part of the wave that extends into vacuum is very loosely bound to the metal surface, but the currents in the metal occur in a well-defined skin depth. For example, copper has a surface impedance of $0.03(1 + i)$ ohms/square at 10 GHz. Using eqns [15] and [16], a surface wave at that frequency extends about 70 meters, or 2300 wavelengths into free space, but less than 1 micron into the metal. For this reason, surface waves are often described simply as surface currents at microwave and radio frequencies, although they are the same phenomenon as the more tightly bound surface plasmons that occur at optical frequencies. Nonetheless, their presence can be seen in a variety of phenomena at RF frequencies, such as antenna radiation patterns.

The above discussion can be generalized to a simple impedance surface, and it can be shown that TM waves are supported on inductive surfaces having an impedance of

$$Z_s(\mathrm{TM}) = \frac{i\alpha}{\omega\varepsilon} \qquad [20]$$

while TE waves are supported on capacitive surfaces, having an impedance of

$$Z_s(\mathrm{TE}) = \frac{-i\omega\mu}{\alpha} \qquad [21]$$

Thus, while ordinary metals, which are inductive, support TM waves, they do not support TE waves, which require a capacitive surface.

Surface waves on metals can be suppressed over a finite frequency band by applying various kinds of periotic textures. For example, at optical frequencies, a lattice of small bumps on a metal surface can create a surface wave bandgap. Surface waves are scattered by the bumps, and form standing waves when one-half wavelength fits between the rows of bumps. Two modes occur, in which the wave nodes lie either on the bumps or between them. These two modes have slightly different frequencies, separated by a narrow bandgap.

At microwave frequencies, more elaborate structures can be built to control the surface properties. One example is a corrugated metal surface, shown in Figure 8. The corrugations can be considered as transmission lines running into the slab, and shorted at the bottom. They are typically one-quarter wavelength deep, so that the short circuit at the bottom is transformed into an open circuit at the top. Because of these resonant structures built into the surface, it has high impedance for waves that are polarized with the electric field transverse to the corrugations, but it has low impedance for waves that are polarized in the orthogonal direction, with the electric field parallel to the metal ridges. For waves propagating transverse to or parallel to the corrugations, the surface can be described as hard or soft, respectively, by analogy to the acoustic surfaces of the same names. Both of these boundary conditions are used in antennas to control scattering properties or

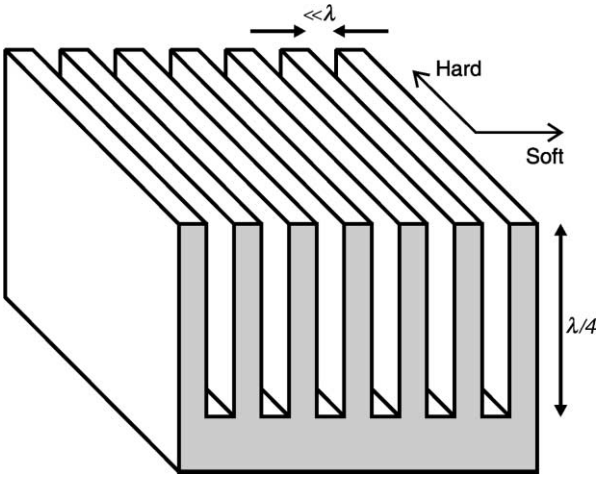

Figure 8 A corrugated metal surface containing quarter-wave resonant grooves presents a soft boundary condition to waves propagating transverse to the grooves, and a hard boundary condition to waves propagating along the grooves.

Table 1 Four basic boundary conditions in electromagnetics, and the surface impedance for each polarization

Electric conductor	0	0
Soft surface	∞	0
Hard surface	0	∞
Magnetic conductor	∞	∞

field profiles. These two surfaces, along with the electric and magnetic conductors, describe four basic boundary conditions for electromagnetics, which are summarized in Table 1. Like the soft and hard surfaces, the magnetic conductor does not exist in nature, but it can be produced artificially over a finite frequency band, using a kind of two-dimensional photonic crystal known as a high-impedance surface.

High-Impedance Surfaces

Just as three-dimensional photonic crystals forbid internal plane waves, two-dimensional photonic crystals can be designed to suppress surface waves. Like the capacitive mesh described earlier, they can be constructed with lumped circuit elements. They can be understood as corrugated surfaces, in which the resonant corrugations have been folded up into resonant LC circuits, and distributed on a two-dimensional lattice. An example of such a structure is shown in Figure 9. It can be built using printed circuit boards, in which flat metal patches are connected to a common ground plane by metal plated vias.

When the plates are small compared to the wavelength, we may treat the surface as an effective

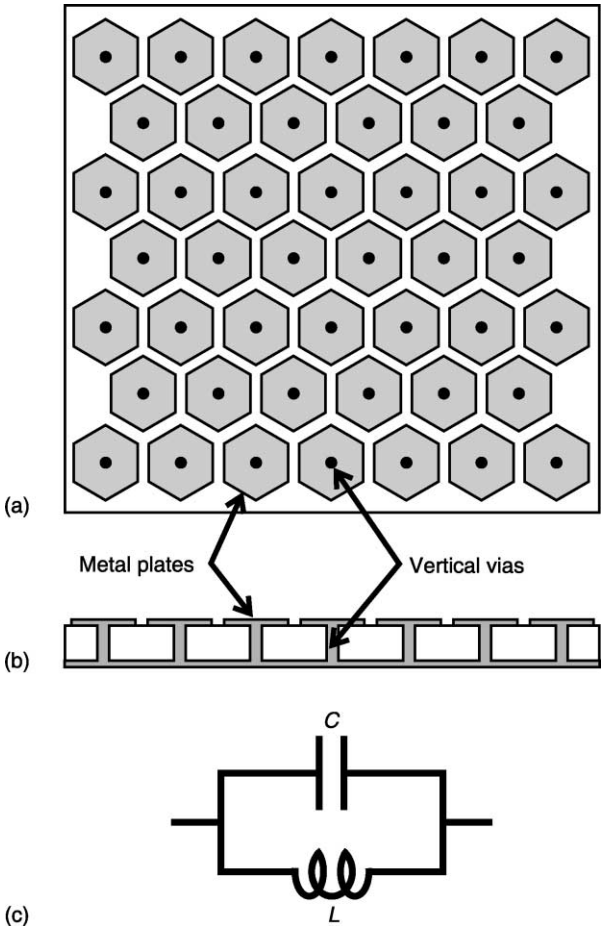

Figure 9 A high-impedance surface, constructed as a printed circuit board. (a) The top view shows an array of hexagonal metal patches; (b) the side view shows metal-plated vias that connect the patches to the ground plane; (c) the effective surface impedance can be modeled as a parallel resonant LC circuit.

medium, with a surface impedance defined by a parallel resonant LC circuit. The proximity of the neighboring metal plates provides capacitance, while the current paths, through the vias and the ground plane, provide inductance. The surface impedance is given by

$$Z_s = \frac{i\omega L}{1 - \omega^2 LC} \qquad [22]$$

and the resonance frequency is

$$\omega_0 = \frac{1}{\sqrt{LC}} \qquad [23]$$

The sheet capacitance, C, is equal to the value of the individual capacitors, multiplied by a geometrical factor that is related to their arrangement. It can be shown that for nonmagnetic materials, the sheet

inductance L is equal to

$$L = \mu_0 t \qquad [24]$$

where t is the total thickness of the high-impedance surface. The surface is inductive for frequencies below resonance, and capacitive for frequencies above resonance. Near the resonance frequency, the magnitude of the surface impedance is very high ($Z_s >> \eta$, where $\eta = 377\Omega$ is the impedance of free space).

For a normally incident wave, the reflection coefficient of the surface is

$$R = \frac{Z_s - \eta}{Z_s + \eta} \qquad [25]$$

The phase $\phi = \mathrm{Im}(Ln(R))$ of the reflection coefficient is plotted as a function of frequency in Figure 10. While a low impedance surface such as a conventional electric conductor reflects with a phase shift of π, a high-impedance surface or artificial magnetic conductor reflects with a phase shift of 0. This can be used to build low-profile antennas, because radiating elements can lie very near to a high-impedance ground plane without being shorted out. For example, a thin wire antenna can be placed within a small fraction of a wavelength of the high-impedance surface, yet retain high radiation efficiency. While image currents in a metal ground plane would normally oppose the antenna current, the currents in a high-impedance ground plane reinforce the antenna current because of the opposite reflection phase. This effect occurs when the reflection phase falls between $\pi/2$ and $-\pi/2$, and the corresponding frequency range defines the practical bandwidth of a low-profile antenna on such a surface.

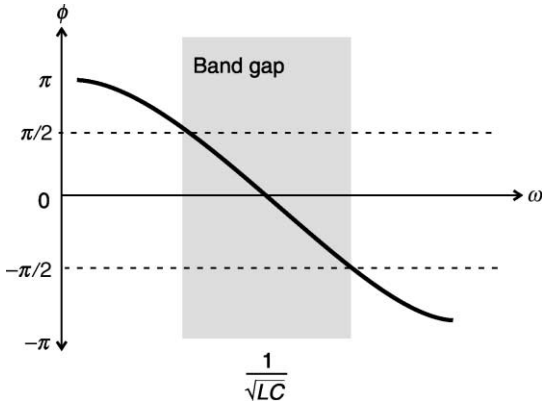

Figure 10 The reflection phase of a high-impedance surface crosses through 0 at the resonance frequency, where the surface appears as an artificial magnetic conductor. The reflection phase falls between $\pi/2$ and $-\pi/2$ for frequencies corresponding roughly to the edges of the surface wave bandgap.

Experimentally this bandwidth is found to be roughly equal to the surface wave bandgap, to be described later.

The reflection phase properties of these materials can also be used to build unique microwave reflectors. Since the phase depends on the resonance frequency, one can vary the local resonance frequency in order to tune the reflection phase as a function of position on the surface. For example, a linear phase gradient can be used for beam steering, or a parabolic phase function can be used for focusing. The resonance frequency can be adjusted by tuning the capacitance of the individual unit cells, using varactors or mechanical motion, to build actively controlled microwave reflectors.

The other important property of these textured ground planes is their surface wave bandgap, which can be used to control the radiation pattern of antennas near the surface. We examine the surface wave properties by considering a wave that decays into free space, as in eqn [6]. From Maxwell's equations, we can obtain

$$k^2 = \mu_0 \varepsilon_0 \omega^2 + \alpha^2 \qquad [26]$$

which can be combined with eqs [20] and [21] to obtain the dispersion relations for TM and TE waves on a general impedance surface, respectively. For TM waves, which occur where $\omega < \omega_0$, we have

$$k(\mathrm{TM}) = \frac{\omega}{c}\sqrt{1 - \frac{Z_s^2}{\eta^2}} \qquad [27]$$

and for TE waves, which occur where $\omega > \omega_0$ we have

$$k(\mathrm{TE}) = \frac{\omega}{c}\sqrt{1 - \frac{\eta^2}{Z_s^2}} \qquad [28]$$

These functions describe, to first order, the dispersion of waves on a high-impedance surface. However, they do not predict the bandgap, which can only be obtained by including the effects of radiation damping.

Consider an oscillating sheet of current that sees the impedance of the textured surface on one side, and the impedance of free space on the other side. At very low, or very high frequencies, the current is shunted through the surface. Near the resonance frequency, where the surface impedance is high, power is delivered to free space through radiation damping. The half power bandwidth of this radiation is defined by the frequencies where the magnitude of the surface impedance is equal to the impedance of

free space:

$$\left|\frac{i\omega L}{1-\omega^2 LC}\right| = \eta \qquad [29]$$

We solve for λ to yield the frequencies of the two bandedges:

$$\omega^2 = \frac{1}{LC} + \frac{1}{2\eta^2 C^2} \pm \frac{1}{\eta C}\sqrt{\frac{1}{LC} + \frac{1}{4\eta^2 C^2}} \qquad [30]$$

The terms in $1/\eta^2 C^2$ are typically small compared to the terms in $1/LC$, so we neglect them to obtain

$$\omega \approx \omega_0 \sqrt{1 \pm \frac{Z_0}{\eta}} \qquad [31]$$

where

$$Z_0 = \sqrt{\frac{L}{C}} \qquad [32]$$

is the characteristic impedance of the surface. For structures that are thin compared to the wavelength, the characteristic impedance is small compared to η. We can expand the square root in eqn [31], to approximate the fractional bandwidth of the radiation as

$$\frac{\Delta\omega}{\omega_0} \approx \frac{Z_0}{\eta} = \frac{\sqrt{L/C}}{\sqrt{\mu_0/\varepsilon_0}} \qquad [33]$$

Using eqn [23], this can be rearranged to obtain

$$\frac{\Delta\omega}{\omega_0} \approx t\frac{2\pi}{\lambda_0} \qquad [34]$$

where λ_0 is the free space wavelength at the resonance frequency. This defines a surface wave bandgap that is centered at the resonance frequency, between a lower-frequency TM band and a higher-frequency TE band. From eqn [34], we see that the bandwidth of a high-impedance surface, or of an antenna on that surface, is limited by its thickness with respect to its free space wavelength at resonance. The term $\lambda_0/2\pi$ is recognized as the radian length, described by Wheeler, who showed that the fractional bandwidth limit of a small resonant antenna is given by its volume with respect to a notional sphere of this radius. Equation [34] represents the equivalent bandwidth limit for a two-dimensional resonant surface.

The surface wave bandgap can be measured experimentally with a pair of small probes placed near the surface. A surface wave probe can be constructed from the end of a coaxial cable with a short section of the inner conductor exposed. Fields from the probe excite surface waves when they are placed near the surface, and the transmission magnitude between the probes can be used to analyze the surface wave band structure. For a high impedance surface, the bandgap can be seen as a range of frequencies with a significant reduction in surface wave transmission magnitude, shown in Figure 11. Within the bandgap, waves are not bound to the surface, and currents on the surface readily radiate energy into free space. The upper edge of the bandgap

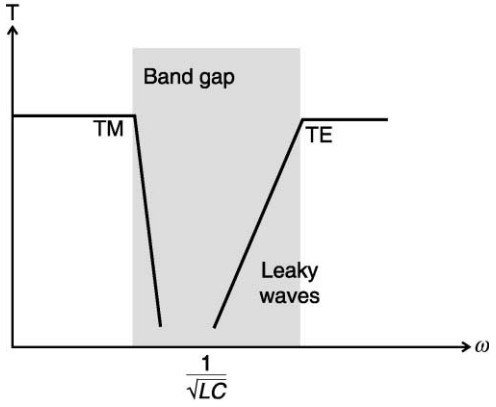

Figure 11 The surface wave transmission magnitude as a function of frequency for a high-impedance surface. TM waves are supported at low frequencies, and TE waves are supported at high frequencies. Leaky TE waves, which are damped by radiation, can occur within the bandgap.

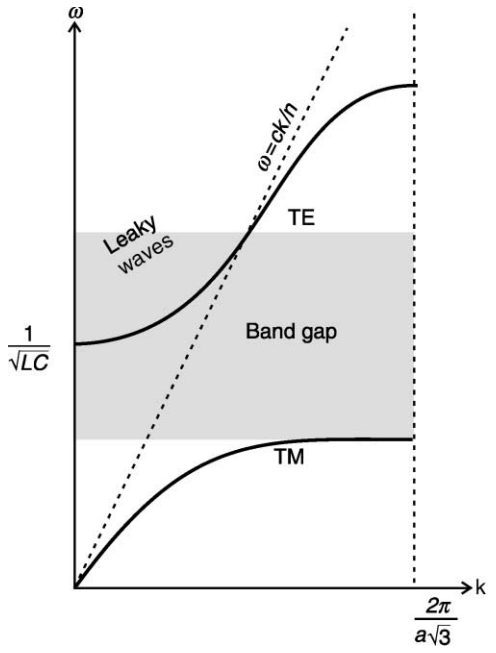

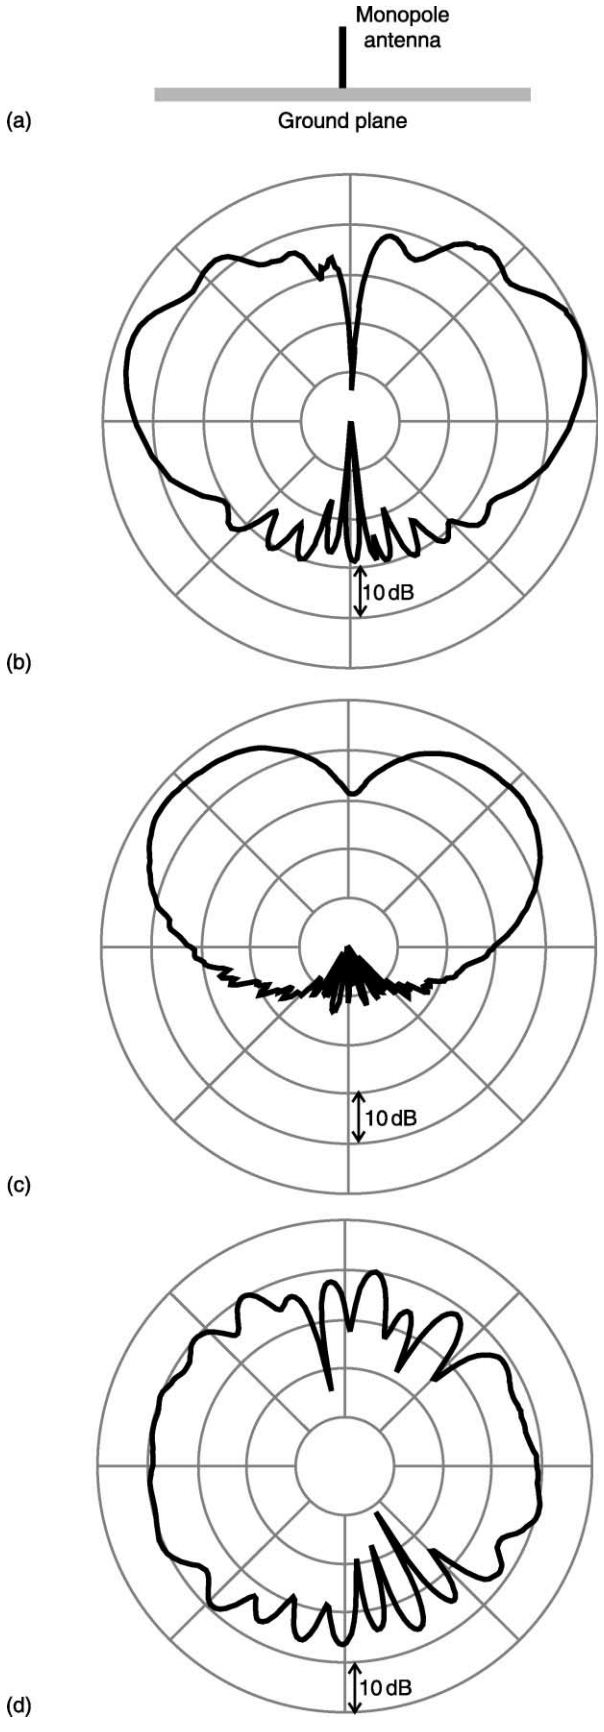

Figure 12 The dispersion diagram for surface waves on a high-impedance surface. The bandgap spans from the upper edge of the TM band, to the point where the TE band crosses the light line. Within the bandgap, electromagnetic waves are not bound to the surface. Modes to the left of the light line represent leaky waves.

is typically less abrupt than the lower edge, due to the presence of leaky TE waves.

The dispersion diagram for surface waves on a high-impedance surface is illustrated in Figure 12. The TM band begins at zero frequency, and bends over flat below the resonance frequency. The TE band begins at the resonance frequency, and slopes upward through the light line. The bandgap, which is the region where bound surface waves are not supported, extends from the upper edge of the TM band to the point where the TE band crosses the light line. This boundary, where $\omega = ck/n$, represents waves in free space propagating parallel to the surface. TE modes, that lie to the right of the light line, are bound to the surface while those that lie left of the light line lose energy to radiation damping. They are not bound to the surface, and are described as leaky waves. The approximate dispersion functions of eqns [27] and [28] are similar to the curves shown in Figure 12, but because they neglect radiation damping, they do not describe these leaky modes. Furthermore, like other photonic crystals, high-impedance surfaces also have higher-order bands and gaps that are not explained by the effective medium model.

The suppression of propagating surface modes can be used for a variety of applications, such as antennas and other microwave structures. One example is to change the radiation pattern of an antenna by covering its ground plane with a textured surface. Figure 13 shows a simple monopole antenna, along with the radiation patterns produced by the monopole when it is placed on a flat or textured ground plane. These plots show the relative magnitude of radiation from the antenna as a function of angle. TM surface currents on the finite metal ground plane form standing waves, which scatter from the edges and corners of a finite ground plane. This causes ripples in the radiation pattern as radiation from the edges interferes with the direct radiation from the antenna. Scattering of the surface currents from the ground plane edges also allows the antenna to radiate power into the backward hemisphere, which would otherwise be shadowed by the ground plane. On the high-impedance ground plane, the suppression of surface

Figure 13 (a) A monopole antenna on a ground plane, used for testing the effect of a textured surface on the radiation pattern. (b) The E-plane radiation pattern of the monopole on a flat metal ground plane shows ripples due to standing surface waves. (c) On a high-impedance ground plane, within the bandgap, surface waves are forbidden, and the radiation pattern is smooth. (d) Outside the bandgap, in the TM band, there is a high density of surface modes.

currents within the bandgap results in a smooth radiation pattern in the forward hemisphere, and very little power in the backward hemisphere. For frequencies outside the bandgap, such as within the TM band, the high density of TM modes can be seen as fine ripples in the pattern, and significant power in the backward hemisphere.

The monopole is useful for illustrating the suppression of TM surface modes, but many other antenna designs are possible. For example, the suppression of both TM and TE surface waves can be used to build patch antennas or aperture antennas with a high degree of symmetry between the E and H planes. Because these materials behave as artificial magnetic conductors, they can also be used to design a variety of thin antennas that would be impractical on conventional metal ground planes. Finally, by incorporating active elements into the surface, tunable or steerable antennas are possible.

List of Units and Nomenclature

Nonlinear Optics in Photonic Crystal Fibers

Introduction

Photonic crystal fibers (PCFs) are very similar to normal optical fibers in that they consist of a core surrounded by cladding, such that light is guided within the core of the fiber. The primary difference between PCF and standard optical fibers is that PCFs feature an air–silica cross-section, whereas standard optical fibers have an all-glass cross-section. An electron micrograph of a typical PCF is shown in Figure 1. The air holes extend along the axis of the fiber for its entire length and the core of the fiber is formed by a defect, or missing hole, in the periodic structure. The core is formed of solid glass, whose refractive index is that of pure silica (or whatever other glass is chosen), and the cladding is formed by the air–glass mixture, whose effective refractive index depends on the ratio of air-to-glass, also known as the air-fill fraction, that comprises the structure. The resulting effective-index of the cladding will be lower compared with that of the core and, as such, will provide the refractive index variation necessary to support total internal reflection at the core-cladding boundary, and guide light in a manner similar to that of standard optical fibers. The fiber design (i.e., size, shape, and the air-fill fraction) dictates solutions to Maxwell's equations for light propagating within the fiber. Valid solutions are referred to as 'modes' which propagate along the fiber in a known manner, and have a well-defined shape in the transverse direction (i.e., they have a well-defined transverse mode structure).

Nonlinear-optical effects in fibers result from the interaction of optical fields with the glass via the $\chi^{(3)}$, or Kerr nonlinearity. The phenomenon of nonlinear refractive index is a manifestation of a light–material interaction mediated by $\chi^{(3)}$. The magnitudes of the components of the third-order susceptibility tensor in glass, $\chi^{(3)}$, are generally quite small compared with the analogous second-order ($\chi^{(2)}$) terms for materials exhibiting such nonlinearities (e.g., lithium niobate, beta-barium borate (BBO), etc.). The relatively small $\chi^{(3)}$ nonlinearity in optical fibers makes them ideal for wavelength-division multiplexed optical communication where light propagation subject to a minimum of nonlinear effects is critical. Nonlinearity does, however, eventually become an issue in wavelength-division multiplexed systems as the launched optical power increases and as the channel spacing decreases. On the other hand, one can utilize nonlinear-optical effects in soliton communication systems and to build useful photonic devices. Despite the weak $\chi^{(3)}$

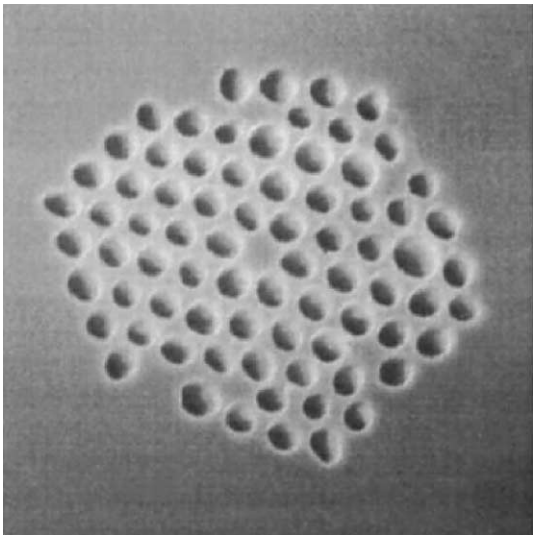

Figure 1 An electron micrograph showing the periodic microstructure of a typical PCF. The core is formed by the 'missing hole' in the center of the microstructure. nonlinearity, the net nonlinear-optical effect in fibers can be large due to the ability to tightly confine intense fields within the core of an optical fiber and maintain the interaction over a long distance as the guided fields propagate through the fiber.

The study of nonlinear-fiber optics has benefited from dramatic improvements in optical fiber and fiber-optic device fabrication. The importance of understanding nonlinear-fiber optics is driven by the need to develop fiber-integrated devices, and also by the need to understand and mitigate the problems that these nonlinearities cause in optical communication systems.

This section introduces the unique linear- and nonlinear-optical properties of PCFs in order to understand the reasons why nonlinear-optical effects are often enhanced in such fibers. These discussions pertain to PCFs which are 'highly nonlinear'. It is essential to clarify that 'highly nonlinear' in this context does not mean that the $\chi^{(3)}$ is any larger than that of standard telecommunication fibers, rather that the effect of this nonlinearity is enhanced due to the fiber's very small core.

PCF Properties

Photonic crystal fibers feature a variety of interesting properties. From the standpoint of nonlinear-fiber optics there are four very useful fundamental properties of PCFs:

- a mechanically robust optical fiber can be fabricated with an extremely small core (a few μm^2);
- a fiber can be made to guide in a single transverse mode over an extremely broad wavelength range (370 nm–1600 nm);
- there are new degrees of freedom that allow one to manipulate the fiber's group-velocity dispersion (GVD) properties; and
- many, but not all, PCFs are polarization maintaining as a result of form birefringence present in the core.

The fact that small-core PCFs can be fabricated is clear from Figure 1 by taking note of the fact that the center defect region which comprises the core is about 1.7 μm in diameter. Photonic crystal fibers with even smaller cores have been fabricated.

Transverse Mode Structure

A widely accepted model used to describe the transverse modal behavior of PCFs is called the effective-index model. The effective-index model can be used to understand why some PCFs are 'endlessly single mode', meaning that the fiber guides in a single transverse mode over an exceptionally wide wavelength range (370 nm–1600 nm). In the effective-index model, the refractive index of the core, $n_{co}(\lambda)$, is that of glass, and the refractive index of the cladding, $n_{eff}(\lambda)$, assumes a value in between that of glass and air. In the context of PCFs, one makes a modification to the standard expression describing single-mode behavior in step-index fibers:

$$V_{eff} = \frac{2\pi\Lambda}{\lambda}\sqrt{n_{co}(\lambda)^2 - n_{eff}(\lambda)^2} < V_{cutoff} \qquad [1]$$

where Λ is the spacing between air holes, λ is the wavelength of light, and V_{cutoff} is the cutoff condition for the PCF. A similar expression for the V parameter is commonly used to understand the modal behavior of standard fibers where the larger the V is, the more transverse modes are supported within the fiber. In standard fibers the cutoff condition below which only a single mode can propagate within the core of a fiber is given by $V_{cutoff} < 2.405$. In the case of PCFs, a numerical method should be used to determine V_{cutoff}. Mechanically robust PCFs can be fabricated where the dispersion in $n_{eff}(\lambda)$ (i.e., the variation of n_{eff} with λ) offsets dispersion in $n_{co}(\lambda)$ and compensates for the $2\pi\Lambda/\lambda$ coefficient in eqn [1]. Therefore, the light within the fiber propagates in a single, Gaussian-like mode because for all wavelengths $V_{eff} < V_{cutoff}$. A graph of the variation of V_{eff} with Λ/λ is shown in Figure 2, where d represents the size of an air hole.

Conceptually, the effective index model can be understood by noting that at short wavelengths the mode field is confined well within the all-silica core, but as λ increases the mode field extends further into the air–glass cladding and V_{eff} and $n_{eff}(\lambda)$ both decrease.

Dispersion in PCF

Other critical differences between PCFs and standard optical fibers lie in the dispersion properties. When light propagates through a fiber its behavior depends on the light's optical frequency:

$$E(t,z) = A(t,z)e^{i[\omega t - \beta(\omega)z]} \qquad [2]$$

Equation [2] describes the mode as it propagates through the fiber. It is decomposed into a slowly varying envelope, $A(t,z)$, and a rapidly varying exponential component where ω is the frequency of the mode, t is time, z is the position along the length of the fiber, and $\beta(\omega)$ is called the mode-propagation constant. The general term used in describing the

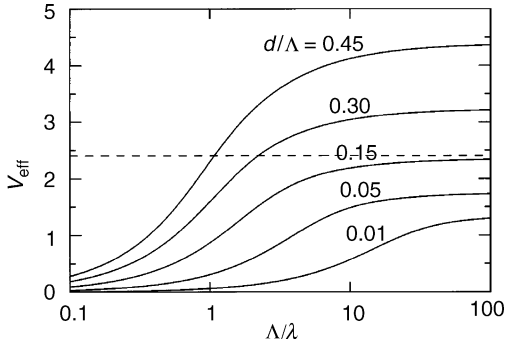

Figure 2 Variation of V_{eff} for different relative hole diameters d/Λ. The calculation assumes a fiber with an air–glass cross-section where the refractive index of air and glass was taken to be 1 and 1.45, respectively. The dashed line marks $V_{eff} = 2.405$, the cutoff value for a step-index fiber. frequency dependence of β is chromatic dispersion, which includes contributions from the material as well as the waveguide. Other types of dispersion present in optical fibers include multi-modal (arising from multiple guided transverse modes) and polarization-mode dispersion.

One way to understand the chromatic dispersion of a mode propagating through an optical fiber is to study the Taylor series expansion of the mode-propagation constant, β, about the center frequency of the field, ω_0:

$$\beta(\omega) = \beta_0 + \beta_1(\omega - \omega_0) + \frac{1}{2}\beta_2(\omega - \omega_0)^2 + \cdots \qquad [3]$$

where $\beta_i = \mathrm{d}^i\beta/\mathrm{d}\omega^i$. The physical significance of the various β_i in eqn [3] are as follows: the phase-fronts of the electric field move at a speed given by $\omega/\beta_0 = v_p$, and the envelope, $A(t,z)$, moves at a group velocity given by $1/\beta_1$. A GVD term, which governs temporal spreading of the envelope, is given by β_2. Higher-order β terms are usually negligible for propagation of pulses of $\geq$1 ps duration in optical fibers and are lumped into the category of 'higher-order chromatic dispersion'.

The notation 'β_2', as defined above, is often used in the literature with dimensions of ps^2/km. However, another expression is frequently used because of its direct relationship to measured quantities. It is straightforward to measure the relative delay, T, between two pulses having different center wavelengths. Choosing a particular wavelength as a reference, one can then measure relative delay as a function of an injected pulse's center wavelength. The first derivative with respect to λ of the relative delay curve gives the GVD according to

$$D = \frac{\partial\left(\frac{1}{v_g}\right)}{\partial\lambda} = \frac{1}{L}\frac{\mathrm{d}T}{\mathrm{d}\lambda} = -\frac{2\pi c}{\lambda^2}\beta_2 \qquad [4]$$

where v_g is the group velocity, and L is the length of the fiber under test. The dimension commonly used for D is ps/(nm km).

Chromatic dispersion in single-mode optical fibers results from two different wavelength-dependent fiber parameters. The medium itself, glass in this case, has a wavelength-dependent refractive index. This 'material' contribution has the same magnitude regardless of the various parameters associated with the waveguide. A second contribution has to do with the design of the optical fiber. This 'waveguide' contribution to dispersion arises from the fact that the wavelength-dependent mode depends on the properties of the waveguide (i.e., the core size and refractive index contrast between the core and cladding). Empirical models can be used to describe the material, waveguide, and total GVD for standard communication fibers. Such a set of curves is given in Figure 3 where it can be seen that it is possible to have positive, negative, or zero values for D. For historical reasons, the regions where D is negative (β_2 is positive) exhibit 'normal GVD', while those where D is positive (β_2 is negative), exhibit 'anomalous GVD'. The wavelength corresponding to $D = 0$ is referred to as the zero-dispersion wavelength (λ_0), which for most silica glass fibers is about 1,300 nm.

In contrast with standard optical fibers, where the waveguide contribution to D is always less than zero, small-core PCFs can be fabricated where the waveguide contribution to GVD is positive and quite large. As such, in PCFs, λ_0 can be shifted to wavelengths shorter than the intrinsic dispersion zero of glass. Control over the GVD is essential for phase matching certain nonlinear-optical interactions involving light

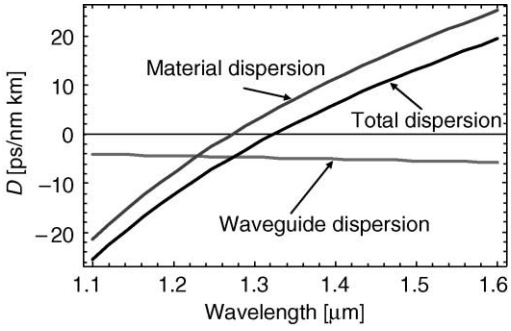

Figure 3 Plots of the theoretical dispersion coefficient, D, as a function of wavelength for a standard optical communication fiber.

of different colors co-propagating within a fiber. Indeed, several exciting applications of nonlinear optics in PCF require a fiber with a $\lambda_0 \sim 800$ nm. The GVD is also of great importance when working with pulsed light in PCF, because GVD results in temporal pulse broadening. It also governs pulse temporal walkoff effects, limiting the effective interaction length between pulses of different colors. This new flexibility to manipulate the GVD curve, by varying waveguide design parameters, is a key advantage associated with using PCFs for nonlinear optics.

Birefringence in PCF

The core of an optical fiber often exhibits some amount of anisotropy. The core may be elliptical in form (shape) which leads to a phenomenon referred to as form birefringence. Since mode propagation depends on the fiber structure, a fiber with an elliptical core will exhibit mode propagation that depends on the electric field's polarization with respect to the axes of the elliptical core. As a result of birefringence, the polarization of the mode varies as it propagates through the fiber (unless care is taken to align the polarization of the injected light with respect to a principal axis of the birefringence).

Polarization-maintaining (PM) fibers are designed to include birefringence in a particular axis of the fiber. By including a well-defined birefringence throughout the length of a fiber that is larger than that induced by external perturbations, fast and slow axes of the optical fiber are created for all guided wavelengths, giving two orthogonal 'polarization modes'. If light is injected into one of the polarization modes (i.e., with its linear polarization along one of the axes) it remains linearly polarized along that axis as it propagates along the fiber. The two polarization modes generally have different group velocities, so pulsed light in each mode will take a different amount of time to propagate through a given segment of fiber. Most PCFs exhibit strong birefringence due to a slightly elliptical core combined with a large core-cladding index difference, and so they behave similarly to PM fibers. Special care must be taken when working with PCF to be sure that the polarization of the light launched into the fiber is aligned with one of the birefringent axes.

In practice, there are a few other features of PCF that are of importance when discussing nonlinear-optic interactions:

- propagation losses are generally larger in PCFs than in standard optical fibers; and
- free-space coupling and splicing are difficult and can result in large coupling losses.

Nonlinear Phenomena

The basic principles determining nonlinear effects in PCFs are the same as those for standard optical fibers (*see* **Fiber and Guided Wave Optics:** Nonlinear Effects (Basics)). It is the new flexibility in PCFs to obtain transverse-modal and GVD behavior different from that of standard optical fibers that makes PCFs truly interesting for nonlinear optics. The relevant nonlinear-optical effects are: self-phase modulation (SPM); cross-phase modulation (CPM); third-harmonic generation (3HG); four-wave mixing (FWM); Raman scattering; and Brillouin scattering.

Self-phase modulation (also known as the optical Kerr effect) refers to the self-induced phase shift experienced by an optical field as it propagates through a fiber. It becomes particularly important for the case of pulses of light propagating through optical fibers. In small core PCFs, SPM is enhanced due to the high-intensity light propagating within the core. Self-phase modulation can lead to substantial spectral broadening of pulsed light propagating along an optical fiber.

When a pulse of light experiences normal GVD (i.e., $D < 0$) as it propagates, the longer-wavelength components travel faster than the shorter-wavelength components. Anomalous GVD (i.e., $D > 0$) leads to the opposite, short-wavelength components traveling faster than the long-wavelength components. Group-velocity dispersion generally leads to temporal broadening of pulses as they propagate along a fiber. Under ideal conditions, however, SPM in combination with anomalous GVD, leads to pulses which propagate without any temporal or spectral broadening. These self-sustaining pulses are called 'optical solitons'.

When waves of light having different wavelengths co-propagate along a fiber, CPM can occur. It can be understood as a phase shift induced on one wave, due to the presence of the other wave. Cross-phase modulation also leads to spectral broadening and solitonic pulse propagation.

In 3HG and FWM, one or more photons are destroyed and others are created. In 3HG, three 'fundamental' photons are destroyed to create one with three times the energy of the fundamental photons. In FWM, two fundamental photons are destroyed while two others are created. While it is straightforward to conserve energy in 3HG and FWM, these interactions must be 'phase-matched', meaning that the interacting waves must be made to propagate in-phase over a meaningful length. Such phase-matching conditions need to be carefully considered when studying 3HG and FWM. Nevertheless, 3HG and FWM can be used to obtain

frequency shifts and all-optical amplification. In comparison with other types of optical fibers, PCFs are particularly useful for 3HG and FWM applications. The small core of the PCF allows interactions to occur at much lower input powers, and the new flexibility associated with the GVD properties permits phase matching in cases which are not possible using standard optical fibers. Finally, the fiber's endlessly single-mode behavior permits very good transverse mode overlap between interacting waves having widely different center wavelengths.

Self-phase modulation, CPM, 3HG, and FWM are photon–photon interactions wherein no energy is exchanged with the medium itself. In contrast, Raman scattering and Brillouin scattering result from photon–phonon interactions. The differences between Raman and Brillouin scatterings lie in the energy of the phonons involved and the direction in which the interactions occur. Raman scattering is an interaction between a photon and an optical–phonon mode of the molecules making up the material. In the case of Raman scattering in glass, the energy shift, associated with molecular vibrational (Raman) modes, corresponds to frequencies of 1–12 THz. Raman scattering occurs in the forward and backward directions. With pulsed light, stimulated Raman scattering can occur when the lower-frequency spectrum of the pulse overlaps with the spectrum of the Raman resonances excited by the higher-frequency spectrum. When this happens, energy can be efficiently shifted in spectrum towards the peak of the Raman resonance. In the forward direction, this 'Raman self-frequency shift' builds up. Additionally, if the Raman self-frequency shift occurs in the presence of anomalous dispersion, a 'Raman soliton self-frequency shift' can result. As the injected power is increased, the spectral shift between the injected pulse and the resulting Raman soliton increases. The principal advantage associated with PCF is the ability to generate Raman solitons for a broader range of wavelengths than was previously possible.

For Brillouin scattering, interaction with the acoustical phonons results in frequency shifts of about 10 GHz and the interaction only occurs in the backward direction. Brillouin scattering is generally a nuisance in fiber-based devices, leading to intensity noise and other problems. The interesting feature of Brillouin scattering in PCFs is that the threshold intensity where problems begin to occur is higher for PCFs than for standard optical fibers. The higher threshold permits further optimization of fiber-based devices wherein Brillouin scattering limits the performance.

Experiment Examples

In the following subsections, a selection of experiments, demonstrating a few of the relevant nonlinear-optical phenomena, are briefly described.

Supercontinuum Generation

One of the most exciting demonstrations of nonlinear optics in PCF is that of supercontinuum generation. In a typical experiment, 100 femtosecond pulses from a mode-locked Ti:Sapphire laser operating at a wavelength of 800 nm were injected into the PCF. As the injected power was increased, a broad continuum of spectrum was generated from wavelengths of 400 nm up to 1,600 nm. Typical data showing the input and output optical spectra are given in Figure 4, where it can be seen that well over an octave of frequency spectrum is generated from an input pulse whose spectral width is only about 10 nm.

It is widely accepted that supercontinuum generation results from a combination of linear and nonlinear optical effects conspiring to generate the broad spectrum. As the pulse propagates through the PCF, SPM, FWM, and Raman scattering are all likely to occur with relative efficiencies depending heavily on the input pulse's spectral and temporal characteristics, as well as the fiber's properties. Indeed, efficient supercontinuum generation can occur in PCFs for pump wavelengths lying near the zero-dispersion point in the normal or anomalous dispersion regime of the PCF, and for fibers as short as a few millimeters in length.

Spectral broadening, due to SPM, is common in standard optical fibers, but what makes this

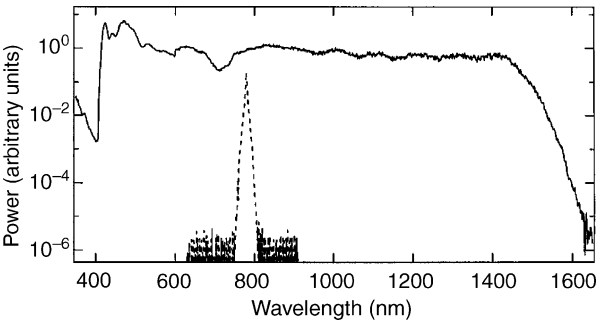

Figure 4 In supercontinuum generation one observes a broad continuum generated after short pulses of light from a Ti:Sapphire laser propagate through a 75 cm section of PCF. The spectrum of the input pulse is shown as a dashed curve, while the output is a solid curve. particular experiment interesting is the remarkable width of spectrum generated with a short piece of fiber (~1 m) and with comparatively small optical powers.

Optical Switching in PCF

Cross-phase modulation can be used to build an all-optical switch. Such a switch can be implemented as a three-port device where the output port for a given optical bit (the signal pulse), is determined by the presence of an optical control (the pump pulse). Switching can then be achieved by dividing the signal pulse equally on two arms of an interferometer and injecting the strong pump pulse only on one arm. Because the pump pulse co-propagates with only one of the two signal pulses, there exists a CPM-induced phase difference $\phi_{NL} = 2\gamma P_p L$ at the output of the interferometer, where P_p is the peak power of the pump pulse and L is the interaction length. By varying the intensity of the pump pulses one can vary the magnitude of this phase difference. If a π-phase shift is achieved, one can switch the interference from destructive to constructive, or vice-versa, thus realizing an all-optical switch.

Figure 5 shows an experimental setup used to observe switching near 1,550 nm (a similar apparatus using bulk-optic rather than fiber-optic components can be used to conduct experiments near 780 nm). The pump and signal are synchronous few-ps-duration pulses with a tunable wavelength separation

of 5–15 nm. The switching characteristics for this implementation are shown in Figure 6. The apparatus has the advantage of requiring short fiber lengths, low switching powers, and allows switching of weak pulses. It demonstrates the feasibility of using nonlinear optics in PCF to perform essential functions in high-speed all-optical processing.

Parametric (Mixing) Processes

The first set of experiments with controlled FWM in a PCF achieved nondegenerate parametric gains over a 30 nm range of pump wavelengths near the λ_0 of the PCF. The experiments also confirmed the wavelength dependence of the GVD coefficient of the PCF near λ_0. Since the dispersion characteristics of these fibers can be adjusted during the fabrication process, the experiments demonstrate the potential for the use of PCFs in broadband parametric amplifiers, wavelength shifters, and other optical communication devices.

The experimental setup used to demonstrate phase-matched FWM in PCF is shown in Figure 7. The pump and the input signal are two synchronous pulsed beams having 3–5 nm wavelength separation with the center wavelength tunable over a 720–850 nm range. The maximum peak power of the pump pulses is ≃12 W. The two synchronous beams are then combined and injected into the PCF. The pump and signal's optical paths are adjusted to obtain temporal overlap in the PCF and their polarizations are aligned by fiber polarization controllers.

Figure 8 shows a typical FWM optical spectrum at the output of a 6.1 m long PCF. Here the strong pump beam and the weak signal beam have wavelengths of 753 nm and 758 nm, respectively. The spectrum shows the undepleted pump, the amplified signal, and the generated idler at 747 nm. The spectra in Figure 8 show that large gain is achievable for a pump-to-signal spacing of 5 nm. Gain values of more than 20 (13 dB) were obtained.

Conclusion

In summary, the advantages of using photonic crystal fibers for demonstrating nonlinear-fiber optical effects arise from four novel properties:

- the nonlinear coefficient is enhanced in small-core PCFs (core area of a few μm^2);
- PCFs can support a single transverse mode over an extremely broad wavelength range (370 nm–1600 nm);
- PCF design parameters allow one to manipulate the fiber's GVD properties; and
- nonlinear interactions are enhanced due to the polarization maintaining properties of PCFs which result from form birefringence present in the core.

These four properties combine to allow efficient interactions to occur in PCFs which are either inefficient or not possible at all in standard optical fibers.

Introduction

Photonic bandstructure engineering, in which the electromagnetic dispersion relations are intentionally modified, can be accomplished by creating one-, two-, and three-dimensionally periodic dielectric materials. These periodic materials, called photonic crystals, can be used to confine and guide light. This article describes the formation of optical resonant cavities and waveguides in these materials. Most of the discussion will focus on two-dimensional photonic crystals. One-dimensionally periodic systems are treated elsewhere in this volume. This article will begin with a short review of the relevant electromagnetic properties of photonic crystals. The formation and properties of resonant cavities will follow this, and the article will conclude with waveguides formed by linear defects in two-dimensional photonic crystals.

Electromagnetics of Photonic Crystals

A two-dimensional photonic crystal consists of a dielectric material in which the dielectric constant is periodic in two dimensions. The period of these materials is on the order of a half-wavelength of the operating optical wavelength. In this section, we briefly review the electromagnetic properties of two-dimensional photonic crystals. For more details, see the article entitled **Spectroscopy:** Raman Spectroscopy in this volume.

There are five Bravais lattices in two dimensions. Most of the research on photonic crystal resonant cavities and waveguides has focused on square and triangular lattices, and in this article we will consider examples based on the triangular lattice. Since these structures are usually defined lithographically however, there is, in principle, no need to confine the investigation to naturally occurring Bravais lattices. Due to the limitations of current nanofabrication technology, much of the research has focused on photonic crystals that have a finite thickness. The important feature of photonic crystals is that the bandgaps in the electromagnetic spectrum opened up by all of the Bragg planes overlap spatially and spectrally, so that a frequency region exists in which no electromagnetic propagation is allowed. These electromagnetic bandgaps can be used to confine optical modes in very small-volume resonant cavities and in waveguides. In high-contrast dielectric systems, such as a semiconductor/air periodic system, only a few lattice periods may be necessary to confine an electromagnetic mode. In the case of finite thickness photonic crystals, this periodicity has the effect of limiting the bandgap formed to the in-plane

directions and in the case of a two-dimensional photonic crystal in a high-index dielectric slab to the formation of a bandgap in the guided modes of the slab. In this case there are still radiation modes of the slab.

Consider a two-dimensional photonic crystal that is periodic in the $x-y$ plane. To start, we can consider materials that are uniform and infinitely extended in z. Electromagnetic fields propagating in the $x-y$ plane are Bloch states. These can be written as:

$$\vec{H}_{k_z,k_\parallel}(\vec{\rho},z,t) = \mathrm{e}^{\mathrm{i}(\omega t-(\vec{k}_\parallel\cdot\vec{\rho}+k_z z))}\vec{u}_{k_z,k_\parallel}(\vec{\rho}) \qquad [1]$$

where $\vec{\rho}$ labels the in-plane coordinates and $\vec{k}_\parallel$ labels the in-plane wavevectors. $\vec{u}_{k_z,k_\parallel}$ is a periodic function in the $x-y$ plane. Modes propagating in the $x-y$ plane in such a system can be classified as transverse electric (TE) waves or transverse magnetic (TM) waves. TE waves have nonzero E_x, E_y, and H_z field components, and TM waves have nonzero E_z, H_x, and H_y field components. A triangular lattice of air holes patterned into a high refractive index dielectric can be used to create a bandgap for both the guided TE and TM modes of the membrane for a range of hole radii. The TE and TM bandgaps that are formed can be over different spectral ranges, however. For laser applications this is unimportant since in practice the emission occurs from electron-hole recombination in a semiconductor quantum well, and for unstrained or compressively strained quantum well materials this emission is TE polarized. In most cases, waveguides have also been designed to work for a single optical polarization. It is generally true that a photonic lattice that consists of a connected high dielectric region is likely to exhibit a TE bandgap, while a lattice formed by disconnected high dielectric regions is more likely to exhibit a TM bandgap. The bandgap in the TE modes is formed between the first and second bands. The first band is called the dielectric band because the field at the Brillouin zone boundary is a standing wave with its intensity concentrated in the high dielectric regions. The second band is called the air band because at the Brillouin zone boundary this field is a standing wave with its intensity localized in the low dielectric regions. Over a reasonable range of lattice parameters, the bandwidth of the TE bandgap can be changed by changing r/a where r is the radius of the holes and a is the lattice constant of the triangular lattice. As r/a gets larger the dielectric band moves up in frequency. This can be thought of as being due to the fact that this mode has a decreasing effective index as r/a increases. The air band frequency increases as r/a increases. Since more of the electric field of the air band is located in the low dielectric regions than the field of the dielectric band, the air band increases in frequency with increasing r/a faster than the dielectric band and the bandgap therefore increases with increasing r/a. This trend holds in photonic crystals of finite thickness as well.

For photonic crystals of a finite thickness, the ability to simply classify modes as either TE or TM is lost. In the most simple finite thickness photonic crystals, that of a high index dielectric slab in which a two-dimensional photonic crystal has been patterned surrounded above and below by the same low index material which may be air of sapphire, or silicon dioxide, the modes can be classified as being either even or odd modes with respect to the mid-plane of the high index slab. In this mid-plane, however, modes can be classified as being either TE or TM, with each containing the same nonzero vector field components as in the infinite case. Away from this mid-plane, however, modes have in general six nonzero electromagnetic field components. The photonic bandgap that is created in this case is in the guided mode spectrum of the high index dielectric slab. There is no gap formed in the radiation modes of the slab. The radiation modes consist of modes with a ray vector that is not totally internally reflected at the high index slab/low index cladding interfaces. Figure 1 shows the dispersion relation, plotted over the irreducible Brillouin zone, of the even modes for dielectric slab with a refractive index of 3.4 in which a two-dimensional triangular lattice of holes has been patterned. The surrounding material is air. The figure shows an electromagnetic bandgap

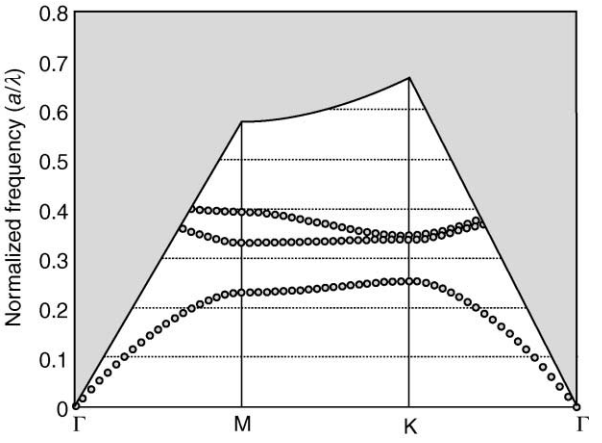

Figure 1 The photonic band diagram for a photonic crystal slab with a triangular lattice of air holes perforating a high-index dielectric slab. The slab, which assumes a refractive index $n = 3.4$, is suspended in the air with a thickness of $d/a = 0.6$. The air holes have radii of $r/a = 0.3$, where a is the lattice constant. Only the lowest three eigenmodes are shown in the plot.

formed between the first and the second guided modes of the slab. Radiation modes of the slab have real valued propagation vectors in the z-direction. These modes lie above the in-plane dispersion relation for air and exist inside the shaded region in the figure. This dividing line between the guided modes and the radiation modes is referred to as the light line.

If the upper and lower cladding layers of the high index slab are different and therefore have different indices of refraction, then the ability to classify modes as being either even or odd about the mid-plane of the slab disappears and it is possible to lose the bandgap in the guided modes altogether. In cases where the refractive index of the bottom cladding is not significantly different from that of the top cladding, such as a case where air serves as the top cladding layer and a material such as sapphire or silicon dioxide forms the bottom cladding, it is found that the even and odd modes describe the field reasonably accurately. To emphasize the approximation involved in the model, these modes are most often referred to in the literature as even-like or odd-like. Overall, there are three primary effects of having asymmetric cladding layers such as an air top cladding and sapphire bottom cladding case. These are a reduction in the effective bandgap width, an increase in the area of the radiation modes on the dispersion relation, and the loss of a rigorous bandgap in the guided modes of the slab. The first two of these effects are the most serious for device designers.

Photonic Crystal Resonant Cavities and Lasers

Photonic crystal resonant cavities can be formed at frequencies inside the bandgap or at the bandedges. Modes in the bandgap are formed as a result of a defect in the lattice. Modes at the bandedge are also sometimes used because the fields with wavevectors at Brillouin zone boundary are standing waves. These standing waves are analogous to the resonant modes that are formed in distributed feedback (DFB) laser structures. Here we will focus on modes confined in the bandgap. Allowed modes in electromagnetic bandgaps in photonic crystal slabs can be introduced by introducing one or more defects into the lattice. By perturbing a single lattice site, we can permit a localized mode or modes that have a frequency in the gap. This phenomenon is similar to the formation of deep levels in an electronic bandgap of a solid due to impurities and identical to the formation of resonant modes in vertical cavity surface emitting lasers (VCSELs) and phase-shifted DFB lasers. In each of these last cases, a defect in the periodicity of a precise thickness occurs between two one-dimensional distributed Bragg reflectors. Defect modes in photonic crystal resonant cavities can be engineered to radiate in a particular direction by trading-off the in-plane versus out-of-plane losses, and the resonant frequency is determined by the parameters of the lattice. Very small mode optical mode volumes can also be obtained in these resonant cavities leading to the possibility of modifying spontaneous emission.

Simple models exist which illustrate the formation of localized modes inside the bandgap as a result of defects in the otherwise periodic lattice. One of these was applied to the formation of deep levels in solids. This model can also be applied to the electromagnetics of defects in periodic structure. For a simple one-dimensional case, assuming that the defect exists at a single unit cell and that the dispersion of the band is dominated by nearest neighbor interactions, this can be solved exactly. Figure 2 shows the allowed frequencies of a ten unit cell chain with a single defect located at the center unit cell. Notice that one mode, called a donor mode, drops out of the band for positive values of $\Delta\varepsilon$ and one mode, called an acceptor mode, rises out of the band for negative values of $\Delta\varepsilon$. This is true in general. A perturbation of the lattice in which the defect has a higher index than the unperturbed lattice will cause a mode to drop out of the air band while a perturbation that has a lower dielectric constant than the background lattice will cause a mode to rise into the bandgap out of the dielectric band. In practice, resonant modes and frequencies in photonic crystals are modeled numerically.

A great deal of variety exists in resonant modes formed by defects in two-dimensional photonic crystal slabs. The simplest examples consist of a single missing hole in a two-dimensional square or

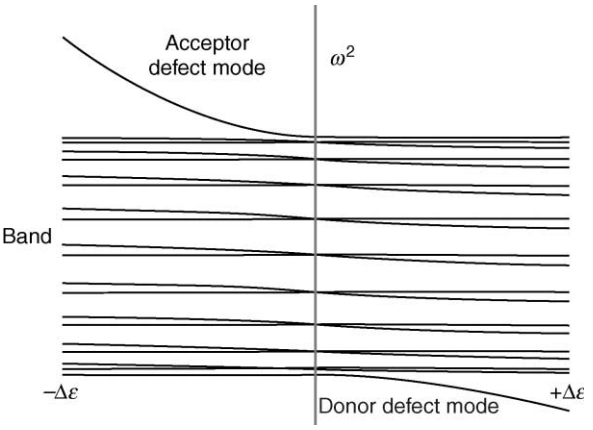

Figure 2 A one-dimensional Slater–Koster model for a single defect in a 10-unit-cell chain, showing the allowed states as a function of the defect perturbation.

triangular lattice patterned into a high-index dielectric slab. However, the resonant mode size, shape, frequency, and polarization can be engineered by tailoring the local dielectric in the region of the resonant mode. Losses in these cavities can be conceptually separated into losses in-plane through the photonic crystal and radiation losses out-of-plane. The in-plane losses are a result of having only a finite number of lattice periods surrounding the localized mode. A finite number of periods results in a finite loss due to tunneling of the fields through the lattice. This loss can in principle be made arbitrarily small by increasing the number of lattice periods surrounding the resonant mode. For a fixed number of lattice periods, the in-plane radiation loss will be reduced as the bandwidth of the photonic bandgap is increased because the magnitude of the in-plane decay constant increases with increasing bandgap width. A resonant mode formed by a defect in a truly three-dimensional photonic crystal will have losses limited by the number of achievable lattice periods and the bandwidth of the photonic crystal bandgap.

Photonic crystal cavities formed by two-dimensional photonic crystals of finite thickness suffer from an out-of-plane radiation loss. Optical confinement in the direction perpendicular to the two-dimensional photonic crystal is due to total internal reflection of the mode that occurs in the high index photonic crystal slab surrounded by lower index materials. Out-of-plane losses are due to the presence of wavevector components in the resonant mode that lie above the light line inside the radiation cone of the cladding. Figure 3 shows the Fourier transform of the magnetic field at the mid-plane of photonic crystal slab in which the resonant mode is formed by a single missing hole in a two-dimensional triangular lattice. In this cavity geometry, a doubly degenerate pair of modes is introduced into the photonic bandgap. The figure shows the Fourier transform of the field for one mode of this double degenerate pair. The boundary of the radiation cone in the figure is marked by the solid circle. Components of the mode inside this circle are not confined to the slab and contribute to out-of-plane radiation losses. These losses can be reduced by engineering the mode so that it has a smaller overlap with the radiation cone. This can be accomplished by allowing the mode to expand in real space in directions in which the wavevectors of the mode extend into the radiation cone. This reduces the spread of the Fourier transform of the mode and reduces the overlap of the mode with the radiation cone.

Symmetry can also be used to reduce the coupling to the radiation fields of the slab. Reducing the resonant frequency of the mode can also reduce out-of-plane radiation losses. This has the effect of reducing the size of the radiation cone in k-space. One way to accomplish this is to reduce r/a in the photonic crystal lattice. This will generally reduce frequencies of all of the photonic crystal modes. It will also, however, generally be accompanied by a reduction in the bandwidth of the photonic bandgap which will increase the in-plane losses. As a result, care must be taken in designing photonic crystal resonant cavities. Nevertheless, in the smallest mode volume photonic crystal resonant cavities, the optical losses will generally be dominated by out-of-plane radiation loss.

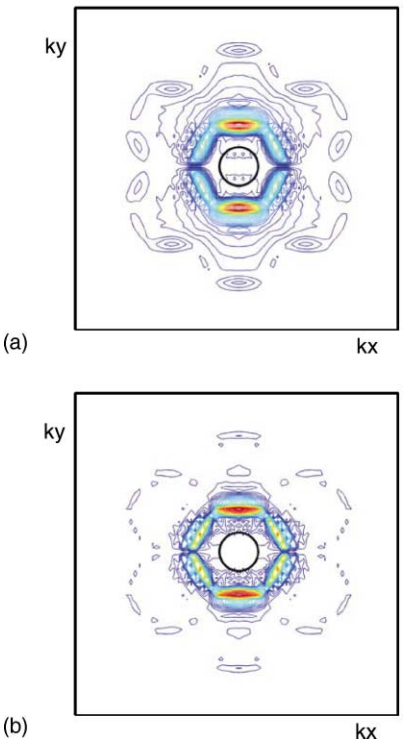

Figure 3 (a) The spatial Fourier transform of the magnetic field component, Hz, of a defect cavity mode at the mid-plane of a triangular-lattice suspended membrane single-defect photonic crystal microcavity. The inner circle indicates the light cone inside which mode components radiate vertically. (b) The spatial Fourier transform of a modified defect cavity mode. The overlap of the mode with light cone has been reduced by modifying the defect cavity.

Quality factors have been predicted to exceed 100 000 in carefully designed photonic crystal resonant cavities in which the optical mode volume is on the order of a few cubic half-wavelengths in the material. Larger resonant cavities formed by introducing multiple defects in the lattice are often less well confined in the real space lattice leading to a reduction in the components overlapping the radiation cone in k-space and a reduction in out-of-plane

radiation loss. These cavities also are much more likely to support multiple resonant modes for a given index perturbation.

In analyzing resonance modes of photonic crystal resonant cavities, one of the most important parameters is the quality factor Q of the cold cavity. Practically, a theoretical prediction of the quality factor requires the use of numerical methods and finite-difference time-domain and finite element techniques are commonly used. There are basically three numerical approaches that can be used to calculate the quality factor of the cavity modes. Two of these methods calculate the quality factor from the time domain fields while the third is a frequency domain approach. The first method is to calculate the slope of the exponential decay of the energy of a given cavity mode with time. This decay of energy from the cavity is described by $\exp(-t/t_{\text{ph}})$ where t_{ph} is the photon lifetime which is related to the quality factor Q, by $Q = \omega t_{\text{ph}}$. This method is most useful for relatively low Q modes where the slope of energy decay is visibly greater than zero.

Another method is to calculate the ratio of the full width at half magnitude (FWHM) of the cavity resonance in the frequency domain, $\Delta\omega$, to the center frequency, ω_0. However, distortion to the spectrum is often introduced because the numerical simulation terminates before the impulse response is fully evolved. This has the effect of viewing the true time-domain response through a rectangular window, which translates mathematically into the convolution of the true spectrum with a sinc function. This must be accounted for in the determination of the quality factor.

A third method calculates the ratio of cycle-averaged power absorbed in the boundary to the total energy in the cavity mode. This last method has the advantage of by being able to separate the radiation losses into different directions:

$$\frac{1}{Q} = \frac{\omega P}{U} = \frac{\omega(P_{\perp} + P_{\parallel})}{U} = \frac{1}{Q_{\perp}} + \frac{1}{Q_{\parallel}} \qquad [2]$$

in which, the effective vertical quality factor $Q_{\perp}$ is given by the ratio of power lost to the absorber at the top and bottom $P_{\perp}$ to the total cavity energy $U(t)$, and the effective in-plane quality factor $Q_{\parallel}$ is similarly given by the ratio of in-plane power loss $P_{\parallel}$ to the total cavity energy.

Photonic crystal lasers and resonant cavities have been demonstrated experimentally. The first demonstration of lasing in a two-dimensional photonic crystal laser occurred in a cavity formed by a single defect in a triangular lattice that was patterned into an InGaAsP membrane. The laser operated under optically pumped conditions at 143 K. Room temperature pulsed operation of photonic crystal defect lasers was reported shortly thereafter. Figure 4 shows an electron micrograph of such a resonant cavity. In the figure, the resonant cavity is formed in a suspended membrane in which a triangular lattice photonic crystal with a defect has been patterned. The fabrication of these devices involves pattern definition by electron beam lithography and pattern transfer by a series of wet and dry etching steps. The observed quality factors are, of course, sensitive to fabrication imperfections. Many other cavity designs and demonstrations have also been reported.

To operate a photonic crystal laser continuously at room temperature, it is necessary to design a high-Q resonant cavity that dissipates heat well. Poor heat dissipation is a major drawback of suspended membrane resonant cavities. One strategy for improving the heat dissipation in photonic crystal laser cavities is to form the two-dimensional photonic crystal membrane cavity on top of a low-index high-thermal-conductivity substrate. Figure 5 shows an electron micrograph of a photonic crystal cavity formed by leaving out 37 holes from a triangular lattice patterned into an InGaAsP membrane. This membrane is bonded to a sapphire substrate, which facilitates heat dissipation. This cavity is capable of room temperature continuous wave operation.

It is believed that these lasers are capable of electrically-pumped room temperature operation. This is based on the fact that large quality factors have been demonstrated in optically-pumped photonic crystal lasers and some quality factor reduction due to free carrier absorption and absorption at metal contacts can be tolerated and still lead to lasing. A reasonable assumption would be that the

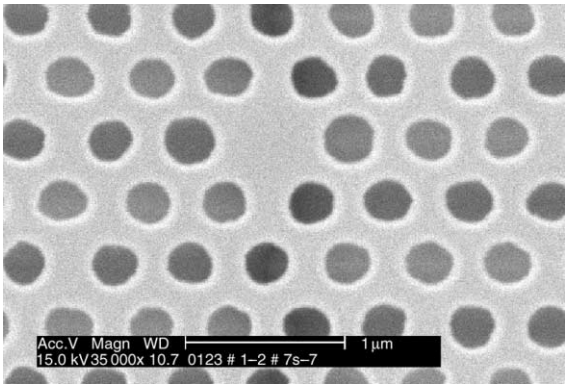

Figure 4 The scanning electron micrograph of a triangular-lattice suspended membrane photonic crystal single defect cavity.

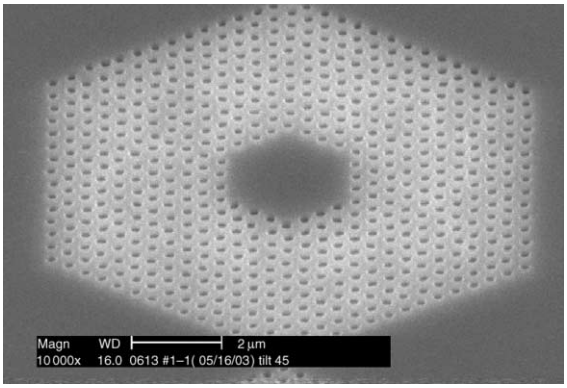

Figure 5 The scanning electron micrograph of a triangular-lattice, 37-missing-hole, photonic crystal defect cavity, bonded on sapphire which serves as lower cladding to improve heat dissipation. CW operation of the laser cavity was demonstrated.

performance of these electrically-pumped photonic crystal lasers would have much in common with the performance of VCSELs. Both VCSELs and photonic crystal cavities have small mode volumes with the cavity formed in some directions by distributed Bragg reflection. The emission direction of photonic crystal lasers can be engineered to be vertical or in-plane, but the basic resonant cavities do have important similarities. The free carrier absorption loss in photonic crystal laser cavities may be expected to be larger than in VCSELs since a photonic crystal laser mode lacks the standing wave behavior in the vertical direction that allows doping at the nodes of the standing wave to reduce the absorption loss. If free carrier absorption loss leads to larger internal losses for photonic crystal lasers than for VCSELs, then some reduction in the achievable slope efficiencies will also occur for photonic crystal lasers.

Photonic Crystal Waveguides

Another important optical element for integrated photonic circuitry is a linear waveguide. Conventional dielectric waveguides confine propagating beams by an index of refraction difference between the waveguide core and the waveguide cladding. Photonic crystal waveguides are most often formed by a linear defect, which consists of a row of modified unit cells of the lattice, patterned into a high index dielectric membrane. The guiding in this case is due to a mixture of total internal reflection at the high index membrane/low index cladding interfaces and distributed reflections from the photonic crystal in-plane. Because this confinement does not exclusively dependent on total internal reflection, the transmission loss through small bending radius waveguide branches and bends can be made very small. Predictions and experimental demonstrations exist which show that

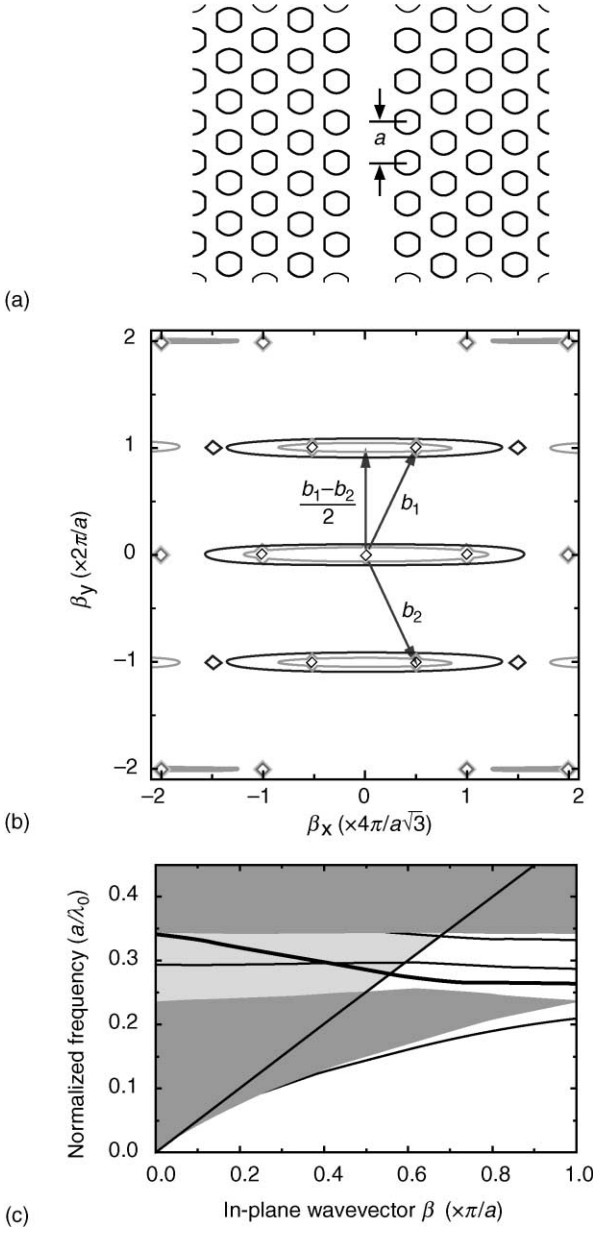

Figure 6 (a) The top view of a triangular lattice photonic crystal single-line defect waveguide with air hole radius $r/a = 0.3$. (b) The 2D spatial Fourier transform of the waveguide dielectric distribution. (c) The photonic band diagram for a suspended membrane single-line photonic crystal waveguide. The membrane has a refractive index of $n = 3.4$ and its thickness is $d/a = 0.6$. The surrounding material is air. The light gray and dark gray area indicate the regimes where field radiates through the air and photonic crystals, respectively.

photonic crystal waveguides are capable of supporting small bending radius waveguide bends with almost total transmission. This makes photonic crystal waveguides a candidate for waveguides in densely integrated photonic circuits.

Figure 6a shows an illustration of the top view of a two-dimensional photonic crystal waveguide.

This is a triangular lattice in which one row of unit cells has been modified. Shown in Figure 6b is the Fourier transform of index of refraction for the situation in which the photonic crystal consists of low index holes in a high index semiconductor. The presence of the linear defects modifies and broadens the reciprocal lattice from a simple reciprocal triangular lattice, before the creation of linear defect, to the distribution shown in the figure. This Fourier transform has components along the direction of propagation at $(\vec{b}_1 - \vec{b}_2)/2$ as shown in the figure where $\vec{b}_1$ and $\vec{b}_2$ are reciprocal lattice unit vectors. These reciprocal lattice components at $(\vec{b}_1 - \vec{b}_2)/2$ couple a planewave with wavevector β to other planewaves with wavevectors $\beta \pm (\vec{b}_1 - \vec{b}_2)/2$. The result of this coupling is that the electric field of the waveguide mode is a Bloch wave. In a photonic crystal waveguide in which the waveguide axis is the z-direction, the Bloch wavefield in the waveguide can be written in the form:

$$\vec{E}(x,y,z,t) = \sum_n c_n \vec{f}_\beta(x,z) \times \exp\left[\mathrm{i}\left(\omega t - \left[\beta + n\left(\frac{\vec{b}_1 - \vec{b}_2}{2}\right)\right]y\right)\right] \quad [3]$$

In this expression the periodic function of the Bloch wave has been explicitly expanded as a Fourier series and each term in the Fourier series is called a spatial harmonic. Note that these fields differ from that of a photonic crystal fiber because the cladding of a photonic crystal waveguide has a periodicity along the direction of a waveguide. A photonic crystal fiber does not.

Most of the realizations of photonic crystal waveguides occur in two-dimensional photonic crystals formed in high index dielectric slabs. The membrane is usually located a few microns above a high index substrate. Because the fields of the guided modes decay exponentially outside the membrane, the effect of a substrate several microns away is very nearly negligible. The photonic band structure for $r/a = 0.3$, normalized membrane thickness $d/a = 0.6$ and refractive index of $n = 3.4$ is shown in Figure 6c. Only the modes with even symmetry along the midplane of the membrane are shown. A bandgap opens for modes with odd symmetry only for large low index filling factors in the triangular lattice. Filling factors large enough to create a bandgap for the odd modes are often impractical so that the odd modes are rarely considered. The even and odd modes are orthogonal, so that plotting the dispersion relation for the even modes only is justified. In reality, even and odd modes may be weakly coupled as a result of fabrication imperfections. The horizontal axis of the dispersion relation covers the in-plane wavevector β along the propagation direction of the irreducible Brillouin zone. The vertical radiation light cone and transverse radiating region of the photonic crystal are mapped as light gray and dark gray areas, respectively. They correspond to the regimes in which light radiates through the air cladding and photonic crystal cladding, respectively. Waveguide dispersion relations can be calculated using two-dimensional approaches in which case the guiding due to the high index slab is accounted for by using an effective index of refraction for the mode. The effective index is the ratio of the propagation coefficient to the free space wavevector of the guided mode of the slab. The two-dimensional

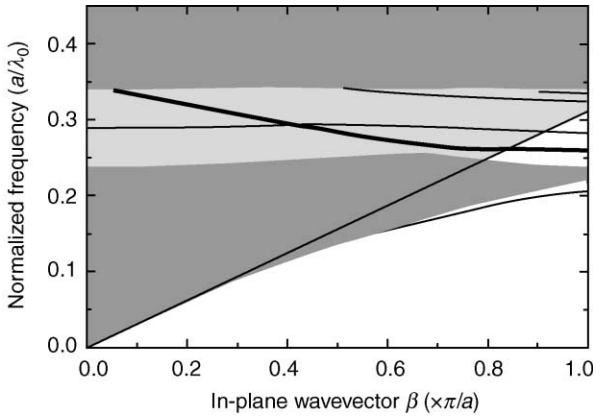

Figure 7 The photonic band diagram for a triangular-lattice sapphire-bonded single-line photonic crystal defect waveguide. The dielectric membrane has a refractive index of $n = 3.4$ and thickness of $d/a = 1.0$. The index of the sapphire bottom cladding is assumed to be 1.6.

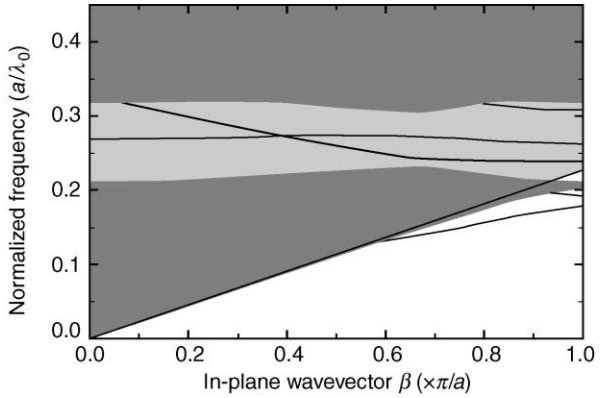

Figure 8 The photonic band diagram for a triangular-lattice deeply etched single-line photonic crystal defect waveguide. The top cladding, guiding membrane, and bottom cladding have an index of refraction of 3.0, 3.4, and 3.0, respectively. Their normalized thicknesses d/a are 1.0, 1.0, and 6.0, respectively.

calculation then uses the effective index of the mode as the high index of material in the photonic crystal. To obtain accurate results, the effective index for each mode calculated separately and the two-dimensional calculation of the photonic crystal waveguide dispersion must be repeated for each waveguide mode.

Examples of photonic crystal waveguide dispersion relations are shown in Figures 7 and 8 for waveguides formed by photonic crystals in dielectric slabs on high index lower cladding layers. Figure 7 is the dispersion relation for an oxide lower cladding layer. The area of the light gray region, which is the projection of the oxide cladding light cone onto waveguide propagation direction, increases as a result of higher index of refraction. Figure 8 shows the dispersion relation for a waveguide with an even larger lower cladding index. In this case the air holes of the two-dimensional photonic crystal are patterned all the

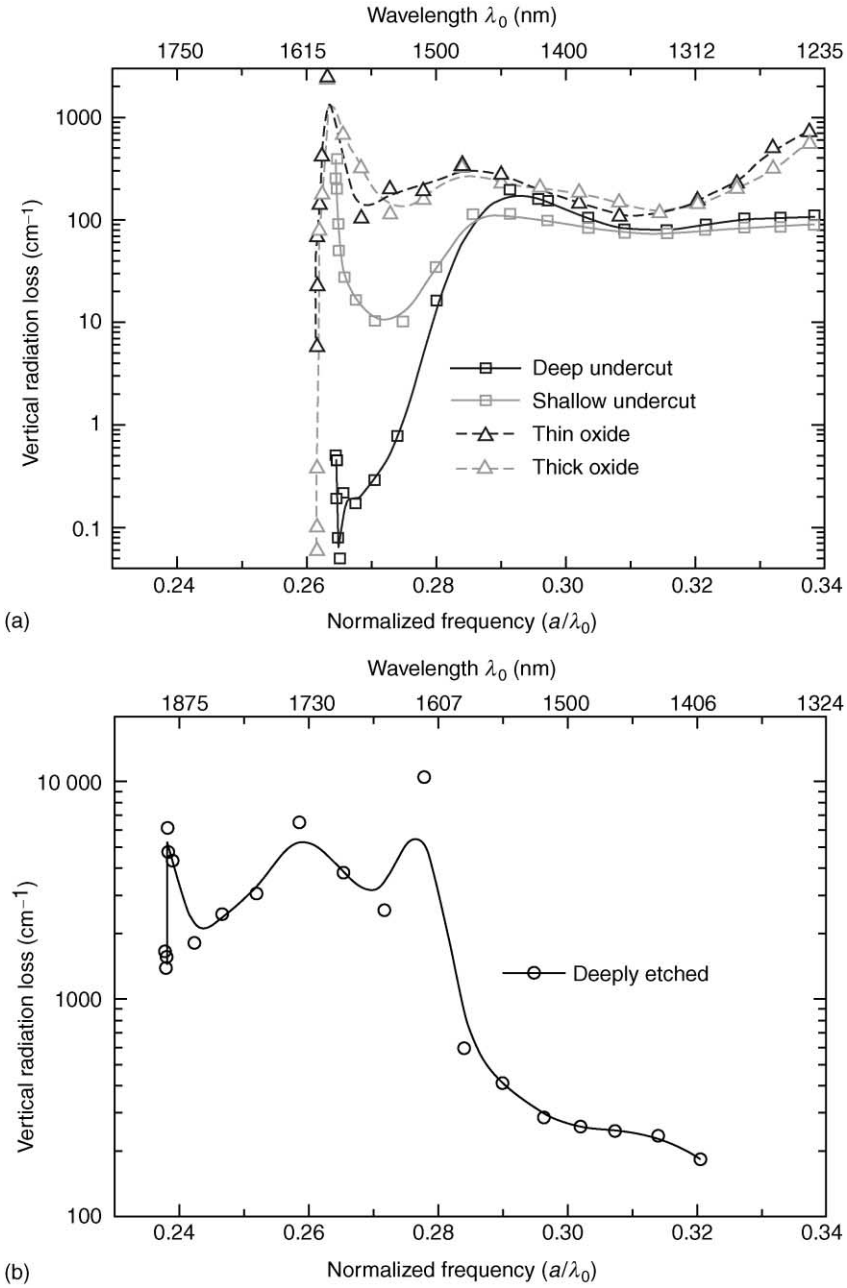

Figure 9 The out-of-plane radiation loss as a function of normalized frequency for the photonic crystal defect slab waveguides illustrated in Figures 6–8. Table 1 Photonic crystal defect slab waveguides considered in the calculations

Waveguide structures	*Suspended membrane*		*Oxidized lower cladding*		*Deeply etched*
	Deep undercut	*Shallow undercut*	*Thin oxide*	*Thick oxide*	
Layer description: Material (normalized thickness d/a)			Air (>3.0)		
	–	–	–	–	AlGaAs (1.0)
	GaAs (0.6)	GaAs (0.6)	GaAs (0.6)	GaAs (0.6)	GaAs (1.0)
	Air (3.0)	Air (1.0)	Al_xO_y (2.0)	Al_xO_y (5.0)	AlGaAs (6.0)
			GaAs substrate (>3.0)		

Refractive index of 3.4 is assumed for GaAs, 3.0 for AlGaAs, 1.6 for Al_xO_y, and 1.0 for air.

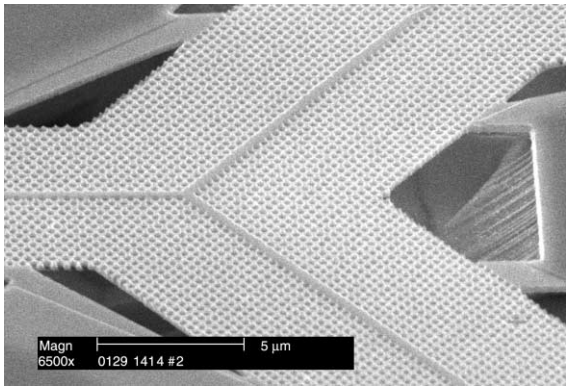

Figure 10 The scanning electron micrograph of a photonic crystal Y-branch fabricated on InP material system.

way through the lower cladding layer, with an index of 3.0, on a high index substrate. The defect modes lying within the in-plane photonic bandgap are all above the cladding light line in this case. Propagation losses are predicted to increase by over two orders of magnitude from the structure with very low index cladding layers shown in Figure 6 to the high index lower cladding structure of Figure 8.

Figure 9a and b shows the results of a fully three-dimensional calculation for the propagation loss of the three structure shown in Figures 6–8. The details of these structures are shown in Table 1. This calculated loss is due to coupling between the guided mode and the radiation modes of the high index substrate. A wavelength scale is also included using $a = 420$ nm in Figure 9a and 450 nm in Figure 9b. The suspended membrane suffers the least vertical radiation loss among all of the waveguides considered and has a minimum loss around 0.2 cm^{-1}. Low-loss waveguides formed on high index cladding layers may be possible, but care should be taken to eliminate coupling between the guided modes and the radiation modes of the cladding. In this case, the design strategy for reducing the optical loss is to reduce the magnitude of the Fourier component of the electromagnetic field inside the light cone. It should also be noted that deeply-etched waveguides formed by removing multiple rows of holes have been demonstrated with significantly lower radiation loss than is predicted for the single line defect waveguides. However, these waveguides are multi-moded at all frequencies. It is also important to remember that the nanofabricated waveguides will suffer additional losses due to fabrication imperfections that were not included in the numerical model. Figure 10 shows a nanofabricated photonic crystal waveguide. The image is an electron micrograph of a y-branch component of a Mach–Zehnder interferometer formed in a two-dimensional photonic crystal waveguide patterned into a suspended InGaAsP membrane.

Finally, it is worth noting that the group velocity of photonic crystal waveguide modes, where the group velocity is given by the gradient of the dispersion surface:

$$v_g = \nabla_{\vec{\beta}}\omega \qquad [4]$$

is very small near the zone boundary. This can be seen from the dispersion relations shown in Figures 6–8. In fact, the slope of the dispersion relations is likely to be a parameter which can be engineered by careful waveguide design. This property may allow photonic crystal waveguides to find applications in optical processing functions such as delay lines.

Introduction

Photonic crystals mimic the role of the atomic structure of a semiconductor in manipulating electrons, in this case for light. Hence, called semiconductors of light, these crystals are not generally found in nature and have to be designed and fabricated. Research and development in this field is taking place at a feverish pace to both understand the various nuances of this concept, as well as to evolve new methods to fabricate such crystals in the laboratory and ultimately on a commercial scale. The driving force behind this is the tremendous potential of these systems. They promise to revolutionize the way light can be used for future devices: from forming perfect, omnidirectional mirrors to the smallest ever lasers, and ultimately, complex optical chips with a wide range of functionality arranged in three-dimensional (3D) circuits.

This article seeks to elaborate on a specific technique to make photonic crystals called colloidal self assembly. Here, we will review the fundamental concepts underlying photonic crystals and see how the above process can lead to a versatile platform in making such systems. We will discuss the basic aspects of this method and look at the various innovative manifestations that have been used to fabricate many types of photonic bandgap materials.

Photonic Bandgap

A key attribute of a semiconductor is the formation of a bandgap, a band of energy states that the electrons cannot acquire. They may exist in the so-called valence band where their energy levels are less than that of the bandgap. Or they may be energized to states above the bandgap, i.e., to the conduction band, but the bandgap is the forbidden region. The continuous band of states that constitutes this bandgap is a result of the long-range order imposed by the crystal structure of the semiconductor, where the atomic lattice presents a periodic potential to a propagating electron. The tremendous usefulness of semiconductors comes from their ability to perform switching and logic functions, which in turn is a result of controlling the availability of electrons above and below the bandgap.

The propagation of light as an electromagnetic wave is influenced by the dielectric properties of the medium. For a waveguide aligned in the z direction, the field is the sum of the two propagating transverse modes, each with the form $E(x) = \Phi(x, y)e^{ik_z z}$, where $\Phi(x, y)$ is the field distribution and k_z is the propagation constant. The wave equation for the transverse mode reduces to

$$\frac{\lambda^2}{4\pi^2}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right)\Phi(x, y) + n(x, y)^2\Phi(x, y) = (\bar{n})^2\Phi(x, y) \quad [1]$$

Here, $\bar{n}$ is referred to as the effective refractive index and is given by $\bar{n} = k_z\lambda/2\pi$.

Equation [1] has the same form as the Schrödinger equation, which describes the wave functions of quantum particles such as electrons. This equivalence helps us to understand the similarity between the attractive potential well structures that bind electrons to the wells created by a local increase in the refractive index that confines light into optical modes.

The creation of a structure with a 3D periodic change in the refractive index (Figure 1) opens a gap, due to Bragg scattering off the dielectric interfaces whereby a set of frequencies of light becomes forbidden to propagate in any direction – a photonic bandgap. To understand the formation of the

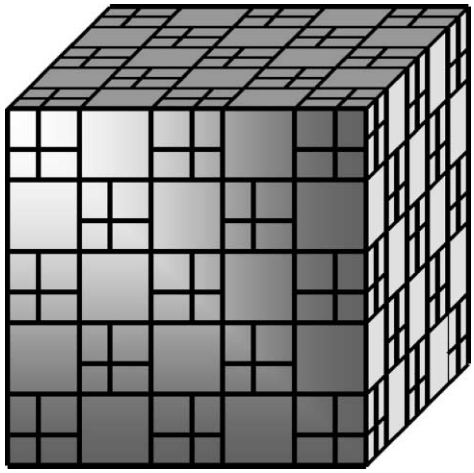

Figure 1 Schematic representation of a three-dimensional photonic crystal. The structure formed is a periodic variation in the dielectric properties of the matrix. Here, the two different dielectric regions are represented by □ and ⊞.

bandgap, one needs to consider the complex pattern of overlapping beams that results from the refractions and reflections from the numerous interfaces. This pattern is determined by the characteristics of light-waves (wavelength and direction of travel) and those of the periodic dielectric variation (pitch and magnitude of the contrast). Thus, for a select band of wavelengths, complete cancellation through destructive interference occurs in all directions.

One way to breach this restriction is by creating a defect or a disturbance in the periodicity, which would allow localized photonic states in the gap. This defect can be a point defect to form a microcavity, or have a 1D trace that behaves as a waveguide or a planar defect. Thus, a photonic crystal with a specific defect structure can be used to manipulate light in unique ways that can be used for a variety of applications, including lasers, filters, switches, waveguides, and for 3D integrated optics circuits. These structures are also interesting because they have been predicted to exhibit enhanced optical nonlinearities.

Photonic Crystals

The lattice constant for the photonic crystal must be comparable to the wavelength of light, typically in the range of 0.5 to 2 μm. This range is three orders of magnitude greater than the lattice constants found in solids and hence photonic crystals need to be synthesized. A common example of such a structure is a diffraction grating in a waveguide, which serves as a 1D photonic crystal. There are also examples of photonics crystal structures found in nature, such as the iridescent colors seen in certain butterflies and opal gemstones. The structure of opal is a 3D photonic crystal consisting of small spherical particles of hydrated silica (SiO_2). These spheres tend to be irregular in size but in rare precious opals, they are monosized. Diffraction from these spheres leads to the remarkable colors seen in opals.

Fabrication of 3D photonic crystal structures, with two materials with sufficiently different dielectric properties, has been extensively investigated over the past several years. Given the requirement of a tightly controlled periodicity, one obvious means of doing this is to use the microlithographic patterning processes that are so well developed for very large-scale integration (VLSI). Since these are planar and not volumetric techniques, several iterations of layer-by-layer deposition, lithography, and etching are necessary. A popular second method is that of colloidal self assembly.

The Self-Assembly Technique

The term 'self assembly' is usually used to describe the act of spontaneous and controlled agglomeration of some basic moieties. These basic units could be molecules, supramolecules, nanoclusters, or particles. It is similar to what is seen in living systems, where organic and inorganic materials are assembled into useful configurations mediated by various proteins. Since there is no intrinsic restriction on the number of such building blocks that can spontaneously organize into periodic structures, this process is readily scalable to large dimensions, and is the main attraction of this process.

The self-assembly technique is well suited for making periodic structures such as photonic crystals. Starting with particles of the appropriately uniform size (in the range 0.5 to 2 μm), one can conceive of organizing them into a periodic 3D array. Particles, rather than molecules or nanoclusters, are the preferred starting materials for photonic crystals because their larger size provides periodicity on the length-scale of optical wavelengths. Large block copolymer molecules have also been used instead, but they are limited in their scope.

The following sections will discuss the salient details of using self assembly to form photonic crystals. The sequence of the discussion follows the path increasing process complexity. To begin, we will examine the simplest of photonic crystals made by neatly packing uniform particles called a colloidal lattice. Given the limited range of monosized particles available, such lattices are inadequate as useful photonic crystals but can be used as templates into

which other materials can be incorporated. We shall discuss one particularly attractive incorporation technique, namely electrochemical deposition, in more detail. Finally, since the process is dominated by surface interactions, diverse classes of particles can be generated by simply functionalizing the particle surface. Looking ahead to the future, this is an important aspect that can vastly increase the capability of a colloidal assembly.

Formation of Colloidal Lattices

Colloidal crystallization has been studied for several decades but has received renewed attention due to both the availability of more uniform powders as well as new applications such as photonic crystals. Fine particles are unwieldy in their dry state due to high solid–gas interfacial energy and are typically dispersed in a liquid. Particle concentration is kept low to avoid agglomeration. Further stabilization of the particles may be achieved by either charging the particles' surface (electrostatic stabilization) or by adsorbing a neutral shielding molecule (steric stabilization). A preferred approach is to induce monosized spherical particles to settle into a tightly packed lattice. The settling rate, v, of particles of diameter d_p is given by the well-known Stokes equation:

$$v = \frac{d_p^2 a \Delta\rho}{18\mu} \qquad [2]$$

where a is the acceleration due to gravity (or a centrifugal field), $\Delta\rho$ is the density difference between the particle and the liquid, and μ is the viscosity of the liquid. Whereas settling is a popular means of self assembling, other methods such as centrifugation, filtering, pressing, or dip coating can be used (Figure 2). For charged particles, electrophoresis, where an electric field induces flow, is applicable.

The typical lattice types in these domains are hexagonal close-packed planes (hcp) as shown in Figure 3 or face-centered cubic (fcc) structures (Figure 4). In fcc crystals, the layer stacking follows the order ABCABC; in hcp it is ABAB. In both stacking sequences, hard spheres occupy a volume fraction of 0.7404 and can be shown to have little entropic differences. However, it is experimentally observed that the preferred ordering of spheres is the fcc close-packed arrangement, which is also the case in high-quality opals.

This method clearly has the advantage of being a simple, cost-effective platform to make 3D photonic crystals that can be readily scaled to various levels. There are no repetitive steps as would be the case in layer-wise lithographic pattering. However, there are still some outstanding challenges. The primary one is the difficulty in ensuring that the organization of the particles does not incur the formation of unwanted defects and domains. Also, introduction of intentional defects such as waveguides is not trivial, although this is being demonstrated in different laboratories. Another shortcoming is the

unavailability of uniformly sized particles of various different chemical compositions.

The formation of monosized spherical particles is a complex problem in its own right. Usually, such particles can be made from specific polymeric materials such as polystyrene or latex, whereas SiO_2 is the best-known inorganic system. These particles are not perfectly uniform but the typical deviations from the mean size of a few percent are acceptable for most applications. Given the attractiveness of photonic crystals for a wide array of applications in optics, research in this field is burgeoning and more breakthroughs are bound to come. Already first-generation photonic bandgap devices, such as fiber gratings or photonic crystal optical fiber, are commercially available.

Colloidal Lattices as Photonic Crystals

Due to the limited range of composition of the particles available, the particle-to-air refractive index contrast provided by straightforward colloidal lattices is small. This results in low diffraction efficiencies and hence colloidal lattices do not have photonic bandgap in all directions. However, these structures can then be used as templates for various additional modifications, as seen later.

On the other hand, a simple colloidal lattice can be more easily modeled. An analytical solution can be achieved for this system using dynamical diffraction theory for a low diffraction efficiency approximation. For a close-packed stacking of spheres in a fcc array, there exists a minimum in the transmission band at a wavelength λ_c which is given by the Bragg–Snell equation:

$$\lambda_c = 2d_s\sqrt{n_{\text{eff}}^2 - \sin^2\theta} \qquad [3]$$

where d_s is the d-spacing between the planes in the $\langle 111 \rangle$ direction, n_{eff} is the effective refractive index of the assembly and θ is the angle between the incident beam and normal to the (111) plane. This minimum in the transmission is referred to as the primary stop-band.

Photonic crystals are characterized using a Michelson or Mach Zehnder interferometer to obtain the phase and amplitude of the transmission (or reflection) as a function of the wavelength of light (Figures 5 and 6). Ideally, the whole band structure can be calculated from these data. In addition to λ_c, the close-packed structures also exhibit a transmission threshold at a wavelength λ_t, as seen in Figure 5. Both λ_c and λ_t depend on the particle diameter and increase with particle size. In a close-packed structure,

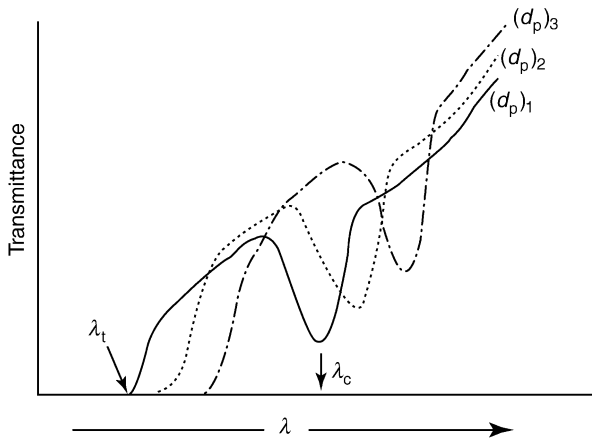

Figure 5 The typical profiles observed from transmission measurements on a photonic crystal. The stopband wavelength (λ_c) increases with d_p, where $(d_p)_1 > (d_p)_2 > (d_p)_3$. The polarization of light is fixed at *s* or *p* polarized.

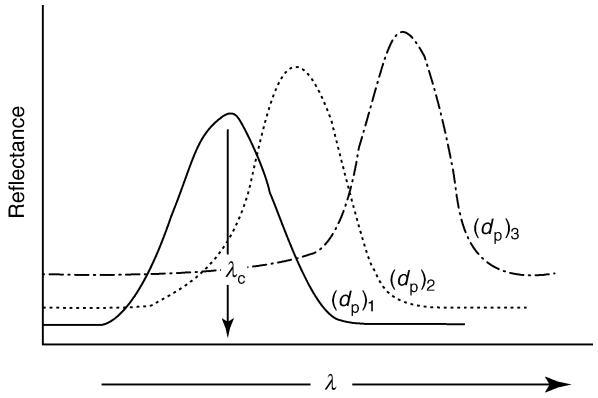

Figure 6 The typical profiles of the reflectance peaks corresponding to the transmission plot seen in Figure 5.

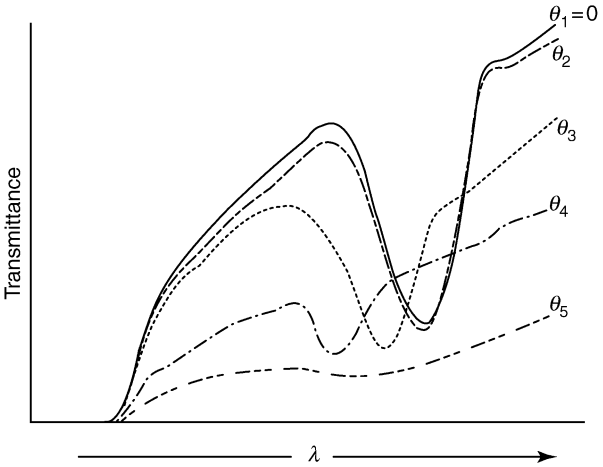

Figure 7 The transmittance profiles as a function of the angle of incidence of light of a fixed polarization. Typical values of θ would be $\theta_1 = 0$, $\theta_2 = 10°$, $\theta_3 = 30°$, $\theta_4 = 50°$, $\theta_5 = 60°$.

the lattice *d*-spacing d_s is related to the particle diameter d_p as $d_s = d_p\sqrt{2/3}$. So when the incident light is orthogonal to the structure, eqn [3] can be simplified to:

$$\lambda_c = 2\sqrt{2/3}(d_p n_{eff}) \qquad [4]$$

Thus, n_{eff} can be obtained from the slope of a plot of the stop-band wavelength λ_c as a function of the particle diameter d_p. The angular dependence of the reflectance spectra is illustrated in Figure 7. These results depend upon the polarization state of the incident light and hence need to be obtained separately for *s* and *p* polarized light.

More Complex Colloidal Lattices

While the use of SiO_2 and polymer microspheres is ubiquitous, they are optically passive materials. New methods are being developed for making uniform spherical particles from other more optically active systems. The zinc oxide (ZnO) system is one such example. The higher refractive index (~2.2) and the light emission ability of this system make it particularly interesting. Monosized particles in the size range of 100 to 600 nm can be made using a two-stage reaction method, which allows extra control over the particle formation. Other optically active systems include rare-earth doped SiO_2, dye doped PMMA spheres, or composite spheres comprised of core–shell configuration with SiO_2 or zinc sulfide (ZnS) cores and gold (Au) or SiO_2 shells, respectively.

Whereas the above discussion focuses on monosized particles, binary crystals can be made using spheres of two different sizes. The strategy here is to vary the particle size during the deposition of every alternate layer. For instance, a first layer of closely packed spheres is followed by the deposition of layers of smaller particles. The resultant crystal structure depends primarily on the concentration of the smaller particles in the dispersion. As seen in Figure 8, the second layer can vary from having three to six particles around every underlying larger particle. Thus the large-small (LS) stoichiometry of these binary crystals can be varied from LS to LS_2 to LS_3 by increasing the concentration of the smaller particles in the suspension phase. Such crystals open up interesting new avenues for complex photonic crystals.

Colloidal Lattices as Templates

By using the colloidal lattice as porous host for a second material, a greater range of photonic crystals can be synthesized. Here, the role of the colloidal array

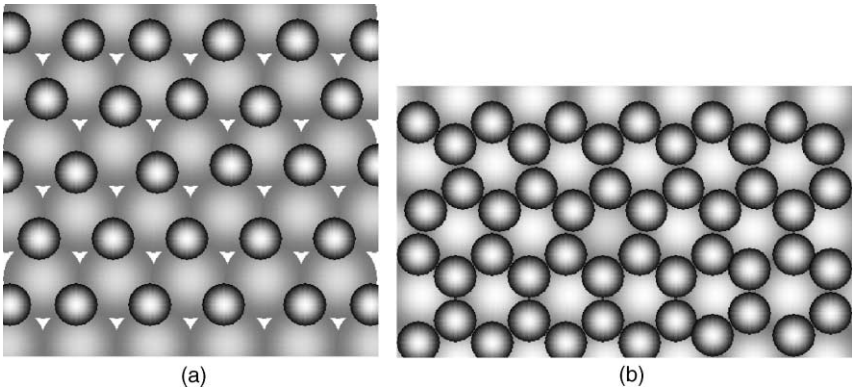

Figure 8 Binary crystals formed using spheres of two different sizes. The large-small (LS) ratio in (a) is 1:1 whereas in (b) it is 1:2.

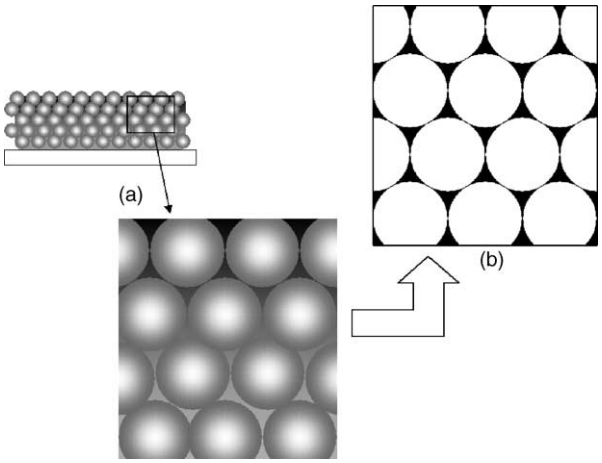

Figure 9 Schematic representation of the templating process using infiltration (a). Upon removal of the particles, a macroporous photonic crystal is formed (b). This is the inverted opal configuration.

is simply as a scaffolding structure. The second material to be infiltrated may be either a liquid (in the form of a dispersion, a solution, or a molten liquid) or a vapor. Both eventually deposit a solid material inside the template. Subsequent selective removal of the template yields a 3D photonic crystal in the form of an inverted opal (Figure 9). This is one of the best and most versatile means of achieving high index contrast, which is required for true photonic bandgap behavior.

It must be noted that to use self-assembled particle arrays as a template, the whole structure has to be often heat treated to confer greater mechanical strength. As assembled, the particles are normally attached by short-range Van der Waals forces and hydrogen bonding, which in the case of SiO_2 is silanol (Si–OH) mediated. Both of these are relatively weak bonds. By heating the assembly, a greater number of siloxane (Si–O) bonds can be formed which additionally strengthens and stabilizes the particulate network. This is important to retain the periodic structure of the assembly during the exposure to high stresses during the infiltration step, for instance. At temperatures around 750 °C, there is significant generation of siloxane bonds but minimal sintering so that the lattice does not change dimensions and retains its original open porosity. With latex particles, the annealing is done just above the glass transition temperature T_g of the polymer for no more than a critical period of time. Longer treatments can destroy the ordering of the spheres.

A template thus strengthened by heat treatment is now ready for infiltration. For example, a template comprised of polystyrene spheres can be infiltrated with a hydrolyzed sol of titanium alkoxide to ultimately form titania in the interstitial regions. Upon standing, the alkoxide sol gels in the interstitial regions leading to a polymeric network called a xerogel. This entire composite can then be further heated to high temperatures (> 300 °C). All organics are removed by decomposition and combustion so as to leave behind a titania matrix with periodic voids (in place of the polystyrene spheres). The templating spheres may also be dissolved, rather than combusted, in solvents such as toluene. The refractive index of titania depends on the crystalline phase that results after heat treatment – anatase is ~2.5 while rutile is ~2.9. High indices can also be achieved with semiconducting materials such as selenium (Se) with an index of ~2.5 or cadmium selenide (CdSe), ~2.9. These chalcogen-derived materials have low absorption in the visible and near infrared, so they are suitable candidates.

When SiO_2 particles are used for templating, they are eventually removed by etching, typically with dilute, buffered hydrofluoric acid at low temperatures. Given the thermal and chemical stability of the SiO_2 particles, molten Se (or other low melting

metals) can be used to rapidly fill the interstitial space. Vapor phase deposition has also been used to fill the porous templates. Examples include the backfilling with silicon (Si) using chemical vapor deposition (CVD), or indium phosphide (InP) using metal-organic chemical vapor deposition (MOCVD).

A variety of structured, macroporous carbon matrices has been made with remarkable optical properties. The templates are artificial opals assembled using SiO_2 microspheres, which are filled with carbon by either: (a) infiltrating with phenolic resin followed by anaerobic pyrolysis of the resin to glassy carbon; (b) CVD of graphitic carbon; and (c) growing diamond-seeded CVD graphite from a plasma. The resultant carbonaceous 'inverse opals' are highly conductive, show intense opalescence due to the ordered arrays of holes, and have a photonic bandgap in the infrared region.

Electrochemical Deposition

One particularly effective backfilling technique is electrodeposition, which has been successfully used to deposit most of the different classes of materials – semiconductors, metals, and polymers. Here, a conducting substrate serves as the appropriate electrode where deposition occurs. By placing a colloidal lattice template on this electrode, the electrochemical deposit is used to fill the interstitial voids in the template (Figure 10). This method has been successfully applied for a host of different metals such as gold (Au), nickel (Ni), platinum (Pt), and alloys such as tin–cobalt (Sn–Co). Likewise, conducting polymers can be efficiently deposited by this method. Although these polymers suffer from inherently low indices, they have favorable electro-optic properties that can be tuned by controlling the composition. In the case of II–VI semiconductors, galvanostatic or potentiostatic deposition can be used: for instance, interstitial CdSe has been deposited (Figure 10) using an acidic solution of electrolytes such as cadmium sulfate ($CdSO_4$) and selenium dioxide (SeO_2).

Electrochemically deposited structures have minimal porosity leading to densities close to bulk density. Hence, they have a higher refractive index and are generally more robust than those made by simple infiltration. Also, they exhibit little change in dimensions and a lower tendency toward cracking during the various physicochemical processes such as drying and sintering that occur en route to forming the photonic crystal. Hence, it is a preferred technique in many cases.

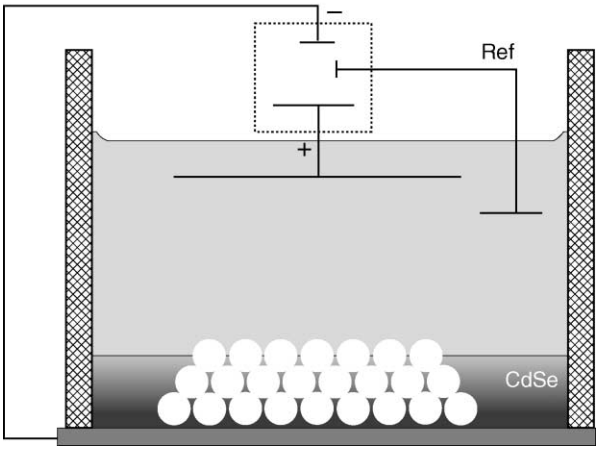

Figure 10 An electrochemical cell for deposition of CdSe from an electrolytic solution on a conducting electrode. The solution contains sulfuric acid (H_2SO_4), $CdSO_4$, and SeO_2. A potentiostat is used to generate the electric fields.

Functionalization

The self-assembly process, whether used directly or as a template to synthesize a photonic crystal, is dominated by surface interactions between particles starting from the organization process through to the thermal stabilization step. These interactions can be tailored by specially treating the surface of the particles with functional groups. Functionalized colloidal templates can enhance the infiltration of the high index material and its properties such as smoothness, density, or optical nonlinearity. Latex spheres can be surface functionalized with sulfate and carboxylic acid groups to increase their surface charging capability, which can lead to more robust self-organization. These spheres can also be coated with a layer of SiOH, which gives them a SiO_2-like appearance on the surface and allows them to be used in conjunction with SiO_2 microspheres. The infiltration of metal (such as Au) nanoparticles into a template crystal of SiO_2 microspheres can be significantly enhanced by functionalizing the SiO_2 surface. This can be achieved using long-chain organic molecules with polar groups on one end that bond with silanols on the SiO_2 surface and thiol groups on the other that strongly latch onto the gold nanoparticles. Simulations of light interaction with ordered three-dimensional arrays of these metallodielectric spheres, show that they are promising starting points for the construction of full photonic bandgap materials in the visible part of the optical spectrum. Also, in these systems, the plasmon resonance of the Au shell particles can be controlled over the visible and infrared region by varying the thickness of the Au shell.

The site-selective attachment ability of biological moieties can also be used effectively here by attaching them onto particle surfaces. DNA oligomers are well known to form conjugate specific bonds – adenine to thymine and guanine to cytosine. Thus particles functionalized with these oligomers can be made to organize in specific sequences that are differentiated, depending on the surface group. These particles can have variable sizes or compositions but their surface properties are controlled largely by the attached biomolecules. Likewise, the antigen–antibody attachment ability can be exploited to improve surface bonding.

Positioning Defects in Photonic Crystals

Much of the work on photonic crystals involves the making of a long-range periodic microstructure with high dielectric contrast because the underlying materials engineering aspects are very challenging. However, the usefulness of photonic crystals depends on the successful placement of defects in precise locations within the crystal. The placement of a point defect leads to a photonic microcavity and that of a line defect, a waveguide for propagation of a light-wave (Figure 11). However, there are certain unique advantages to this style of propagation, such as the possibility of bending light around sharp corners. Line defects in the form of air cores have been introduced in a photonic crystal using a combination of lithography and self assembly. First, ridges are defined in a photoresist on top of the substrate by optical lithography (Figure 12). Upon forming a colloidal lattice on top, the ridges are converted to linear voids by removing the photoresist using combustion or etching. Another technique is to infiltrate a photopolymerizable monomer into a colloidal crystal and preferentially polymerize the liquid by focusing a light beam inside the crystal. Thus the locus of the focused beam defines the waveguiding region that is formed upon removal of the unpolymerized liquid.

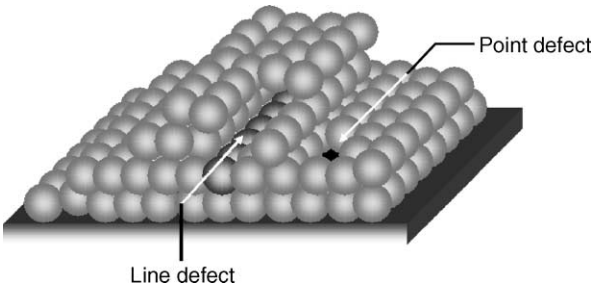

Figure 11 Two common defects in colloidal lattices.

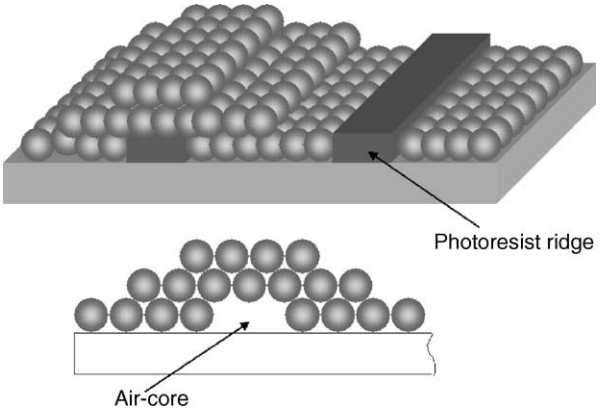

Figure 12 Formation of intentional defect using a lithographic process to define an air-core. This structure can also be used as a template for backfilling a high dielectric material.

Tunable Photonic Crystals

The holy grail in many photonic devices is tunability, and photonic crystals are no exception. Given the wide spectral range that constitutes the domain of light, the ability of devices to switch or translate their performance to another wavelength through an external stimulus is indeed very attractive. The two parameters that can be externally tuned are the dielectric contrast, which would result in a change in the n_{eff} of the crystal and the periodicity of the grating. One technique to tune the former is to form an interference pattern that organizes liquid crystals dispersed in a polymer matrix into droplets to form the photonic crystal. Applying an electric field that changes the refractive index of the droplets can therefore alter the transmission spectrum of the photonic crystal.

To control the lattice parameter, the size of or the spacing between the spheres need to be varied. This concept has also been demonstrated using self-assembled hydrogel-based nanoparticles, which are made of a thermo-responsive material such as poly-*N*-isopropylacrylamide. These particles are soft and conformable and their sizes can be tuned depending on the water content of the system. This ordered matrix is in the form of a gel that can be made to swell and compress upon changing the temperature as water is exchanged between the gel and the ambient. Wavelength tunability of one nanometer has been achieved this way. Tunability has also been sought using methods such as straining the lattice. Calculations show that a 2 or 3% shear strain ought to create a 52–73% distortion of the bandgap. In one novel approach, SiO_2 or polystyrene microspheres were strongly surface charged and ordered with a less than dense packing within a poly-acrylamide

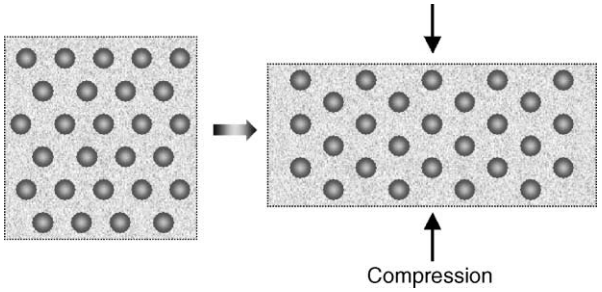

Figure 13 Tunable photonic crystal. Spherical particles are assembled in a compressible media like a hydrogel, which deforms upon applying a stress. The deformation can be used to tune the lattice parameter and hence the optical properties of the photonic crystal.

hydrogel housing (Figure 13). Due to the strong charging the arrangement tends to be body centered cubic (bcc) with the lattice spacing that depends on the concentration of the particles. When the hydrogel is deformed by applying mechanical stress, the diffraction peaks were shown to be tunable over almost the whole visible light wavelength spectrum.

Photonic crystals made from self-organized hydrogels have been used as sensors. Here, they are functionalized with chemical recognition agents that cause the gels to swell upon binding to the analyte. The resultant change in the lattice parameters causes a measurable change in the color. Specific examples include the detection of the toxic organophosphate, parathion, using acetylcholinesterase or of glucose using boronic acid and polyethylene glycol. Utilizing the same principle, even metal ions such as copper can be detected using a hydroxyquinoline-based hydrogel. These serve as a good illustration of the multifaceted potential of photonic crystals.

Summary

Photonic crystals have aroused tremendous interest with their promise to lift the field of photonics to a new level of capability. These crystals are conceptually analogous to electronic semiconductors in their function and hence are called photonic bandgap materials. The big challenge lies in synthesizing them artificially without defects. One of the few methods to synthesize these crystals is by self assembly of micron-sized building units. Self assembly leads to formation of a uniform array of monodispersed particles, typically silica or latex. This process can be further embellished by permeating a second, high-index material using the particulate assembly as a template. Useful applications of photonic crystal require them to have specifically positioned defects and tunability. These aspects, which currently constitute the state-of-the-art research in this field, promise to deliver unique devices and applications.

List of Units and Nomenclature

a	Acceleration (typically due to gravitational or applied centrifugal force)
d_p	Diameter of the particle
d_s	d-spacing or distance between lattice planes
E	Electric field
k_z	Propagation constant for travel in z direction
n	Refractive index of the medium
$\bar{n}$	Modal effective refractive index
n_{eff}	Effective refractive index of the colloidal assembly
v	Settling velocity
$\Delta\rho$	Density difference between the particle and the fluid in which it is suspended
θ	Angle between the incident beam and normal to the lattice plane in question
λ	Wavelength of the lightwave
λ_c	Stopband wavelength
λ_t	Threshold wavelength for the photonic crystal
μ	Viscosity of the suspending fluid
Φ	Electric field distribution

Introduction

The topic of this article is a survey on the main applications of free-electron lasers (FELs) in physical sciences. The merits of FELs are discussed with respect to other available laser sources. For the wavelength ranges, where FELs contributed significantly to advances in physical sciences, specific examples of the research with FELs are given.

The basic physics of FELs, their historic development, and the state of the art of these laser sources are described in detail in this Encyclopedia (*see* **Lasers:** Free Electron Lasers). The present article covers the applications of FELs in physical sciences, but excludes all phenomena involved in the physics of FELs themselves. From the application point of view, one should regard an FEL as any other laser, as a source of coherent electromagnetic radiation with high power, narrow bandwidth, and a diffraction limited beam. Thus, the radiation produced by an FEL significantly differs from that generated by synchrotrons (*see* **Incoherent Sources:** Synchrotrons). The specifications of the FEL, such as wavelength, temporal structure of the output intensity, and peak power, determine the possible applications of the laser. One might now ask, why it is worthwhile to write – and read – an article on its own devoted to the applications of FELs. The answer to this question is the uniqueness of the radiation produced by FELs, which enables certain classes of experiments and applications in specific wavelength ranges not covered by other laser sources, such as gas, solid state, or semiconductor lasers.

Since the construction and operation costs of an FEL facility are usually orders of magnitude higher than those for the equipment of a conventional laser spectroscopy laboratory, FEL facilities have been built, and are planned for the future, in different places all over the world as dedicated-user facilities. These user facilities allow researchers from universities and industry to exploit the unique properties of FEL radiation for their research and provide the basic infrastructure and support for setting up the experiments. Usually potential users apply using a standard procedure for beam time at an FEL by submitting a short proposal to the facility. The proposals are judged by a panel which distributes the available beam time to the different users. So researchers active in the field of optics should keep in mind that these facilities exist and are available to anyone who has specific needs which can be fulfilled by an FEL facility. A list of all major FEL facilities is given in Table 1.

Table 1 FEL user facilities. Facilities marked with an asterisk are under construction at the time of publication

Facility name	*Wavelength ranges*
iFEL (Osaka, Japan)	230 nm–1.2 μm 1–6 μm, 5–22 μm 20–60 μm, 50–100 μm
Duke University Free Electron Laser Laboratory (US)	193–400 nm 2–9 μm
Vanderbilt University Free Electron Laser Center (US)	2.1–9.8 μm
FELIX–FOM (Rijnhuizen, Netherlands)	4.5–250 μm
Stanford Picosecond FEL Center (US)	3–15 μm 15–65 μm
CLIO–LURE (Orsay, France)	3–90 μm
Jefferson Lab (US)	3–6.2 μm
FEL–SUT–Science University of Tokyo (Japan)	5–16 μm
UCSB Center for Terahertz Science and Technology (US)	63–338 μm 338 μm–2.5 mm
ENEA Compact FEL (Frascati, Italy)	2–3.5 mm
FELBE (Dresden, Germany)*	5–150 μm
SCSS SPring-8 Compact SASE Source (Japan)*	X-ray
Institute for Plasma Research (India)*	sub-mm
BESSY FEL (Germany)*	deep UV–X-ray
Brookhaven–NSLS SDL DUV–FEL (US)*	deep UV
University of Maryland–MIRFEL (US)*	far-infrared
University of Hawaii (US)*	UV–far-infrared
SLAC SSRL X-ray FEL–LCLS (US)*	X-ray
TESLA X-ray FEL, DESY (Germany)*	X-ray
Daresbury 4GLS (UK)*	IR, X-ray
MIT Bates Lab X-ray FEL (US)*	X-ray
INFN SPARX X-FEL (Italy)*	X-ray
Tel Aviv University (Israel)*	far-infrared
Center for Advanced Technology (India)*	far-infrared

The basic principles of an FEL are briefly summarized here, while for an in-depth description the reader is referred to the article on free electron lasers (*see* **Lasers:** Free Electron Lasers). As with any other laser, the FEL consists of a laser cavity and a gain medium. The gain media are free electrons, which travel with a velocity close to the speed of light in vacuum through a periodic array of magnets called an undulator or wiggler. The magnets are arranged in a way that the electrons feel an alternating magnetic field. Due to the Lorentz force, the electrons perform an undulating or wiggling motion perpendicular to the magnetic field, which gives rise to spontaneous electromagnetic radiation into the forward direction. The radiation, emitted in due course of the passage of the electrons through the undulator, superposes constructively. The FEL may operate in such a way that the gain from one passage of an electron bunch is high enough to produce a coherent light pulse. This regime is known as self-amplified spontaneous emission (SASE) regime which is especially desirable for short wavelength operation in the UV and X-ray region, where the manufacturing of adequate resonator optics is difficult. At longer wavelengths, a laser cavity provides the feedback for the build-up of the coherent light field. The laser starts lasing when the amplification exceeds the losses of the cavity, including the light intensity coupled out of the cavity.

One of the distinct properties of FELs, in comparison to other laser sources, is their continuous tunability. The emission wavelength of an FEL is given by the following relation (*see* **Lasers:** Free Electron Lasers):

$$\lambda = \frac{d}{2\gamma^2}\left(1 + \frac{K^2}{2}\right) \qquad [1]$$

with d the period of the magnet array, the γ-parameter is the relativistic factor related to the electron velocity u via $\gamma = 1/(1 - u^2/c^2)^{1/2}$, and the K-parameter is given by d, and the magnetic field B as $K = 0.934 \times B[\mathrm{T}] \times d[\mathrm{cm}]$. From eqn [1] it becomes obvious that the emission wavelength of the FEL can be continuously tuned via the electron energy and the magnetic field. This is in distinct contrast to other laser sources, where the emission wavelength is fixed by the energy separation of electronic levels in atoms or by the bandgap energy of semiconductors.

The main advantage of FELs concerns the high power, both average and peak, which can be obtained. In addition, an FEL provides short optical pulses due to the fact that the electron beam passing through the undulator consists of short electron bunches. The temporal width of these electron bunches can be below one picosecond (10^{-12} s), so that optical pulses in the sub-picosecond to picosecond range are obtained. These pulses are extremely adjuvant for performing nonlinear optical experiments (*see* **Spectroscopy:** Nonlinear Laser Spectroscopy) and pump-probe experiments with high temporal resolution (*see* **Chemical Applications of Lasers:** Pump and Probe Studies of Femtosecond Kinetics). Typically the optical pulses are Fourier transform limited, i.e., the product of the spectral bandwidth $\Delta\nu$ times the pulse duration $\Delta\tau$ equals a constant, which depends on the specific shape of the pulse. For a pulse of Gaussian shape in frequency and time, this so called time-bandwidth product is given as $\Delta\nu\,\Delta\tau \geq 0.441$. From this equation the minimum spectral width (temporal duration) can be calculated for a given temporal duration (spectral width) of the laser pulse. When the electron beam driving the FEL is produced by a superconducting radio frequency linear electron accelerator, the repetition rate of the pulses is in the

range of some tens of MHz. The energy per optical pulse is obtained by dividing the average power of the FEL through the repetition rate. The peak power within an optical pulse is obtained by dividing the energy per pulse through the pulse duration, which can be in the picosecond to sub-picosecond range. Typical values for FELs are energies per pulse in the μJ to mJ range, pulse lengths from some 100 femtoseconds to a few picoseconds, and accordingly peak powers in the range of kW to GW. Depending on the type of electron accelerator employed, the pulse structure of an FEL may have further peculiarities. Superconducting radio-frequency accelerators provide a quasi continuous-wave (CW) train of electron pulses, thus enabling the FEL to emit a continuous optical pulse train. Electrostatic accelerators provide macropulses of electrons at some Hz repetition rates with a duration of several μs. These macropulses consist of micropulses with MHz repetition rates and picosecond or sub-picosecond duration. Hence the FEL output has the same temporal characteristics with the FEL turning on at the beginning of each macropulse.

Another important development is the synchronization of table-top short-pulse laser systems to FELs. This is accomplished by stabilizing the repetition rate of the table-top laser system via a movable intracavity mirror accurately to the repetition rate (or a higher harmonic of the FEL) of the FEL. Using a high-frequency electronic phase-locked loop, a timing jitter, down to 500 femtoseconds between the FEL pulses and those from a mode-locked titanium-sapphire laser, have been obtained. Nonlinear frequency conversion of the near-infrared pulses from the synchronized titanium-sapphire allows one to perform multi-color pump-probe measurements in a broad spectral range in combination with the FEL.

In the following, FELs will be discussed with respect to the wavelength range which they cover. For each wavelength range alternative laser sources are given and compared to FELs. It should be noted that these alternative sources evolve very rapidly and thus pose challenges on the justification of FELs in certain wavelength and power ranges. For each wavelength region selected scientific achievements obtained from experiments performed with FELs are given.

FELs in the Far Infrared Region

The far infrared region is roughly defined as the wavelength (energy) range from 20 μm to 300 μm (62 meV to 4 meV). At the long wavelength end (wavelengths larger than 220 μm) radiation can be obtained from pure electronic devices, so-called backward wave oscillators (BWO). Furthermore, optically pumped gas lasers operate at certain discrete wavelengths in this range where there exists one fundamental problem for realizing a semiconductor laser based on transitions between the conduction and the valence bands. Auger recombination, where an electron and hole combine by transferring another electron high into the conduction band, becomes increasingly important for smaller bandgaps. Recent advancements in this field are based on quantum cascade lasers, which use inter-sub-band transitions of quantum structures for achieving lasing in the wavelength range from 105 μm to 3.4 μm. Another possibility to generate coherent radiation in this wavelength range is optical rectification or difference frequency mixing of femtosecond laser pulses at near-infrared wavelengths. However, none of these sources outperform FELs in terms of peak or average power, making FELs the most important tunable laser source in this wavelength range.

In the far-infrared, several scientific opportunities exist. In condensed matter many important elementary excitations exist in this frequency range, e.g., phonon-polaritons, plasmons, polarons, and magnons. The quantum confinement in semiconductor heterostructures leads to the formation of discrete electronic levels with energy separation typically in the far-infrared. The associated radiative transitions, so-called inter-sub-band transitions, can be arbitrarily tuned by varying the materials and the dimensions of the confining potential. In surface science, intramolecular vibration of molecules adsorbed to surfaces are of large interest. They can be studied by resonant nonlinear optical experiments such as sum-difference frequency generation or second harmonic generation, giving information about the energy transfer between the molecules and the surface. In biophysics, low-frequency modes of large bio-molecules lie in the far-infrared, whose dynamics can also be studied.

Important scientific results have been obtained with FELs in the following fields, which exclude the important fields of molecular science, chemistry, biology, and medical research.

Scanning Near-Field Optical Microscopy (SNOM)

Increasing the spatial resolution is an important task in spectroscopy. Free-space focusing of a laser beam is diffraction-limited to a spot with the dimensions of the wavelength. Especially in the far-infrared region this would allow to resolve objects larger than 10 μm only. However, the imaging of elementary excitations in solid state or of collective excitation in biomolecules on a sub-μm scale, would be highly desirable. SNOM allows to circumvent the diffraction limit. Several different SNOM techniques have been

introduced in recent years, most of them working with apertures smaller than the wavelength. Imaging is performed by scanning the aperture over the sample or vice versa. An evanescent electromagnetic field is present at the aperture which can couple to the specimen brought into the proximity of the aperture. Since the aperture is smaller than the wavelength, the light intensity drops by order of magnitudes. It is here that the high power available from FELs becomes advantageous. Usually, the end of a fiber is tapered and metalized, leaving a small aperture at the tip of the fiber. In the far-infrared region the problem exists in the absorption of the fiber material. Chalcogenide fibers are capable of transmitting in the 2–12 μm range, while hollow glass capillaries coated with metals inside work also at longer wavelengths. Recent approaches try to work without apertures, e.g., by coupling the light locally via a nanometer metal tip to the sample. Another interesting approach is to use the focus of visible laser light to create a small highly reflective spot on a material. By creating free-carriers with the visible laser light in the material, the reflectivity of the far-infrared light of the FEL can be strongly increased, thus a reflecting spot is created which is diffraction-limited by the wavelength of the visible light rather than that of the infrared light. The techniques described here are, of course, not limited to the far-infrared region but may also be applied successfully, for example, in the mid-infrared region.

Rabi Oscillations

Rabi oscillations are a fundamental phenomenon in a quantum mechanical two-level system driven by a light field. The light field promotes electrons from the lower to the upper state and back, depending on the duration and intensity of the light field, i.e., the population oscillates between the lower and upper state of the two-level system with the oscillation period depending on the intensity of the light field. This phenomenon has been studied extensively in atoms. In semiconductors, scattering processes strongly aggravate the observation of Rabi oscillations. By using the Santa Barbara FEL Rabi oscillations between the ground and excited state of a hydrogenic, impurities in GaAs could be observed. From the excited state of the impurity, electrons are transferred to the conduction band, thus changing the photoconductivity of the crystal, which is measured as a function of time delay. Overdamped oscillations with frequencies changing with the laser intensity could be clearly resolved.

Optical Nonlinearities in Semiconductors

An important concept of nonlinear optics is based on the nonlinear susceptibility $\chi^{(n)}$ of a material, where n denotes the order of the nonlinearity. The nonlinear susceptibility has tensorial character and determines, for example, the efficiency of second harmonic generation and difference frequency mixing ($\chi^{(2)}$), third harmonic generation, and the Kerr nonlinearity ($\chi^{(3)}$), etc. Hence the knowledge about the dispersion and the absolute value of $\chi^{(n)}$s is both of fundamental and practical importance. Due to the lack of tunable laser sources, these values are not well known in the far-infrared. Especially close to fundamental lattice resonances in the far-infrared, a strong dispersion is theoretically expected. Here FELs play an important role in the determination of these values. For example, in GaAs, the dispersion of the $\chi^{(2)}$ has been recently determined from second harmonic generation experiments below the fundamental optical phonon resonance at 8 THz, i.e., wavelengths larger than 37 μm, where a resonance enhancement at half the phonon frequency could be observed.

Relaxation Kinetics in Semiconductor Quantum Structures

The investigations of inter-sub-band transitions in semiconductor heterostructures have opened the pathway for the realization of the quantum cascade laser. In these devices, the radiative and nonradiative transition rates between different electronic quantum levels are of prime importance for a working device. The relevant time-scales have been obtained from pump-probe experiments with FELs. In semiconductor quantum dots, the strong coupling of phonons to inter-sublevel transitions could be observed and the polaron lifetime could be determined.

Bloch Oscillations in Semiconductor Superlattices

Bloch oscillations are an intriguing concept of solid state physics. When an electron experiences the force of an electric field in a periodic potential, the resulting dynamics is oscillatory in the absence of scattering events. However, since in real solid state the scattering rates are much higher than the expected oscillation period, such oscillations cannot be observed and the application of an electric field leads to a net electric current. However, in artificial semiconductor superlattices, the Bloch oscillation period can be tailored to be smaller than the scattering rate, leading to the observation of Bloch oscillations and the associated THz emission. The inverse effect of a Bloch oscillator, i.e., the generation of a photocurrent by tuning an FEL to the Bloch oscillation frequency, could be observed.

Cluster Physics

FELs can be an important tool for studying the dynamics of clusters and molecules in the gas phase by

infrared resonance enhanced multiphoton ionization (IR-REMPI). In IR-REMPI, the species of interest are irradiated by pulsed, tunable IR radiation from a free electron laser. When the radiation is resonant with a vibrational mode of the molecule or cluster, the absorption of many – up to several hundred – photons can take place. When the internal energy is high enough, the thermal emission of an electron can take place. The resulting ions can be detected mass selectively in a time-of-flight mass spectrometer. Monitoring the mass specific ion yield as a function of IR wavelength then yields the IR spectrum of that species. This technique has given important information on the IR absorption spectra of interstellar dust.

FELs in the Mid-Infrared Region

This wavelength (energy) range extends from 20 μm to 2 μm (62 meV to 0.62 eV). Alternative sources in this wavelength range are nonlinear optical parametric generators and amplifiers (OPGs/OPAs) which compete against FELs in terms of peak power. However, there still exists a large number of interesting phenomena where FELs are better suited, e.g., due to their higher repetition rate in the MHz range as opposed to the kHz repetition rate of OPGs/OPAs and their higher average power exceeding several W up to kW as compared to mW for OPGs/OPAs. These high-power levels find applications in material processing and recently in surgery. Since these applications cover such a wide variety of different materials, we refer the reader to publications from users of the Jefferson Laboratories FEL and the Vanderbilt University FEL (see Table 1). The advantage of FELs in this context is that their wavelength can be tuned exactly to a resonance of the material under preparation. The following significant spectroscopic application was performed with FELs.

Vibrational Relaxation of Defects in Semiconductors

The heat dissipation in submicron electronic devices is of prime importance for the failure behavior of such devices. As the device size shrinks to the nanometer scale, atomic defects play an important role. In silicon, hydrogen passivation of defects is a standard process step in the production of metal-oxide-semiconductor electronic devices. Hence detailed knowledge about the stability and heat dissipation of hydrogen defects is very important. By employing nonlinear optical methods such as four-wave mixing or a transient bleaching technique, the vibrational lifetime of hydrogen vibrational modes in silicon (around a wavelength of 5 μm to 6 μm) could be determined and important information on the dependence of the local atomic arrangement and the vibrational lifetime could be obtained.

FELs in the Near-Infrared to the UV Region

The wavelength (energy) range from 2 μm to 200 nm (0.62 eV to 6.2 eV) is the realm of solid state lasers. Especially diode pumped solid state lasers have made tremendous improvements in terms of power and stability in the past years. Nonlinear frequency conversion of ultrashort optical pulses generated from titanium-sapphire lasers and amplifiers cover almost all of this wavelength range. Hence there is no specific need for operating FELs in this wavelength range for applications in physical sciences.

FELs in the Extended UV to X-ray Region

In the wavelength (energy) range shorter than 200 nm (larger than 6.2 eV) the availability of laser sources is very scarce. In this wavelength range, solid state lasers have the problem of the reabsorption of the laser light by the crystals' hosts. Also nonlinear frequency conversion processes are hampered by the absorption of the nonlinear crystals in this wavelength range. The generation of ultrashort pulses at the wavelength of the Cu K_α line has been obtained on the basis of amplified femtosecond titanium-sapphire pulses, thus enabling the study of the lattice vibrations in the time domain via a modulation of the X-ray diffraction. Since these sources are limited in their wavelength and output power, the development and operation of FELs in this wavelength range is truly important.

Only recently the first experimental verification of the feasibility of a SASE FEL at short wavelengths was obtained at the DESY facility. The lasing wavelength was 110 nm. Since several of these sources are presently under construction worldwide, there are as yet no experimental results published. However, the future development of short-wavelength FELs will enable new types of time-resolved experiments in atoms, solid state physics, chemistry, and biology. One prominent example is protein crystallography with X-ray pulses. The high intensity of FELs in this wavelength range should allow one to obtain a diffraction pattern of a single protein or other important bio-molecules in a single shot on a subpicosecond time-scale, i.e., before the protein is fragmented. The short-pulse duration opens the pathway to study the dynamical behavior of such

structures in pump-probe experiments with solid-state lasers synchronized to the FEL. In solid state physics, such experiments could yield important insights into the dynamics of phase transitions.

Other Developments

Beyond the use of an FEL as a light source in the above described wavelength ranges, there exists the possibility of using FEL facilities in a broader way. One example is the development of a high-intensity γ-ray source which can be accomplished by Compton backscattering of FEL photons from the relativistic electrons driving the FEL. This work has been performed at a storage ring FEL (OK-4/Duke University), where 12.2 MeV γ rays were obtained by backscattering 379.4 nm free-electron laser photons from 500 MeV electrons circulating in the storage ring. The advantage of these γ rays is that they are highly monochromatic and linearly polarized, thus making them an ideal source for nuclear spectroscopy and investigations in cancer therapy.

Industrial Applications

Introduction

Lasers are seeing increasing application in industry, driven by emerging market demand and continuing enabling advances in laser technology. Core laser technology advances are based on robustness, performance, and cost. A combination of gas and solid-state lasers currently see application across the spectrum, from the extreme ultraviolet (EUV) to the infrared (IR). Industrial applications continue to emerge across the spectrum and are being extended to the extreme ends of the spectrum at terahertz (THz) and X-ray frequencies (see Figure 1).

Where a step in level of performance is offered by a laser based tool, that is robust enough and cost-effective for industrial application, it can be anticipated that new applications and markets will emerge. For this reason, many established laser manufacturers and new entries in the 1980s and 1990s were driven in part by the exploitation of laser technology advances, as opposed to market application demand. As markets mature for lasers applied to materials processing and diagnostics, so the driver across industry is beginning to shift from being predominantly set by the capability of emerging laser technology, to a combination of laser technology drive and application demand.

Figure 2 shows the current and emerging picture of laser technologies across a core range of wavelengths and pulse durations. Current technologies are shown along with emerging technologies expected to see industrial application in this decade, opening up new applications and markets. Currently established technologies include: CO_2 gas lasers at 10 μm; excimer and KrF gas lasers emitting in the ultraviolet at 248 and 193 nm, respectively; direct diode lasers emitting in the near infrared and visible; and solid state lasers emitting in the near infrared and visible. Current technology developments are centered on extending the range of performance of both gas and solid-state lasers: gas lasers are being extended to the ultraviolet with gases such as F_2; diode lasers are being extended to the ultraviolet with materials such as nitride-based semiconductors and to the infrared with the incorporation of quantum cascade technology; and solid-state diode pumped lasers are being extended to the infrared and ultraviolet via nonlinear conversion. In essence, achievable laser parameter space is seeing continued expansion, not only in terms of pulse duration and wavelength, but also in terms of average power, pulse energy, beam quality, robustness, and cost. Laser technology has now arrived as a major driver for industrial and social change through this decade and into the next.

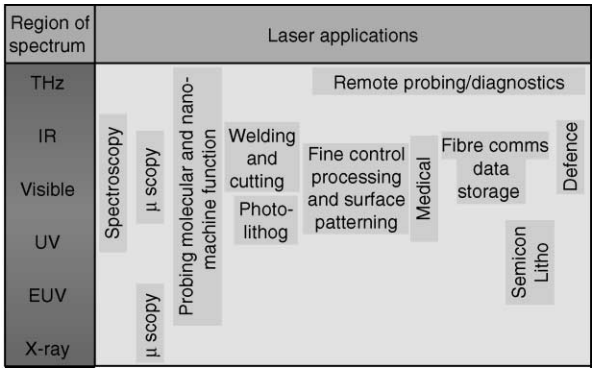

Figure 1 Industrial laser applications across the spectrum.

Infrared wavelengths directly stimulate nuclear motion, coupling to heat without necessary recourse to electronic excitation. Visible wavelengths couple to electronic transitions and at high laser intensities can ionize via multiphoton absorption. Ultraviolet wavelengths couple to electronic transitions and for wavelengths in the region of or below 200 nm, ultraviolet radiation can directly result in bond breaking. For materials processing applications, ultraviolet radiation can have advantages in reducing the laser threshold required for ablation, translating to reduced thermal load imparted to the material.

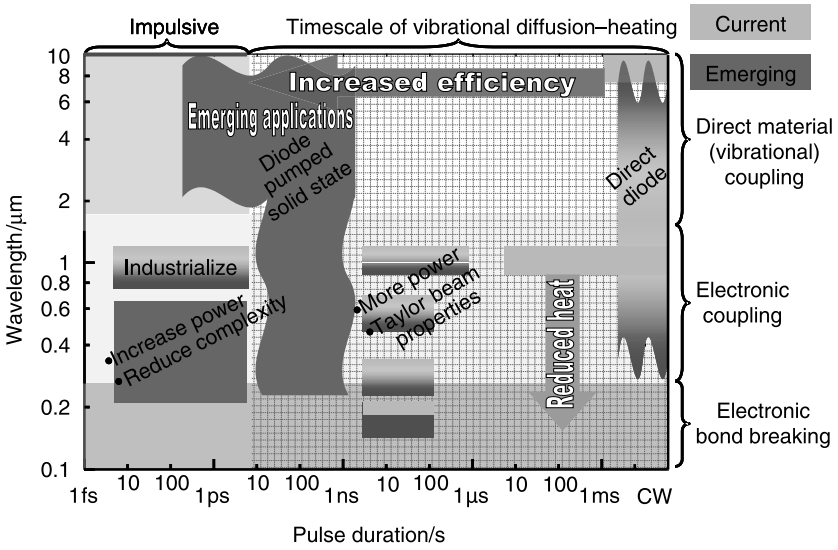

Figure 2 Current and emerging laser technologies across the spectrum as a function of laser pulse duration. Currently established technologies (light gray) are shown with technologies expected to emerge during this decade (dark gray).

Nuclear motions in materials cover a range of timescales of dynamics from 100 ps ($0.3\,cm^{-1}$) to 10 fs ($3000\,cm^{-1}$). As the laser pulse duration is reduced below 1 μs, the effects of thermal diffusion are mitigated in solids and as the pulse duration is further reduced below 100 ps, the interaction between radiation and matter is seen to adopt impulsive behavior. Reduction in pulse duration below the microsecond regime can lead to increased efficiency for material ablation combined with improved quality.

Materials Processing – Photochemical

Lithography in Semiconductor Manufacture

Laser technology's role in semiconductor and microelectronics fabrication is growing as manufacturers move towards producing smaller, more powerful devices. The overriding commercial driver for a generation has been to increase the number of integrated components per area of silicon. This has been achieved by reducing the feature size of a transistor on silicon and this trend is anticipated to remain in place through to 2010.

Features on silicon are chemically etched following lithographic exposure. To meet the increasing demand in resolution and throughput, lasers have been applied with a trend in development towards shorter (ultraviolet) wavelengths, with increasing power and reliability.

The semiconductor industry is currently in transition from 248 nm (XeCl gas) to 193 nm (ArF gas) ultraviolet (UV) pulsed laser technology to expose silicon wafers of diameter 30 cm. A typical laser power available at this time at 193 nm, is 40 W at a repetition rate of 4 kHz. To continue the reduction of feature sizes by a factor of two every four to five years, the industry is considering moving to 157 nm (F_2 gas) pulsed laser technology. As wavelengths reach the deep ultraviolet (DUV), transmission through gas is significantly reduced, requiring a move to vacuum-based systems. Associated technologies relating to translation (stepper), mask, and image relay optics also require significant advancement. A technology also being considered at this time is to image the mask to silicon through a medium with refractive index greater than unity, thereby reducing the minimum feature size afforded by diffraction theory, whilst maintaining the same laser wavelength and numerical aperture.

It is estimated that at a feature size of approximately 80 nm, the above technologies will be reaching their resolution limit. This will necessitate a switch to electron beam projection lithography or extreme ultraviolet (EUV, 13 nm) technology. Electron beam projection carries a disadvantage in terms of projected rates of wafer throughput and as such, emphasis has been placed by the industry on the current development of EUV technology. EUV radiation can be produced by laser interaction with a gaseous volume.

Computer to Plate Printing

A common advantage where lasers are replacing current technologies is to reduce the number of associated processes and thereby reduce the cost of process ownership. Computer to plate (CTP) printing involves the laser exposure of a printing plate without the use of a film intermediate. This technology is finding fast traction within the printing industry and is applicable to drum or flat bed platforms. CTP first gained serious attention in the 1990s and has since substantially advanced, with a wide range of technology suppliers (Figure 3).

Traditional methods have involved offset printing plates, imaged used traditional film, and high-power

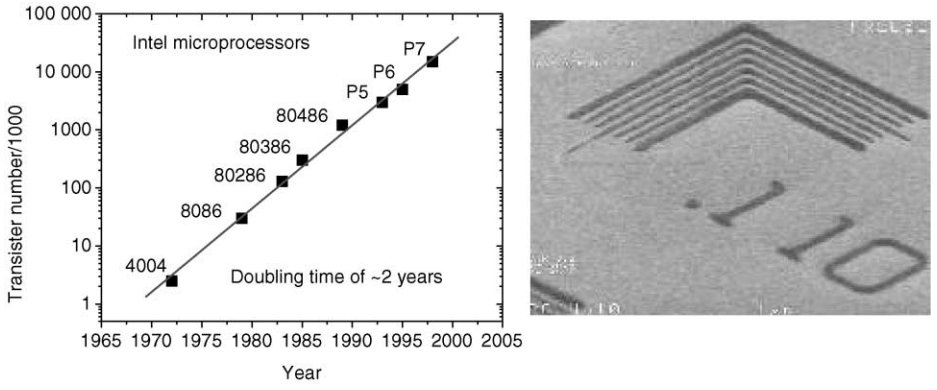

Figure 3 Moore's Law: continuing growth in computing power, showing a doubling in the number of transistors per unit area of silicon every 2 to 2.5 years. Also shown are 110 nm dense lines on silicon (state of the art in 2002). Source: International Sematech.

UV lamps. In contrast, CTP exposes the plate directly with laser radiation. The major saving reported by users of CTP is a faster turnaround time. For color printers, CTP gives almost instant color register on the press and there is a reduced requirement to stop the press to delete dust marks and scratches, as was the case with film. As the industry sees transition to reduced press run lengths, so the importance of CTP is increasing.

Digital plates generally use a high-quality, grained, and anodized aluminum substrate, as for analog plates (see Figure 4). High tolerance electrochemical graining and anodizing ensure stable ink/water balance and good-quality printed results and translates to predictable press behavior. Multiple coatings are applied for CTP, in contrast to a single coating for offset printing, and these take the form of a photopolymer or silver halide and a thermally responsive layer.

On the press, ink and water rollers are continually rolled over the plate. The grained and anodized aluminum substrate serves as a hydrophyllic surface volume to attract water. Ink is oil based and is repelled from areas of water absorbed into the substrate, but is attracted to the hydrophobic dot material.

Silver halide is rated for runs up to 350 000, proving a popular choice for commercial and newspaper applications. It is straightforward to sensitize for a range of writing wavelengths and is the fastest to write.

Thermal plates offer high resolution, equivalent to silver halide and can be baked to enable the longest application lifetimes. Typically the plates are exposed to 830 nm radiation on the external surface of a drum. This technology has served the industry well, but has struggled to find full application in the newspaper business, due to its disadvantage in writing speed.

The most common CTP technology used for newspapers uses a photopolymer coating, which is fast to write and durable. Resolution has traditionally been limited, with Agfa, for example, rating their N91 photopolymer plate to a maximum of 175 lines per inch (LPI), whilst thermal and silver plates are able to image at 200 LPI and above. However, recent advances in shorter wavelength violet diode lasers and violet sensitive polymers have improved resolution. Launched in 2000, violet technology is seeing widespread takeup. This technology is a spinoff from the DVD industry and with laser lifetimes estimated at 10 to 20 years, cost of ownership is one of the drivers. Both silver halide and photopolymers can be sensitized to violet. Current typical laser parameters are for: silver halide, 2–3 $\mu J/cm^2$ at 405 nm; photopolymer, 0.2 mJ/cm^2 at 488 or 532 nm; and thermal, 0.1 J/cm^2 at 830 nm.

The chemical composition of the CTP surface layers is balanced to determine the response to different laser wavelengths, as well as performance characteristics in different print applications. The plate coatings undergo a photochemical change during laser exposure. This is a critical stage since it is important that the plate surface is not under- or over-exposed.

Chemical post processing after exposure is generally required for CTP to date, with the exception of ablative CTP, to remove unexposed material. After imaging, thermal plates go through a pre-bake step, during which the system heats the plate to 130 °C (266 °F) for about 30 seconds. The energy from this

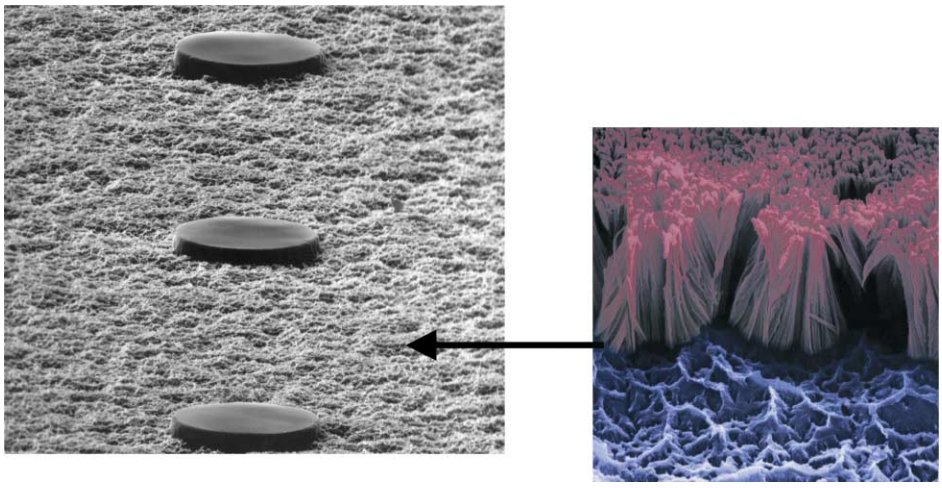

Figure 4 Three typical polymer dots of a few microns depth on an anodized aluminum substrate. Also shown is a further magnified electron microscope image of the substrate material, with the anodized layer cut away for presentation. The porous structure increases water retention. Oil-based ink is repelled from areas other than the dots. Figure courtesy of Agfa (Tony King, tony.king1@agfa.com).

heating stage completes cross-linking of polymer chains in the exposed portions of the emulsion. Chemical processing consists of processing the plate through an alkaline developer solution where the polymer that is not cross-linked washes away. Following the wash is a rinse and application of a coating. After chemical processing, some plates require baking to 200 °C (392 °F) for 35 minutes. Afterwards, the plate continues on to rinsing.

The machine tools required for these processing steps measure 30 feet long and take up to 7 minutes to process a plate after imaging. For both polymer and thermal plate processing, the temperatures are carefully controlled to prevent the aluminum substrate from deforming during the baking stages.

The effluent from thermal and other photopolymer plate processors is fairly benign and is typically directly disposed without significant environmental concern. Spent photopolymer chemistry can, however, pose problems with waste flow, it being a plastic sludge that can solidify and over time, clog plumbing systems.

Silver diffusion plate processors are relatively compact and tend to process plates in less than a minute. Environmental precautions are required with the disposal of accumulated silver particulates. Relatively simple systems are available, which neutralize the pH of the effluent and filter out silver until concentration levels are below 3 parts per million. Under these circumstances, most jurisdictions allow drain disposal.

Ablative plates do not require post processing, other than a rinse to remove residues. This is an emerging technology that has not taken hold at this time in the printing industry and requires more powerful lasers to ablate a layer from the plate. These plates use layers of ink-repellent silicon on top of an aluminum substrate to provide the non-inking portion of the plate. Variations of this technology use a laser to ablate the silicon from the substrate in the image areas of the plate, or to transfer material from a donor layer to the aluminum substrate. A weakness of this technology has been the limited durability of the plates in press. There is continuing development to produce ablative plates with other surface layers that are more durable on press.

Materials Processing – Heating

One way in which lasers can be applied to materials processing is as a directed source of heating. With material quickly raised in temperature to the point of melting and vaporization, applications lie in drilling, welding, cutting, and scintering.

The exploited characteristics of a laser source are its directionality and discrete color. Directionality enables the formation of a restricted area for heating as well as an extended working distance, whilst a discrete color enables absorption to be optimized for the material being worked. Laser technologies typical in application to materials processing through heating, range from diodes at 808 and 940 nm to flashlamp or diode pumped solid state lasers at 1 μm, and CO_2 gas lasers at 10 μm. A recent entry technology is in diode pumped fiber lasers, reaching output powers in the kilowatt regime at a wavelength of 1 μm and typically being continuous in emission or pulsed with a pulse duration in the millisecond regime.

Direct diode lasers (see Figure 5) have advantages in simplicity and robustness and with the minimum of additional assembled optical components, costs can be expected to continue to reduce, fed by Moore's law for the cost of semiconductor manufacture. Typical powers range from 1 to 10 kW and light can be fiber delivered to the work piece. A disadvantage of direct diode emission is the reduced directionality in comparison with alternative laser sources. For example, a current typical numerical aperture of emission from a diode bar array emitting a power of 60 W, is 10 and 60 degrees in directions parallel and perpendicular, respectively, to the array. These divergences can be reduced to a numerical aperture of approximately one degree with the addition of micro-optics, at a device cost increment of approximately 20%. For an array of diode bars with emitting powers in the kilowatt regime and with emitting dimensions sided 2 cm, a typical optical quality is one thousand time diffraction limited, translating to working distances are on the order of centimeters for a laser spot size at a work piece that is on the order of 1 mm.

CO_2 gas lasers and solid state lasers offer the advantage of reduced divergence and corresponding greater working distance, combined with a smaller laser spot size at the work piece for finer processing.

Figure 5 Diode bar array, with an output power exceeding 500 W. Courtesy of Rofin.

Both laser technologies can operate in the kilowatt regime, for application to sheet metal cutting and welding.

With the interaction process involving high temperatures and the ejection of material, a high-pressure gas bathes the area of illumination to remove smelt and either reduce exothermic chemical reactions, or where process acceleration is required, to utilize an assist gas to increase heating through exothermic reaction. Oxygen is typically used as an assist gas for the processing of low-alloy steels, with the process being typically known as laser flame cutting. The gas is, in general, injected coaxially with the laser beam. Laser flame cutting is used in industry for material up to 4 cm thick, albeit the width of the cut becomes significant at this thickness. Both CO_2 and Nd:YAG lasers are applied for this application, the choice of which is dependant on the cut geometry, the cycle time, and the material. Typical cutting speeds are, for example, in the region of 10 meters per minute for 1 mm, 3 meters per minute for 6 mm, and 1 meter per minute for 15 mm thick material.

In the case of high-alloy steels and aluminum, in particular, the material is bathed with an inert gas such as nitrogen or argon. The material is heated solely by the energy in the laser beam, and is typically referred to as laser fusion cutting (see **Figure 6**). The laser power required is higher than for laser flame cutting. Laser fusion cutting reduces oxidization to the cut edges, which is particularly important where welding is the next process step after cutting.

Laser fusion cutting is used in industry for material up to 25 mm thick, albeit the width of the cut becomes significant at this thickness.

Figure 6 Laser fusion cutting. Courtesy of Rofin.

As with laser flame cutting, both CO_2 and Nd:YAG lasers are suitable for this application, the choice of which is influenced by the geometry of the cut, the cycle time, and the material. Typical cutting speeds in steel are, for example, in the region of ~8 meters per minute for 1 mm, 4.5 meters per minute for 3 mm and 1.5 meters per minute for 8 mm thick material.

Materials Processing – Localized Heating

As a material is heated in a localized volume to the point of vaporization, so also is the surrounding material, which can melt and experience cracking or changes in phase. Such heating is mainly considered deleterious, reducing process tolerances and reducing the tensile strength of the surrounding material.

As the pulse duration is reduced for a localized laser heating source, so are the dimensions that experience heating around the interaction volume (the heat affected zone), translating to improved part quality, with the length for thermal diffusion, l_{th} given by:

$$l_{th} = \sqrt{Dt} \qquad [1]$$

where D is the thermal diffusivity and t, the time of diffusion. As the pulse duration is reduced, the pulse energy required to ablate material is also reduced, with the laser pulse energy required to raise the material temperature to the point of vaporization being proportional to the volume heated. For an example such as silver, a pulse duration of 200 fs is associated with a diffusion length of 6 nm. Extrapolating, a pulse duration of 100 ps, 100 ns, and 100 μs are associated with diffusion lengths of 0.1, 4, and 130 μm, respectively. For typical metals and dielectrics, the process quality and pulse energy threshold for ablation become decoupled from variation in pulse duration for pulse durations less than a few picoseconds. In this regime, the volume for heating is dictated more by the depth for optical absorption and further, the physical mechanism for absorption changes to that of material breakdown and multiphoton ionization (**Figure 7**).

Additional advantages of operating in the short-pulse regime are a sharpening of threshold to ablation, enabling the processing of features of dimension less than that of the laser spot size and an increase in the number of materials that can be processed by the same color laser source.

Given the advantages of the short-pulse regime, it should be noted that this is currently juxtaposed with the complexity and cost of the required laser sources. Solid-state laser technology is, however, advancing, significantly reducing the number of optical components required to deliver short pulses at multi-kHz

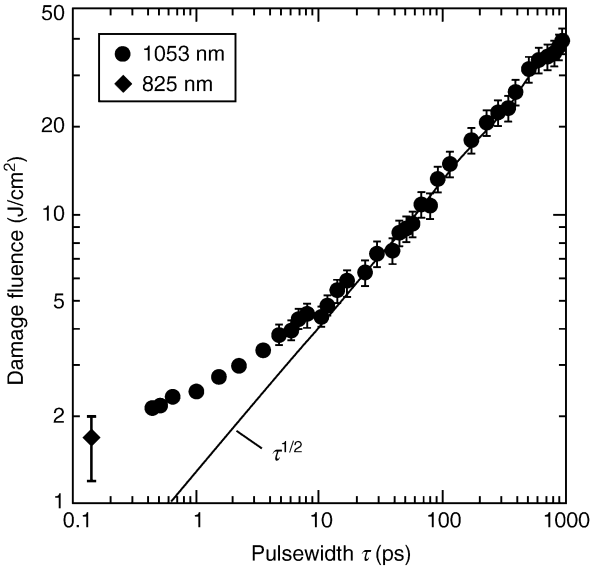

Figure 7 Pulse duration dependence of threshold damage fluence for fused silica. Reproduced with permission from Stuart BC, Feit MD, Herman S, Rubenchik AM, Shore BW and Perry MD (1996) Nanosecond-to-femtosecond laser-induced breakdown in dielectrics. *Physics Review B* 53: 1749. Copyright (1996) by The American Physical Society.

repetition rates and multi-mJ pulse energies. At this time of evolution in laser technology, solid-state, diode-pumped high repetition rate (>10 kHz), high pulse energy (>40 mJ) nanosecond (1–200 ns) lasers at a wavelength of 1 μm are seeing increasing application. Such laser sources offer a combination of robustness and cost-effectiveness, combined with a process quality improvement over sources with longer pulse duration.

In the nanosecond regime, the nature of light-matter interaction remains dependent on the wavelength of the laser source and the material properties. In particular, wavelengths in the UV exhibit reduced pulse energy threshold and can offer improved process quality. UV wavelengths less than 300 nm are currently produced by excimer and ArF gas lasers, emitting at 248 and 193 nm, respectively, or solid-state sources that are wavelength converted with nonlinear optical parametric materials to emit at 354 or 256 nm. Significant laser development effort is underway to improve optical parametric materials for nonlinear conversion, to enable greater robustness for solid-state UV sources that then offer reduced overall laser tool cost and complexity.

Semiconductor Lithography

The advantage of nanosecond and shorter pulsed lasers for materials processing extends from localization of heating. With heating being localized, a greater temperature can be achieved. This behavior is fundamental to the production of EUV radiation for application to next-generation lithographic processing.

EUV lithography is considered as an attractive candidate to succeed deep DUV-based optical lithography within this decade. EUV wavelengths around 13 nm will allow the reduction of structure sizes to less than 80 nm in semiconductor devices.

For such a high-power light source that emits at a wavelength of 13 nm, solutions are currently being pursued by multiple industry players in electrical plasma discharge and laser produced plasmas (LPP) (**Figure 8**). Electron beam and synchrotron sources could, in principle, satisfy the application requirements, but suffer from restriction relating to cost, size, and throughput. The choices of technologies remain to be finalized. It is, however, accepted across the industry that Moore's Law should remain intact and that a solution is required that is scalable to high throughput rates for wafer exposure.

For a laser-produced plasma, the peak wavelength of the light emitted from a plasma is determined by its temperature, T, where according to the blackbody formula:

$$T \sim E_{\mathrm{ph}}/3 \qquad [2]$$

where E_{ph} is the photon energy associated with the wavelength of maximum emission. Liner photopolymerization (LPP) schemes use pulsed laser radiation to heat a target to the optimum temperature required for efficient EUV production. For plasma-emitted light which peaks at a wavelength of 13.5 nm, the optimum temperature is approximately 3.5×10^5 Kelvin (30 eV).

A laser is focused onto a target, transferring its energy into the target in such a way that a plasma is formed and heated. A range of targets have been investigated for use in LPP schemes ranging from gaseous and cluster targets, to liquid targets and macroscopic solid targets. The interaction begins with the production of free electrons via multiphoton ionization, which is strongly dependent on the peak intensity of the laser. As heating progresses, there is further ionization from inelastic collisions between heated electrons and ions to reach a pseudo-equilibrium state, where cooling competes with heating on nanosecond timescales. Given this time-scale for cooling and requirements on source size and temperature, the optimum laser pulse duration lies in the regime of nanoseconds and the optimum laser pulse energy is hundreds of millijoules. Laser technology

suited to this application is diode-pumped Nd:YAG, emitting at a wavelength of 1 μm and pulsed at multikilohertz repetition rates.

Fine Control Material Removal

Localized heating afforded with the application of lasers with pulse durations in the nanosecond regime and shorter, is seeing increasing takeup to replace processes ranging from wet etching and electro-discharge machining (EDM) in applications such as scribing, drilling, and differential layer removal. Laser methods are seeing advantage in direct ablation of material, for feature sizes on the order of microns to hundreds of microns. Large areas on the order of 2 m^2 are now becoming cost-effective to process with direct laser ablation, with the advent of high average power laser sources of hundreds of watts of average power, combined with nanosecond regime or shorter pulse durations. Typical sources are gas excimer or diode-pumped solid-state.

The finest processing is advantaged by the application of pulse durations in the picosecond regime. A restriction in application of this technology has been robustness and cost of the laser sources to date; however, such technology is continuing to see rapid improvement and may be expected to see wider takeup in industry by 2010.

Also seeing application, are wavelengths in the UV regime combined with nanosecond pulse durations. UV radiation in general offers a reduced threshold of ablation, translating to reduced heating and improved process quality. High absorption at UV wavelengths in most materials, combined with photon energies that can exceed bond energies of the material, contribute to the removal of material with the minimum of heating. Excimer, KrF, and ArF gas lasers are applied here (Figure 9), but it is expected that solid-state lasers will emerge by 2010 to capture a large part of the UV market. CO_2 gas lasers are used for fine processing where the material being ablated is of low thermal diffusivity, which is typical for dielectrics or ceramics. Materials of low thermal diffusivity are associated with a low heat affected zone (see eqn [1]).

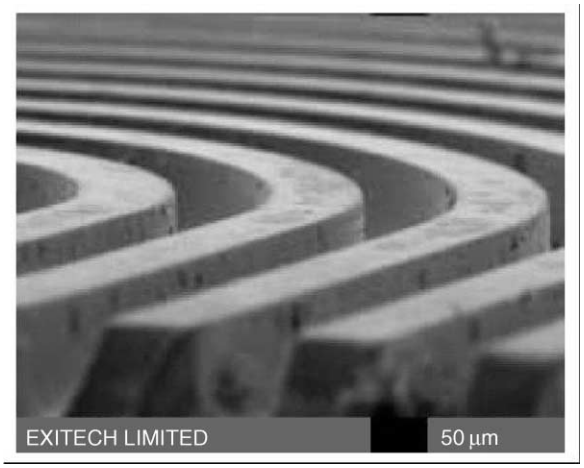

Figure 9 KrF laser micromachined microfluidic channels in polyester for application to lab-on-a-chip technologies or sensing devices. Courtesy of Exitech Ltd.

Scribing is required for dicing of wafers such as silicon and other low-*k* materials, both for computing device manufacture and for solar cell manufacture. Nanosecond and shorter pulsed lasers have seen recent application in this area, enabling higher aspect ratio scribing and a reduced material affected zone. This application has seen laser wavelengths applied from the UV to near-infrared. Short pulse laser scribing can see advantages of high throughput yet reduced or eliminated chipping, delamination, and film peeling.

Fine drilling is required for a wide variety of applications and markets ranging from constructing vias for through-layer interconnects in printed circuit board (PCB) fabrication, to ink jet nozzles (Figure 10) and high aspect ratio holes in hard materials, such as steel or alloys for application to combustion engines.

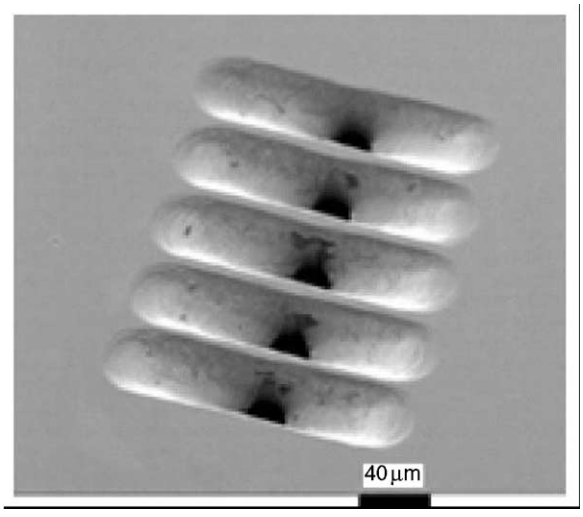

Figure 10 A laser drilled hole in steel and an array of shaped holes in polyamide for inject nozzle application. Courtesy of Exitech Ltd.

Excimer and CO_2 laser drilling has seen industrial application in the drilling of via holes for electronics interconnection packages, since early investigations in the 1980s. More recently, high repetition rate diode-pumped solid-state lasers, nonlinearly converted to emit in the UV, are seeing application. In parallel with the increasing density of transistors in silicon processors, the density of packaging of multichip modules (MCM) and PCB components has also been increasing, requiring the drilling of blind vias on the order of 100 microns in diameter to enable interconnects between multiple conducting layers (Figure 11). Also, as processor power increases, so does the number of connections required to devices. Microvias have enabled the application of two-dimensional grid array connections to the underside of devices, reducing overall package size, including processor electrical connections, by a factor of five.

Laser drilling of microvias in PCBs is expected to increase as packing density increases. PCBs remain cheaper than MCMs and traditionally have been mechanically drilled. As via sizes are reduced below 100 μm, however, it is expected that pulsed CO_2 and Nd:YAG lasers will be applied.

Thin layer ablation is required for applications ranging from surface cleaning to display manufacture and for polymers, dielectrics, and metals. For example, manufacture of plasma displays currently incorporates lithography combined with wet etching, to pattern layers of thin conducting oxide onto a substrate. Multiple process steps can be replaced by application of direct laser ablation and increased laser average power combined with pulse durations in the nanosecond regime are allowing millions of cells to be processed per minute, with the accommodation of process areas currently greater than 2.5 m^2 (see Figure 12).

Laser-Based Diagnostics

With a continuing increase in reliability, performance, and range of specifications, lasers are seeing growing industrial application for process monitoring and diagnostics, ranging from gas phase detection of molecular specific concentrations to *in vitro* microscopy in the life sciences. Markets are emerging, driven in a large part by advances in laser technology. Chemical sensing with application of lasers is a vast field, which is difficult to cover here completely. Following, are some applications seeing current industrial application and growth.

Microscopy

Confocal microscopy has seen large uptake, in particular, for the application to imaging of cell and membrane function, with more than fifteen manufacturers now supplying confocal microscope tools including Zeiss, Biorad, Leica, Olympus, and Nikon. Confocal microscopy enables increases in resolution and contrast compared to standard microscopy. Techniques such as fluorescence resonant energy transfer (FRET), fluorescence recovery after photobleaching (FRAP), fluorescence loss in photobleaching (FLIP), fluorescence lifetime imaging (FLIM), or fluorescence correlation spectroscopy (FCS), where married with confocal microscopy and, in particular, where relevant molecular structures are known in advance, can offer the additional advantages of specific molecular and structural specificity through the incorporation of tracer fluorophores. This is seen as color coding of the resultant image, with sophisticated microscopes currently offering differential imaging stimulated by three laser colors and with six selectable colors for detection.

The confocal microscope operates with advantage over a standard microscope, by illuminating only a small area in the sample with dimensions of the resolution limit of the objective and re-imaging emission from that area through a pinhole spatial filter (**Figures 13** and **14**). Structures outside of the illuminated area or at a depth outside that of the focus, are suppressed from detection. Fluorophores (tracers) can be inserted into protein sequences at predetermined locations and are stimulated by either single or two-photon absorption of the stimulating laser light.

Two photon absorption has the additional advantages of increased resolution and detected contrast over single photon absorption. Laser sources applied are generally modelocked oscillators operating near 800 nm, with a pulse duration on the order of 100 fs. This technology is continuing to improve in robustness, with fiber and direct diode pumped solid-state sources available from multiple vendors.

FRAP and FLIP monitor diffusion or transport of fluorescent labeled molecules into or out of the laser focal volume, respectively. FCS monitors the fluctuations in detected signal from emissions within the laser focal volume, to determine the rate of diffusion with sensitivity achievable to the single molecule level (**Figure 15**).

FRET is seeing application for the probing of protein interactions in cells or at cell membranes. FRET involves the nonradiative transfer of excitation energy from one fluorophore to another, which subsequently emits at a different wavelength. The fluorophores are inserted into molecules, the

interaction of which is being investigated. FRET effectively enables sensitivity to relative position at fluorophore separations less than 10 nm; a significant advance over the 200 nm resolution provided by a standard optical microscope. Concentrations of binding events can be monitored over time (Figure 16).

Raman Methods and Microscopy

Raman spectroscopy sees broad application in chemistry in the analysis of chemical composition and molecular structure, being used, for example, in pharmaceuticals, polymer materials science, bioclinical science, and forensic science.

The history of Raman scattering stems from theoretical predictions in the early 1920s,

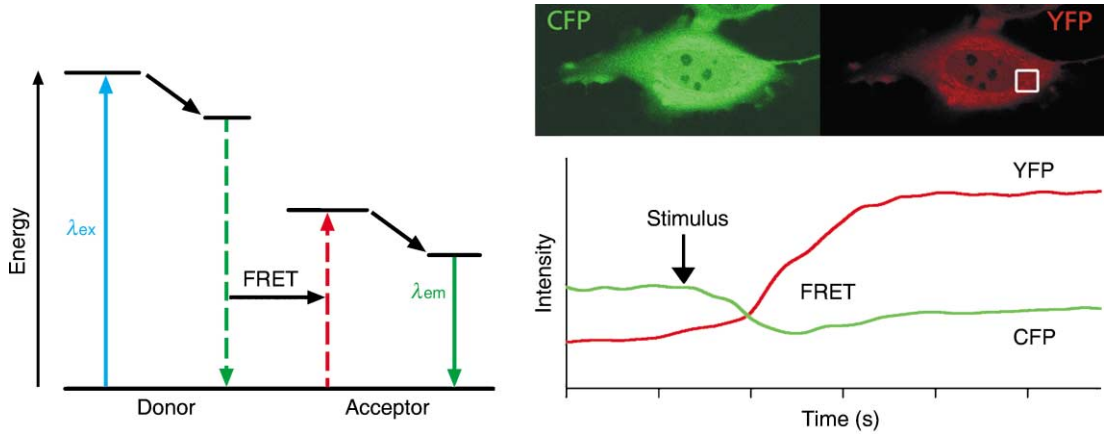

Figure 16 Fluorescence resonant energy transfer mechanism and example relating to cytoplasmic Ca^{2+} concentration. Cyan Fluorescent Protein (CFP) and Yellow Fluorescent Protein (YFP) are acceptor and donor, respectively, for the FRET. Courtesy of Carl Zeiss, Germany.

accompanied also in the 1920s by early measurements, notable being those of C.V. Raman for which he was awarded the Nobel prize, soon followed in the 1930s by hundreds of chemistry papers describing this technique. Raman used for his early experiments filtered sunlight, a prism spectrometer, and visual observation. This was followed by application of filtered Hg emission and photographic plates. Lasers first saw application to Raman scattering in the 1960s, shortly after their innovation (see Figure 17).

In the simplest form of application of the Raman effect, UV or visible radiation illuminates a sample, coupling to excite electronic transitions near or on resonance. Spontaneous emission is shifted to a longer wavelength than that of the excitation (Stokes emission) and this is filtered and detected. In general, a broad spectrum of fluorescence is superimposed by weaker, narrow features that originate from vibration-electronic coupling (Raman emission). Inclusion of laser excitation increases the rate of

data collection and also enables nonresonant interaction of the stimulating radiation with the sample whilst maintaining data collection rates. Nonresonant interaction preferentially reduces electronic emission of fluorescence relative to that of the narrow featured Raman emission. Lasers applied to spontaneous Raman spectrometers in general emit in the visible or near-infrared running nonpulsed, such as Ar-ion, Nd:YAG or He:Ne.

Further enhancements are made to deliver spatial as well as vibration-specific information, through tight focusing of the stimulating radiation on to the sample in a confocal microscope arrangement, delivering spatial resolution down to 200 nm (Figure 18).

A limitation of standard Raman spectrometers and microscopes is the rate of signal collection, requiring concentrated samples for interrogation. The restricted signal level derives from a typical cross-section for the spontaneous emission of Raman radiation being $10^{-30}\,\mathrm{cm}^2$; 10^{10} to 10^{14} times less than that typical for spontaneous electronic fluorescence. Enhancements in the level of signal and the ratio of signal to background noise may be made through coherent laser stimulation of anti-Stokes Raman emission, known as coherent anti-stokes Raman scattering (CARS) (Figures 19 and 20).

It can be anticipated that bond-specific imaging will see wide industrial application in future, employing Raman as well as resonant infrared techniques. Application of CARS to microscopy involves two laser colors. A vibration transition is exited at the beat frequency of the two laser frequencies and the shorter laser wavelength is subsequently scattered from the sample to a yet shorter wavelength of emission. Such a coherent process has the advantage of signal scaling proportional to the square of emitters at the sample, thereby increasing the signal over that of spontaneous Raman scattering. Typical laser pump and Stokes powers range from less than 1 mW to 10s of mW, with laser repetition rates ranging from multi-kHz to greater than 100 MHz and typical pulse durations from 10s of picoseconds to 100 fs.

Infrared Methods

Infrared absorption spectroscopy provides a wealth of information on bond-specific sample concentration

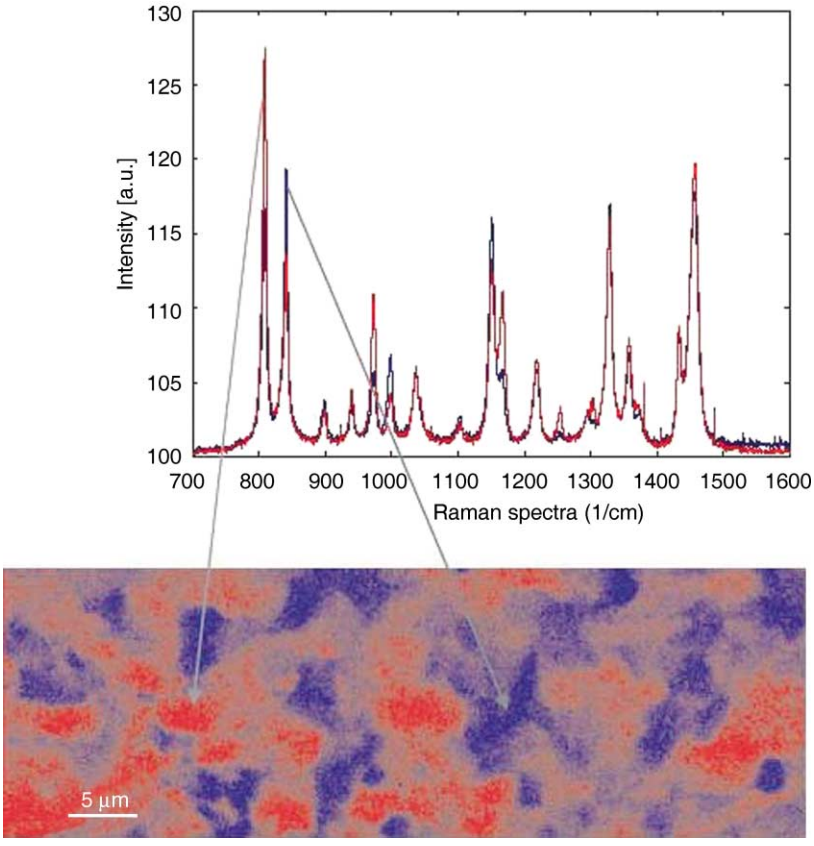

Figure 18 Confocal Raman image of semicrystalline polypropylene film. Two typical Raman spectra are shown. The ratio of the Raman lines at 809 and 841 cm increases with the degree of crystalline order, delivering a two-dimensional image (Hendra *et al.* 1995). Courtesy of Witec GmbH.

and has become a standard tool for the chemistry laboratory. Interaction between the radiation and sample is via resonant vibrational absorption and is otherwise analogous to the operation of a standard optical absorption spectrometer. Applied to a microscope arrangement, resolution on the order of 10 μm is standard. One restriction associated with infrared absorption spectroscopy applied to solution, is that absorption lineshapes are broadened and the spectra lose detail at room temperature, hindering identification of the contributing species.

A technique showing early promise for application in bond-specific molecular detection in solution, is coherent resonant infrared wavemixing. Here, cross coupling between vibrational modes are detected, promising information more detailed than that of infrared absorption. Figure 21 shows an example of triply vibrationally enhanced four-wave mixing, where two infrared laser beams mix to deliver cross peaks representing vibration mode coupling. Here, the 2D spectrum contains two sets of cross-peaks corresponding to the couplings of the two strong IR modes at 1943 and 2002 cm^{-1} of $Ni(CO)_2(PPh_3)_2$ and 1996 and 2068 cm^{-1} of $Ni(CO)_3PPh_3$. Concentrations in solution are on the order of 10 mM. Such methods provide a means sensitive to chemical structure without a requirement for fluorophores.

Current application requires complex laser equipment delivering microjoule pulse energies, tunable between 3 and 10 microns, with pulse durations on the order of 1 ps. However, following the example of other laser diagnostic techniques in application

across industry today, as laser technology advances over this decade, we can expect such methods of probing chemical systems to see significant uptake, in particular in the bio-industries.

Laser Diagnostics and Treatment of Tumors

For clinical medicine, fluorescent detection is applied in the visualization of malignant tumors. Important natural chromophores emitting fluorescence in the blue-green region are elastin, collagen, NADH, and NAD^+, whilst administered agents such as porphyrins and phthalocyanines yield sharp peaks in the dark red.

Excitation is via UV or violet light. Where emission is monitored in both the blue-green and red regions of the spectrum and the ratio taken, an enhanced tumor differentiation is possible from that of normal tissue whilst simultaneously reducing sensitivity to geometry, illumination, and detection efficiency. Fiber optic probes are generally applied for delivery and collection of radiation.

Such detection can be combined with techniques of laser photodynamic therapy (PDT) to preferentially remove cancerous tissues. Typical laser wavelengths for photodynamic therapy are in the visible region of 600 to 700 nm with a pulse fluence of tens of joules/cm^2, a pulse duration in the nanosecond regime and a repetition rate from single shot to 10 Hz. Where combined with diagnostic detection, the PDT can be carried out by exciting the same administered sensitizer, with subsequent transfer of ground-state triplet oxygen to a toxic singlet state.

Remote Chemical Sensing

The atmosphere can be monitored by absorption and laser-induced fluorescence (LIF). Three-dimensional mapping of chemical distribution can be achieved with light detection and ranging (LIDAR), using a pulsed laser as a transmitter and an optical telescope as a receiver. Information collated includes pollution concentration, temperature, humidity, and wind velocity. Strong quenching prohibits LIF at atmospheric pressures; however, it does become practical to monitor for example, Li, Na, K, and Ca layers in the mesosphere. Pollution monitoring in the troposphere is most frequently performed with differential absorption LIDAR (DIAL). Range resolved optical transients are taken as a ratio of two laser wavelengths; on and just off resonance for the species of interest. Typical ranges for detection of SO_2, O_3, NO_2, NO, and Hg are 500 m to 5 km, making this technique suitable for urban and industrial monitoring. Sulfur dioxide is the most common pollutant emitted when fossil fuels are burned or sulfide ores are roasted and this technique sees application for the monitoring of industrial emissions. Figure 22 shows a DIAL trace recorded from Mount Etna, from which emissions of SO_2 are estimated at 75 tonnes/h. Laser wavelengths used are 300.02 and 299.30 nm for on and off resonance for absorption, respectively.

Important to the widespread application of LIDAR and LIF for atmospheric chemical monitoring, has been the advance in robustness and flexibility of the associated laser technologies. The laser technology applied for the above measurement is based on solid-sate Nd:YAG, nonlinearly converted via optical parametric amplification to wavelengths tunable between 220 nm and 4 μm, delivering up to 20 mJ in the mid-infrared at a repetition rate of 20 Hz and with bandwidths of less than 0.2 cm^{-1}, in a pulse duration of 4 ns.

Sum-Frequency Generation at Surfaces

M B Raschke and Y R Shen, University of California, Berkeley, CA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Under sufficiently intense illumination the optical properties of a material system depend nonlinearly on the strength of the electromagnetic field. Related to this nonlinear optical response is a large number of phenomena and fundamental processes which are discussed in various articles of this encyclopedia. This article will focus on second-harmonic generation (SHG) and sum-frequency generation (SFG) for the investigation of surfaces and interfaces. The intrinsic surface sensitivity of these techniques allows for investigations of surface properties not readily accessible by other spectroscopies. Here, the basic principles of these optical processes as well as their experimental implementation are discussed, and a summary of the applications to different material systems is given.

Among the various techniques employed for the characterization of surfaces and interfaces, those using light are particularly attractive. They are applicable *in situ* to all interfaces accessible by light, are nondestructive, and offer unprecedented time resolution. However, the penetration depth of optical radiation in matter is generally of the order of a wavelength, which makes isolation of the surface or interface contribution to the optical response from the bulk contribution difficult. In contrast, for reasons of symmetry, SHG and SFG are intrinsically surface sensitive in media with inversion symmetry, and hence the signal generated mainly originates from the topmost surface layer where the inversion symmetry is broken. By means of electronic or vibrational SHG or SFG spectroscopy, information on surface structure, chemical composition and bond or molecular orientation at solid and liquid interfaces can be deduced. To date, SFG and SHG have been well established as important tools for the investigation of surfaces and interfaces of solids ranging from metals and semiconductors to insulators and magnetic materials, liquids, polymers, biological membranes, and other systems. The studies are motivated by fundamental interests as well as applications in many areas such as heterogeneous catalysis, electrochemistry, device fabrication, epitaxial growth, and environmental science.

Theory

The nonlinear optical response of a material, in the electric-dipole approximation, can often be described by an induced polarization in the form of a power series,

$$\begin{aligned}\boldsymbol{P}(\omega) = \epsilon_0[&\chi^{(1)}(\omega)\boldsymbol{E}(\omega) \\ &+\chi^{(2)}(\omega=\omega_1+\omega_2)\boldsymbol{E}(\omega_1)\boldsymbol{E}(\omega_2) \\ &+\chi^{(3)}(\omega=\omega_1+\omega_2+\omega_3)\boldsymbol{E}(\omega_1)\boldsymbol{E}(\omega_2)\boldsymbol{E}(\omega_3)+\ldots]\end{aligned} \quad [1]$$

where $\boldsymbol{E}(\omega_i)$ is the optical field with frequency ω_i and $\chi^{(n)}$ is the nth-order linear ($n=1$) or nonlinear ($n>1$) susceptibility tensor. The second term, being the lowest-order nonlinear optical response, is responsible for sum-frequency generation and second-harmonic generation (with $\omega_1=\omega_2$). In the electric-dipole approximation, all even-order terms ($\chi^2, \chi^{(4)}$, etc.) are forbidden in media with inversion symmetry. At the surface or interface, however, the inversion symmetry is necessarily broken and hence $\chi^{(2)} \neq 0$. This makes SHG and SFG surface-sensitive and specific. While electric-quadrupole and magnetic-dipole contributions from the bulk may not be totally negligible, in many cases it has been shown that the surface contribution clearly dominates.

Surface SFG and SHG is best described by radiation from a surface polarization $\boldsymbol{P}_s^{(2)}(\omega)$ induced in a thin sheet with dielectric constant ε' sandwiched between two linear media (1) and (2) as shown schematically in Figure 1. This surface polarization has an in-plane wavevector component equal to the sum of the in-plane wavevector components of the incident fields:

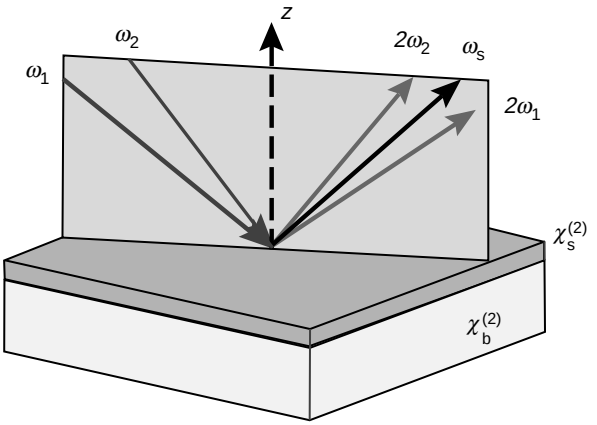

Figure 1 Schematic of SHG and SFG geometry in reflection and transmission from an interface.

$\boldsymbol{k}_\parallel(\omega) = \boldsymbol{k}_\parallel(\omega_1) + \boldsymbol{k}_\parallel(\omega_2)$. The ratio of $\boldsymbol{k}_\parallel(\omega)$ to $\boldsymbol{k}(\omega)$ then determines the direction of the sum-frequency output that appears in both transmission and reflection. The reflection geometry is often used in order to minimize the bulk contribution.

With $\boldsymbol{P}_s^{(2)}$ as the source term, the sum-frequency output can be obtained from the solution of the wave equation. With the proper boundary conditions the sum frequency (SF) intensity is given by:

$$\begin{aligned}I(\omega) = &\frac{8\pi^3\omega_s^2\sec^2\theta_\omega}{\hbar c^3\sqrt{\epsilon_1(\omega)\epsilon_1(\omega_1)\epsilon_1(\omega_2)}} \\ &\times |\boldsymbol{e}^\dagger(\omega)\cdot\boldsymbol{\chi}_s^{(2)} : \boldsymbol{e}(\omega_1)\boldsymbol{e}(\omega_2)|^2 I_1(\omega_1)I_2(\omega_2)\end{aligned} \quad [2]$$

In this expression, $\chi_s^{(2)}$ is the surface nonlinear susceptibility defined by $\boldsymbol{P}_s^{(2)} = \varepsilon_0\boldsymbol{\chi}_s^{(2)} : \boldsymbol{E}(\omega_1)\boldsymbol{E}(\omega_2)$; the quantities $\boldsymbol{e}(\omega_i)$ correspond to the unit polarization vectors after the appropriate Fresnel correction, $\boldsymbol{e}(\omega_i) \equiv \boldsymbol{F}(\omega_i)\hat{\boldsymbol{e}}(\omega_i)$, with $\boldsymbol{F}(\omega_i)$ being the transmission Fresnel factor and $\hat{\boldsymbol{e}}(\omega_i)$ the unit polarization vector of $\boldsymbol{E}(\omega_i)$; θ_ω denotes the SF output angle with respect to the surface normal, $\varepsilon(\omega_i)$ is the dielectric constant at frequency ω_i, and I_i is the input pump intensity at ω_i.

The surface nonlinear susceptibility $\chi_s^{(2)}$ is a third-rank tensor. In Cartesian coordinates it has 27 tensor elements ($\chi_{ijk}^{(2)}$), many of which could vanish or depend on others due to the surface structural symmetry. As an example, $\chi_{ijk}^{(2)}(\omega=\omega_1+\omega_2)$ for an isotropic surface, with the z-direction defined by the surface normal, has only four independent nonvanishing elements: $\chi_{xxz}^{(2)} = \chi_{yyz}^{(2)}, \chi_{xzx}^{(2)} = \chi_{yzy}^{(2)}, \chi_{zxx}^{(2)} = \chi_{zyy}^{(2)}$, and $\chi_{zzz}^{(2)}$. Different combinations of input and output beam polarizations in SFG measurements are often used to deduce values for the non-vanishing elements. Such measurements then allow the determination of surface symmetry or surface molecular orientation. Being a third-rank tensor, $\chi_s^{(2)}$ can reflect up to three-fold rotational symmetry. $\chi_{s,ijk}^{(2)}$ is related to the molecular nonlinear polarizability or hyperpolarizability $\alpha_{\xi\eta\zeta}^{(2)}$, where $\hat{\xi}$, $\hat{\eta}$, and $\hat{\zeta}$ define the molecular coordinates, through the coordinate transformation

$$\chi_{s,ijk}^{(2)} = N_s\left\langle(\hat{\boldsymbol{i}}\cdot\hat{\boldsymbol{\xi}})(\hat{\boldsymbol{j}}\cdot\hat{\boldsymbol{\eta}})(\hat{\boldsymbol{k}}\cdot\hat{\boldsymbol{\xi}})\right\rangle\alpha_{\xi\eta\zeta}^{(2)} \quad [3]$$

The angular brackets denote an average over the molecular orientational distribution, and N_s is the surface molecular density. For simplicity, microscopic local-field correction is neglected in eqn [3]. Knowing $\chi_{s,ijk}^{(2)}$ and $\alpha_{\xi\eta\zeta}^{(2)}$ thus permits deduction of information on the orientational distribution.

An explicit expression for the nonlinear optical polarizability is obtained from a second-order quantum mechanical perturbation calculation:

$$\alpha^{(2)}_{s,ijk}(\omega_s) = -\frac{e^3}{\hbar^2}\sum_{g,n,n'}\left[\frac{\langle g|r_i|n\rangle}{\omega_s-\omega_{ng}+i\Gamma_{ng}} \times\left(\frac{\langle n|r_j|n'\rangle\langle n'|r_k|g\rangle}{\omega_2-\omega_{n'g}+i\Gamma_{n'g}} + \frac{\langle n|r_k|n'\rangle\langle n'|r_j|g\rangle}{\omega_1-\omega_{n'g}+i\Gamma_{n'g}}\right)+\cdots\right]\rho^{(0)}_g \quad [4]$$

This expression shows how the nonlinear polarizability or susceptibility depends on material parameters such as the dipole transition moments $\langle n|r_i|g\rangle$ and energy levels. It contains a sum over eight resonant terms. The quantities ω_{ng} and Γ_{ng} are the frequencies and half-widths for the transitions between quantum states $|n\rangle$ and $|g\rangle$, and $\rho^{(0)}_g$ denotes the population in $|g\rangle$. It can be seen that $\alpha^{(2)}$, and hence the SF output, should be resonantly enhanced when the pump frequency ω_1 or ω_2 and/or the sum frequency $\omega_1+\omega_2$ approach resonance. The resonant enhancement provides spectral information and makes SHG and SFG effective spectroscopic tools. The resonances could be electronic or vibrational, or more generally, any surface characteristic transition.

Experimental

Here we deal with basic considerations concerning the optical setup for SHG or SFG experiments in reflection from a surface as is shown schematically in Figure 2. In general, the pump radiation from pulsed laser sources is directed onto the surface. High-power tunable light pulses can be obtained from optical parametric generation and amplification (OPG/OPA) together with harmonic, sum- or difference-frequency generation, preferably pumped by picosecond or femtosecond lasers with high repetition rates. By this means radiation tunable from near UV at ~200 nm to mid IR at ~18 μm can be generated. For SFG the input pulses with frequencies ω_1 and ω_2 are directed to overlap spatially and temporally on the sample. The sample could be the surface of a liquid or solid in air, a single crystalline surface in ultrahigh vacuum, buried interfaces, etc. Polarizers and half-wave plates allow for tuning of incident power and polarizations at the sample. Together with the polarizer in the output path, different input/output polarization combinations can be chosen. In the detection system the signal has to be discriminated against reflected and scattered pump light. This is achieved by spatial and spectral filtering with apertures, dielectric mirrors, and interference and color glass filters. An optional monochromator can also be used for additional stray-light suppression. The signal is then detected by a photomultiplier tube and gated electronics are used for signal integration or photon counting.

From eqn [2] the expected signal strength for SHG/SFG can be estimated. With a typical value of $\chi^{(2)}_s$ of 10^{-21} m^2 V^{-1}, a single 1-μm pump pulse, incident at $\theta = 45°$ having pulse energy $E = I\,A\tau = 100$ μJ, beam cross-section $A = 1$ mm^2, and pulse duration $\tau = 10$ ps, can generate about 10^3 photons per pulse of SHG. By means of photon counting a minimal count rate of 10^{-3} photons/pulse

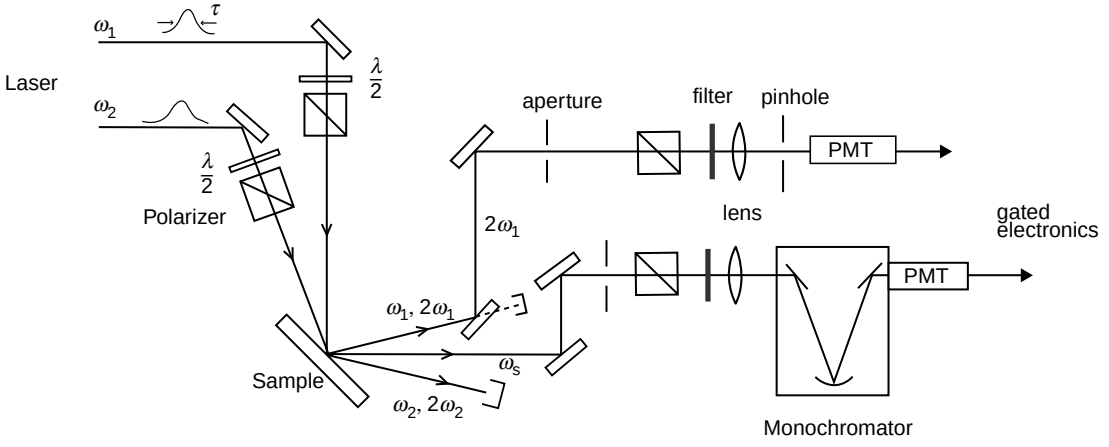

Figure 2 Schematic of experimental setup for second-harmonic and sum-frequency generation.

can be achieved which allows the detection of $\chi_s^{(2)}$ as small as 10^{-24} $m^2\,V^{-1}$. The spectral resolution is limited by the spectral width of the pump pulses. In order to obtain accurate spectral data over a wide tuning range or to obtain absolute values for $\chi_{s,ijk}^{(2)}$ of the material investigated, a reference material such as *z*-cut quartz with known values of χ is to be measured for comparison.

The simplest kind of experiments are SHG at a fixed pump frequency. From the signal variation in response to surface modification one can probe kinetics and dynamics of adsorption, desorption, diffusion, surface melting, phase transitions, etc. By tuning the pump wavelength, second-harmonic spectroscopy can give information on surface electronic states. For surface vibrational spectroscopy, however, IR-vis SFG must be employed. In the latter case, tunable IR input is mixed with visible input to yield a SF signal in the visible region.

Surface Specificity

In many cases, the surface contribution to SFG or SHG from a centrosymmetric medium clearly dominates over the bulk contribution. This generally occurs when the surface or interface is composed of a polar oriented molecular layer. An example is shown in Figure 3, where the vibrational spectra in the C–H stretch region of three buried solid–liquid interfaces are presented. The spectrum for hexadecane ($C_{16}H_{34}$)/fused silica shows no C–H peaks. This is in spite of the fact that liquid hexadecane has strong infrared and Raman activity in this spectral range. The result indicates that the bulk signal contribution is negligible. In contrast, strong resonances are observed from the hexadecane/OTS/silica system, where OTS is a monolayer of octadecyltrichlorosilane ($CH_3(CH_2)_{17}SiCl_3$) chemisorbed on the fused silica plate. A similar spectrum is obtained for the CCl_4/OTS/silica interface. This clearly indicates that it is the contribution from the OTS monolayer that dominates the spectra.

Another example is described in Figure 4 where the SFG spectrum in reflection from a free liquid water surface is shown. The resonant features between 3000 and 3600 cm^{-1} are due to the O–H stretches of hydrogen-bonded OH groups. The sharp peak at 3700 cm^{-1} can be identified with the free OH bonds. Since no dangling OH bonds can exist below the surface its presence indicates that the spectrum must originate from the topmost layer of water molecules. Furthermore it can be shown that the surface water molecules are oriented with one of the OH bonds directed out of the liquid. In addition to the above examples, the surface sensitivity and specificity has been demonstrated and successfully applied to a large number of systems as will be shown below.

A note on the definition of surface or interface is in order. In SHG and SFG, the surface or interface layer refers to a thin layer between two adjacent bulk media that has a different structure from the bulk media and lacks inversion symmetry. If molecules in the surface layer are polar-ordered, then SHG and

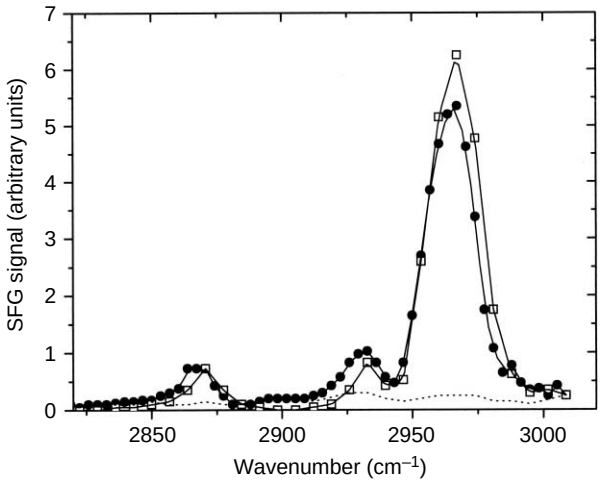

Figure 3 SFG spectra of different interfaces obtained with *ssp* polarization combination: hexadecane/silica (dashed), CCl_4/ OTS/silica (solid circles), and hexadecane/OTS/silica (open squares). OTS refers to a monolayer of octadecyltrichlorosilane.

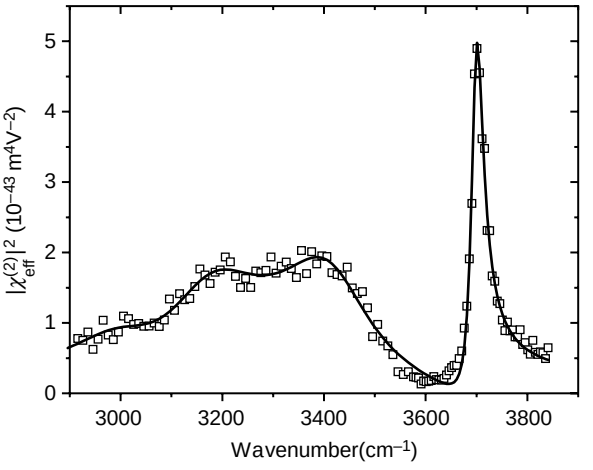

Figure 4 SFG spectrum of the liquid–vapor interface of pure water (*ssp* polarization combination). The mode at 3700 cm^{-1} is due to the dangling OH bonds at the surface.

SFG are often dominated by contributions from the surface layer. However, the bulk contribution is not strictly zero even if the media have inversion symmetry, as $\chi^{(2)}$ can arise from electric-quadrupole and magnetic-dipole contributions. Separation of surface and bulk contributions in SHG and SFG is a subtle problem in general. Experimentally, how surface modification affects the signal can be used to evaluate whether or not the surface contribution dominates.

A special case concerns materials that lack bulk inversion symmetry, for example, III–V and II–VI semiconductors such as GaAs and ZnSe. In this case, the bulk contribution to SHG and SFG is electric-dipole allowed and may be very significant. With an appropriate choice of polarization combinations and surface orientation, it can nevertheless be well suppressed, leaving the surface contribution dominant.

Applications

Both SFG and SHG have been applied to a wide variety of surface and interfacial systems. To illustrate their capabilities and versatility as surface spectroscopic tools, the focus of this summary will be on examples where the information deduced cannot readily be obtained by other techniques. (For details, readers are referred to the review articles cited in Further Reading and the original papers cited therein.)

SFG and SHG have been used for the study of adsorbates at surfaces even under ambient conditions. The adsorbate alters electronic or structural properties of the substrate and the signal is thus related to the surface density of the adsorbate and its orientation.

Elementary surface reactions, in particular adsorption, dissociation, or desorption of simple molecules such as CO, hydrogen, oxygen, or water on metal and semiconductor single-crystal surfaces under ultra-high-vacuum conditions, have been investigated. Sensitivity into the sub-percent monolayer regime is achieved and allows the identifictation of competing reaction channels and adsorbate dynamics on surfaces. Such studies can help to understand epitaxial growth or heterogeneous catalysis because the techniques are applicable at any gas pressure and surface temperature. Related to this is the study of surface diffusion, which can be probed following the temporal decay of a diffracted SHG signal off a submonolayer adsorbate grating formed by laser-induced desorption.

Making use of the spectroscopic capabilities of SHG, the surface electronic structure of selected metals and semiconductors, in particular silicon, were studied with an emphasis on the effects of temperature, crystallographic orientation and different adsorbates. Among buried interfaces, the Si/SiO_2 interface has been the subject of intense investigations and the sensitivity of SHG to static electric fields at the interface and to inhomogeneous strain was also demonstrated.

Different in-plane surface symmetries associated with different crystallographic orientations or surface reconstructions yield different SHG and SFG responses. This allowed for the investigation of surface reconstructions (e.g., $Si(111)2\times1 \rightarrow 7\times7$), order–disorder transitions (e.g., $Si(111)7\times7 \rightarrow 1\times1$, Au/Si(111)) and surface melting (e.g., single-crystal ice, Si(111), Ge(111)), providing information on latent heat, superheating, and its dynamics using pump-probe techniques. Magnetization-induced SHG was also used for probing surface and interface magnetism of ferromagnetic metals and bimetallic systems.

Many unique applications of spectroscopic SFG have been developed based on its capability to study large molecules, in particular under ambient conditions. Surface vibrational spectra with different input/output polarization combinations and sample geometries provide information on orientation, conformation and alignment of surface molecules and the composition and structure of the surface layer. The study of self-assembled monolayers (e.g., OTS on quartz) to deduce the orientation and conformation of the alkyl chains in the monolayer is an example. The effect of molecular density and temperature on the spectrum gives information on intermolecular interactions and phase transitions. Another example concerns the adsorption of liquid crystal molecules on nanostructured polymer substrates. Both the chain orientation at the polymer surface and its effect on the alignment of adsorbed liquid crystal molecules can be addressed.

Surface structures of liquids, especially those of pure liquids, are of great interest in science and technology, and SFG is a unique spectroscopic tool for probing liquid surfaces and interfaces. For example, the SFG vibrational spectrum for the water–vapor interface in **Figure 4** gives information on the density and orientation of the surface water molecules at the water–vapor interface. The surface layer was found to be more ordered compared to the bulk as was also observed for various other organic liquids studied with SFG. In other cases soluble and insoluble organic molecules at a liquid–vapor,

liquid–liquid, or liquid–solid interface have also been studied. They appear as adsorbed monolayer films and their structure and phase behavior are relevant to many applications. Identification of the adsorbed molecular species at solid–liquid interfaces is also important for understanding electrochemical processes. Various studies with SFG have addressed bonding of, e.g., CO, CN^-, and SCN^- at electrodes and its variation with electrode potential.

SFG spectroscopy also finds unique applications in studies of polymer surfaces and interfaces most relevant to modern science and technology. The observed surface vibrational spectra of polymers provide information on surface composition, molecular orientation, and conformation of neat and blended polymers. The effect of environment and surface treatment on the surface structure can also be studied. Investigation of the biological functions of complex molecular systems has attracted increasing interest, and SHG and SFG have been applied successfully to selected systems ranging from the isomerization of retinal – a molecule involved in the vision process – to functional aspects of model membranes.

Both SHG and SFG can be combined with microscopy techniques for surface microscopic studies. Microscopic imaging can be achieved by rastering the probe beam or, preferably, the sample position. Near-field SFG/SHG spectroscopy has recently been developed.

Performing surface SHG and SFG experiments in the time domain can provide information on surface dynamics. Pump-probe experiments allow for measurements of energy relaxation and phase coherence of excitations such as surface electronic states and surface phonons and vibrations.

Outlook

Although SHG and SFG were established as surface analytical tools more than 15 years ago, it is still an active field of research with much potential that has not yet been explored. As an example, it has only recently been demonstrated that doubly resonant infrared–visible SFG, as a two-dimensional spectroscopy, can give access to couplings between vibrational modes and surface electronic transitions. With the commercial availability of suitable laser sources, the techniques can be extended to a much wider range of applications. This includes possible investigations of ultrafast surface dynamics, nanostructures, and biological systems.

Introduction

Polarization is one property of light waves and will be defined after a brief overview of the properties of light. Light is part of the electromagnetic spectrum of waves that have both particle-like and wave-like properties. Light waves carry energy in the form of photons which act like particles; the photon energy increases in proportion to the frequency of the wave. The particle-like properties of light and other electromagnetic waves are described by quantum mechanics. Light also acts like transverse waves that travel in straight lines in air and vacuum and can be described by classical electromagnetic theory. Polarization deals with the wave-like properties of light, and is described mathematically by Maxwell's equations, the key relations in electromagnetic theory. Polarization effects occur when light interacts with matter. In order to understand polarization, there will be a brief introduction to the subject of electromagnetic waves.

For a more in-depth treatment of the material in this article, the reader is directed to the Further Reading list at the end of this article and in particular to the two chapters on 'Polarization' and 'Polarizers' written by the author in Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. I, chapter 5 and vol. II, chapter 3. New York: McGraw-Hill Inc.

Electromagnetic waves have both electric and magnetic fields associated with them. These are vibrations in directions perpendicular to the direction the wave is traveling, i.e., the direction of propagation. $\vec{E}$ represents the vector of the electric field and $\vec{H}$, perpendicular to $\vec{E}$, represents the magnetic field vector. Both these vectors are complex and have real and imaginary parts. Polarization effects are always associated with the $\vec{E}$ vector. Specifically, the plane of polarization is defined as the plane in which the $\vec{E}$ vector is vibrating. Waves having different amplitudes, phases, or angular orientations (azimuths) of their electric or magnetic vectors can be combined by conventional vector addition methods. Also the $\vec{E}$ vector of a particular vibration can be resolved into two components in mutually perpendicular directions that are vibrating in phase.

If a light source such as the sun, a candle flame, or an electric light bulb is considered on a microscopic scale, each vibrating atom or molecule emits linearly polarized light (see the definition below). But the individual atoms or molecules do not act together, so their vibrations have no fixed phase relationships to each other and they cannot be added into a single linearly polarized beam. Thus, we call light from these sources unpolarized. In an unpolarized light beam, the $\vec{E}$ vector vibrates in all directions perpendicular to the direction of propagation. If a snapshot is taken at a particular instant of time, different parts of the beam will have $\vec{E}$ vectors vibrating with different amplitudes and phases at different angles to each other, but all in a plane perpendicular to the direction of propagation. In the most common convention used in optics, the wave travels in the $+z$ direction in a right hand coordinate system and the $\vec{E}$ vectors are all vibrating at various angles in the $x-y$ plane. The angle of vibration is measured from the positive x axis in a counterclockwise direction when the observer is looking against the direction of propagation of the light beam.

For linearly polarized or plane polarized light, if a snapshot of a light beam is taken at a particular instant, the $\vec{E}$ vector will be vibrating at a certain angle in the $x-y$ plane. As time (or position on the traveling wave) varies, the amplitude of the $\vec{E}$ vector will vary in a sinusoidal manner, but the vibration will remain at the same angle in the $x-y$ plane. As an example, the real part of the electric vector of a linearly polarized beam that is vibrating in the $+x$ and $-x$ directions and traveling in the $+z$ direction is

given by the relation:

$$\vec{E}_x(z,t) = \hat{i}E_0 \cos(kz - \omega t) \quad [1]$$

where t is the time, $\hat{i}$ is a unit vector in the $+x$ direction, E_0 is the amplitude of the vibration, $\vec{k}$ is the propagation vector in the direction the wave is traveling, i.e., the z direction (its magnitude is $2\pi/\lambda$), and $\omega = 2\pi f$ where f is the vibration frequency of the wave. In free space, $\omega = 2\pi c/\lambda$ where c is the velocity of light and λ is the wavelength of the vibration.

Light can also be circularly or elliptically polarized. Circularly polarized light is produced by adding the electric vectors of two waves, each having the same amplitude but which are 90° out of phase; the resulting vibration sweeps out a circle in the x–y plane. When the first wave is vibrating in the $+x$ and $-x$ directions (eqn [1]), the second wave is vibrating in the $+y$ and $-y$ directions:

$$\vec{E}_y(z,t) = \hat{j}E_0 \sin(kz - \omega t) \quad [2]$$

and is added to the first wave. The resultant wave is the sum of eqns [1] and [2]:

$$\vec{E} = E_0[\hat{i}\cos(kz - \omega t) + \hat{j}\sin(kz - \omega t)] \quad [3]$$

The direction of vibration of this wave will rotate in a circle as either the time increases or as the distance along the wave increases, but the amplitude of the vibration will not change. As time increases, the vibration will make a circle in the clockwise direction (to negative angles). This light is defined to be right circularly polarized. If the + sign between the two parts of eqn [3] is changed to a minus sign, as time increases, the vibration will make a circle in the counterclockwise direction (to positive angles) and the light is now defined to be left circularly polarized. These definitions are for conventional (traditional) optics. However, the opposite definitions with right (left) circularly polarized light defining circles in the counterclockwise (clockwise) direction are also in use. In modern physics, there is still another convention that defines right (left) circularly polarized light as having negative (positive) helicity.

Right and left elliptically polarized light beams have the same angle conventions as for circularly polarized beams but are produced by adding two electric vectors that have different amplitudes. In eqns [1] and [2], the amplitude terms will be, for example, E_1 and E_2 instead of E_0 and eqn [3] can no longer be used. There is now a major axis and a minor axis of the ellipse. If $E_1 > E_2$, the major axis will be along the x axis; for $E_1 < E_2$, the major axis will coincide with the y axis.

The preceding discussion has dealt entirely with the electric vector of the electromagnetic field. However, one cannot observe the $\vec{E}$ vector. The irradiance (energy per unit area per unit time), $\vec{E}\vec{E}^*$, is what can be observed visually and measured by electronic detectors. Thus, measurements of the polarization are irradiance measurements. Light transmitted by a polarizer is called the transmittance of the polarizer; similarly, light reflected from a polarizer is called the reflectance of the polarizer.

One of the most important parts of the subject of polarization is how to produce linearly polarized light starting with unpolarized light. This is done by using polarizers, as discussed in the section on polarizers below. Certain materials have special properties that make them able to polarize light. Depending on the application, different kinds of polarizers are preferred. Optics textbooks by Hecht and Guenther discuss the most important polarizers and two articles by Bennett describe many kinds of polarizers including special ones (see the Further Reading at the end of this article for full references). Only the basic principles will be described here.

Sunlight scattered by air molecules in the atmosphere (Rayleigh scattering) is also partially linearly polarized. The air molecules act like tiny dipoles and vibrate when they absorb sunlight. They emit radiation that is polarized in certain directions relative to the vibration direction. When the viewer is at a 90° angle with respect to the sun, the polarization of the skylight is a maximum. Rayleigh scattering is the subject of several books and will not be further discussed here.

Retarders are used to change linearly polarized light into circularly or elliptically polarized light and compensators, which are a form of retarders, can analyze an unknown type of polarized light and determine its composition. They are discussed below.

Polarimetry and ellipsometry are closely related techniques that are used to determine the optical properties of a material by shining a known type of polarized light on the material at non-normal incidence and analyzing the polarization properties of the light after it has been reflected from the material. These subjects are treated in other articles in this encyclopedia and in several references at the end of this article.

Changes can be produced in the optical properties of some materials by applying an electric field, a magnetic field, an acoustic field, or another form of variable pressure. The materials changed in these ways are said to be electro-optic, magneto-optic, or piezo-optic. The changes in the optical properties modify some parameter of a light wave passing through a material or reflecting from it.

The amplitude, phase, frequency, polarization, or direction of the light wave can be modified. In this article, we are only concerned with modifications that produce changes in the polarization; these are discussed towards the end of this article.

Matrix methods have been developed to handle problems involving polarization and there is also a visual representation of the matrix algebra that is based on the Poincaré sphere. Both topics are covered at the end of this article.

Polarizers

Basic Relations for Polarizers

A linear polarizer is anything which, when placed in an incident unpolarized beam, produces a beam of light whose electric vector is vibrating primarily in one direction with only a small component vibrating in the direction perpendicular to it. The transmittance T of the linear polarizer is

$$T = \tfrac{1}{2}(T_1 + T_2) \qquad [4]$$

where T_1, the principal transmittance of the polarizer, is $\gg T_2$, the transmittance of the polarizer at 90° to the principal transmittance. Thus, a perfect polarizer would transmit only 50% of an incident unpolarized beam.

If a linear polarizer is placed in a linearly polarized beam and is rotated about an axis parallel to the beam direction, the transmittance will vary between a maximum value T_1 and a minimum value T_2 according to the law:

$$T = (T_1 - T_2)\cos^2\theta + T_2 \qquad [5]$$

where θ is the angle between the plane of vibration of the principal transmittance and the plane of vibration of the electric vector in the incident beam.

The extinction ratio ρ_P of a polarizer is defined as

$$\rho_P = \frac{T_2}{T_1} \qquad [6]$$

and the degree of polarization of a polarization P is

$$P = \frac{T_1 - T_2}{T_1 + T_2} \qquad [7]$$

When two identical polarizers are placed in an unpolarized beam, and the directions of their principal transmittances, T_A and T_B, are inclined at an angle θ to each other, the transmittance of the pair will be

$$T_\theta = \tfrac{1}{2}(T_1^2 + T_2^2)\cos^2\theta + T_1 T_2 \sin^2\theta \qquad [8]$$

Thus, when the directions of the principal transmittances are aligned, $T_\parallel = \frac{1}{2}(T_1^2 + T_2^2)$, and when they are perpendicular, $T_\perp = T_1 T_2$.

Birefringent Materials (Calcite)

The majority of high-quality polarizers are made from calcite. This is a birefringent (doubly refracting) crystalline material that is uniaxial (i.e., there is one preferred direction in the crystal). A birefringent material acts differently for light going in different directions through the crystal. For example, if an unpolarized light beam passes through the crystal in a certain direction, it will be split into two spatially separated beams that are parallel but are linearly polarized at right angles to each other. A uniaxial crystal has an optic axis (i.e., a certain direction in the crystal). When light rays travel parallel to the optic axis, they travel at the same velocity and there is no difference between them. When light passes through the crystal in other directions, the ray whose vibration direction is perpendicular to the optic axis is governed by the ordinary laws of geometrical optics (the same as for isotropic materials) and is called the ordinary ray. The ray whose vibration direction is parallel to the optic axis does not follow the normal geometrical optics laws and is called the extraordinary ray. One ray travels faster than the other, so there is a phase retardation for one ray relative to the other. This is the principle of a retarder or retardation plate (see the next section).

Calcite is a negative uniaxial crystal which means that the refractive index for the ordinary ray is larger than the refractive index for the extraordinary ray. When the ordinary ray enters a block of calcite from air at non-normal incidence, it is bent more than the extraordinary ray.

Calcite can be easily cleaved along three distinct planes, making it possible to produce rhombs of the form shown in Figure 1. The optic axis, going in the HI direction, makes equal angles with all three faces at point H. Any plane, such as DBFH, which contains the optic axis and is perpendicular to the two opposite faces of the rhomb ABCD and EFGH is called a principal section. If the plane of incidence of light on the rhomb coincides with a principal section, the light entering the crystal will be split into two components polarized at right angles to each other which travel in slightly different directions and leave the crystal as two beams slightly displaced but parallel to each other.

The large birefringence of calcite and its excellent transmission through the visible spectral region and into the ultraviolet and infrared regions has made it possible to make excellent high extinction ratio

polarizers with different designs. Some of these are shown in Figure 2. There are two main types: Glan types with rectangular shapes and Nicol types with rhombohedral shapes. The polarizers are made of two pieces of calcite cemented together. Glan types have their optic axes in the plane of the entrance face. In the Nicol types, the principal section is perpendicular to the entrance face, but the optic axis is neither parallel nor perpendicular to the face. The two halves of conventional polarizing prisms are cemented together with cement that has a refractive index intermediate between the ordinary and extraordinary refractive indices. This enables one ray (generally the extraordinary, or *e* ray) to be transmitted and the other to be reflected at the cut, so that only one ray exits from the prism in the direction of the incoming ray. The Glan types are also used without cement with only an air space between the two halves. They can be used at shorter wavelengths in the ultraviolet where the cement absorbs. The extinction ratio can be very high for air-spaced prisms. For example, for a Glan–Foucault prism (an air-spaced Glan–Thompson prism, Figure 2), the extinction ratio can be better than 1×10^{-5} and the prism is usable from about 0.214 μm in the ultraviolet to 2.3 μm in the infrared. However, air-spaced polarizers have very small field angles, so they are mainly used with laser sources where the beam is parallel.

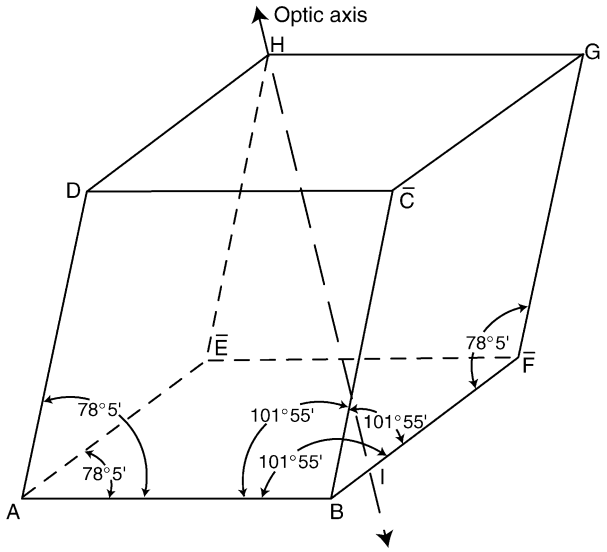

Figure 1 Schematic representation of a rhombohedral calcite crystal showing the angles between faces. The optic axis passes through corner H and point I on side BF. (Reproduced with permission from Bennett JM (1995) Polarizers. In: Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. II, chap. 3. New York: McGraw-Hill, Inc.)

The extreme paths of light through a cemented Glan–Thompson prism are shown in Figure 3. This prism has a length that is three times the width of the entrance aperture (i.e., an *L*/*A* ratio of 3). The optic axis is perpendicular to the plane of incidence which is in the plane of the paper. In the first half of the polarizer, the paths of the ordinary and extraordinary rays, both of which follow the conventional law of refraction (Snell's Law, eqn [8] above) nearly coincide. Ray A is incident on the entrance face of the polarizer at an angle such that the angle of incidence on the cut is the smallest angle for which the *o* ray is totally internally reflected. Ray B is incident at an angle such that the angle of refraction in the first half of the prism is essentially equal to the cut angle, S, so that the *e* ray just passes through the cut. The field angle of the polarizer is twice the smaller of angles θ_A and θ_B. Thus, all rays having angles of incidence between rays A and B will be polarized

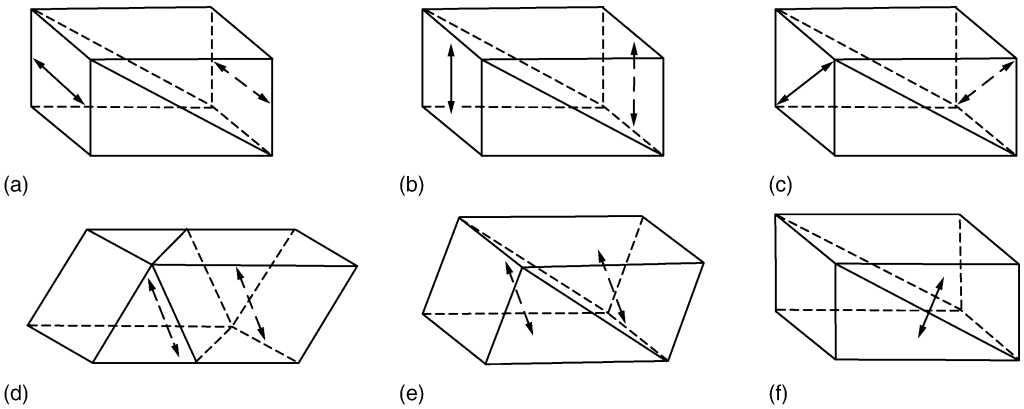

Figure 2 Types of polarizing prisms. Glan types: (a) Glan-Thompson, (b) Lippich, and (c) Frank-Ritter; Nicol types: (d) conventional Nicol, (e) Nicol, Halle form, and (f) Hartnack-Prazmowsky. The optic axes are indicated by the double-pointed arrows. (Reproduced with permission from Bennett JM (1995) Polarizers. In: Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. II, chap. 3. New York: McGraw-Hill, Inc.)

when exiting the prism. The paths of similar rays can be traced through the other prism designs.

In addition to conventional polarizing prisms, there are also polarizing beamsplitter prisms and Feussner prisms. In polarizing beamsplitter prisms, the two beams that are polarized at right angles to each other both emerge from the prism but are separated spatially. Figure 4 shows a diagram of several types of polarizing beamsplitter prisms and Figure 5 shows the paths of rays through side views of these prisms.

A Feussner prism is made of isotropic material but the film separating the two halves is birefringent. These prisms have the advantage that much less birefringent material is required but they have a more limited wavelength range when calcite or sodium nitrite (another birefringent material) is used because the transmitted ordinary ray has a shorter transmission range than the extraordinary ray which is transmitted by the conventional and air-spaced polarizing prisms.

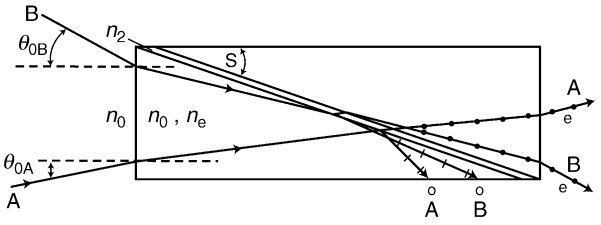

Figure 3 Extreme rays (A and B) that can pass through a cemented Glan-Thompson prism. Both rays change to ordinary and extraordinary rays in the calcite. Both ordinary rays are reflected at the boundary between the two halves of the prism and the extraordinary rays exit in the directions indicated. Rays entering the prism between rays A and B would be transmitted by the prism. The field angle of the prism is twice the smaller of the two angles of incidence (ray A).

Dichroic Absorbers

A dichroic material is one that absorbs light polarized in one direction more strongly than light polarized at right angles to that direction. Dichroic materials are different from birefringent materials because the latter usually have negligible absorption coefficients for both the ordinary and extraordinary rays. Stretched polyvinyl alcohol sheets treated with absorbing dyes or polymeric iodine are the most common type of dichroic absorbers and are primarily sold under the tradename Polaroid. These polarizers do not have as good an extinction ratio as the calcite prism polarizers (see above), but they are inexpensive, come in large sizes, are easily rotated, and produce negligible beam deviation. Also, they are thin, lightweight, and can be made in any desired shape. One of their main advantages is that they are insensitive to the degree of collimation of the beam and can be used in strongly convergent or divergent light.

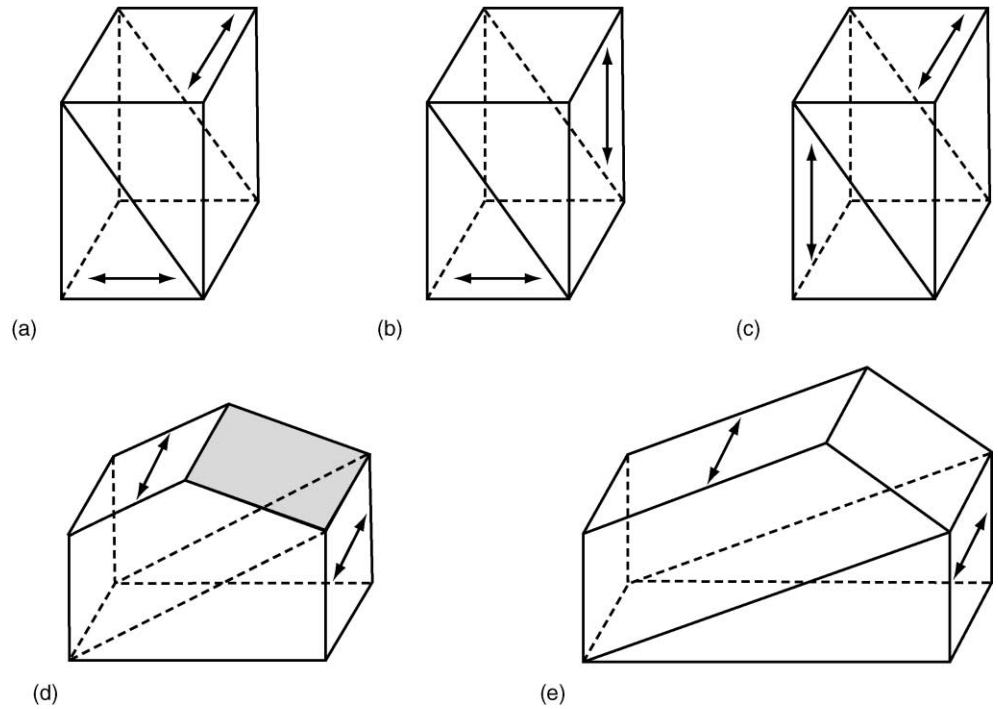

Figure 4 Three-dimensional views of various types of polarizing beamsplitter prisms: (a) Rochon; (b) Sénarmont; (c) Wollaston; (d) Foster (shaded face is silvered); and (e) beamsplitting Glan-Thompson. (Reproduced with permission from Bennett JM (1995) Polarizers. In: Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. II, chap. 3. New York: McGraw-Hill, Inc.)

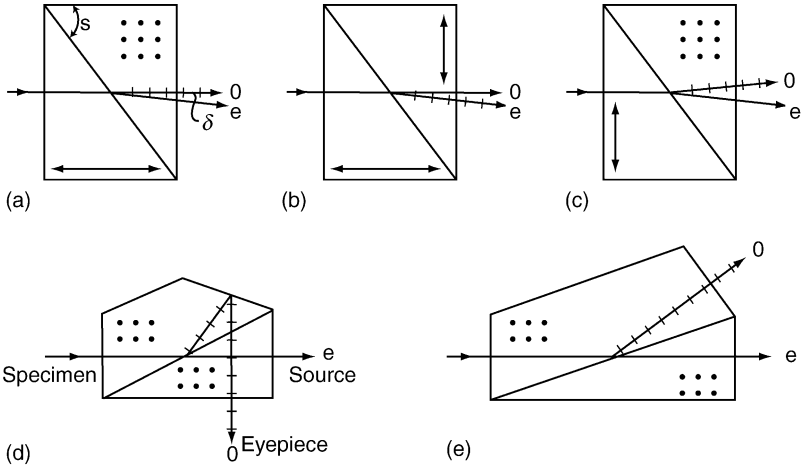

Figure 5 Side views of the polarizing beamsplitter prisms in **Figure 4**. The directions of the optic axes are indicated by the dots and the heavy double-pointed arrows. When the Foster prism is used as a microscope illuminator, the source, specimen, and eyepiece are in the positions indicated. (Reproduced with permission from Bennett JM (1995) Polarizers. In: Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. II, chap. 3. New York: McGraw-Hill, Inc.)

Depending on the density and type of absorbing dye used to make the polarizer, the transmission can be maximized for the visible or near infrared spectrum. The extinction ratio of the Polaroid HN-22 sheet compares favorably with that of the Glan–Thompson prisms throughout the visible spectral region, but the transmission of the Glan–Thompson prism is superior. As the dichroic polarizer transmission increases, the extinction ratio becomes worse. Transmission and extinction ratio curves for various types of dichroic polarizers are shown in Bennett JM (1995) Polarizers. In: Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. II, chap. 3. New York: McGraw-Hill, Inc.

A wire grid polarizer is another kind of dichroic absorber. It is made of a series of equally spaced conducting bars or wires that are either free standing or deposited onto a transparent substrate (backing plate). Energy that is polarized parallel to the length of the bars is absorbed out of the incoming wave by inducing oscillations in the electrons in the metal. Thus, only light polarized perpendicular to the bars will be transmitted. In order to have an appreciable degree of polarization, the wavelength must be at least twice the spacing between grids in the polarizer. Because of the difficulty of making wire grids with small enough spacings, these polarizers are limited to the mid- and long-wavelength infrared spectral region, beyond about 5 μm. The polarizer will have the best extinction ratio if the substrate has a low refractive index; if a high refractive index substrate such as silicon or germanium is used, it must be covered with an antireflection coating before the grid is deposited.

Most of the wire grid polarizers have been used with microwaves, so the theory is in the form for transmission lines. Similar transmission line theory has been applied to infrared polarizers in the form of bars and wires.

Reflection and Transmission

Light can be polarized by reflecting it from the flat surface of a material inclined at non-normal incidence to the light beam or by transmitting it through a transparent plate at non-normal incidence. These polarizers work because light has different reflectances when the electric vector is linearly polarized parallel and perpendicular to the plane of incidence. The plane of incidence contains both the incoming light beam (incident beam) and the reflected light beam. The angles for both the incident and reflected light beams are measured relative to an axis perpendicular to the surface (the surface normal). The reflection coefficients are given by the Fresnel equations and, for nonabsorbing materials, are:

$$R_s = r_s^2 = \frac{\vec{E}_s^2(\text{reflected})}{\vec{E}_s^2(\text{incident})} = \frac{\sin^2(\theta_0 - \theta_1)}{\sin^2(\theta_0 + \theta_1)} \qquad [9]$$

$$R_p = r_p^2 = \frac{\vec{E}_p^2(\text{reflected})}{\vec{E}_p^2(\text{incident})} = \frac{\tan^2(\theta_0 - \theta_1)}{\tan^2(\theta_0 + \theta_1)} \qquad [10]$$

where R_s and R_p are called the reflectances (previously called the intensity reflection coefficients), and r_s and r_p are the amplitude reflection coefficients. $\vec{E}_s$ ($\vec{E}_p$) is the incident or reflected electromagnetic

wave vibrating perpendicular (parallel) to the plane of incidence and θ_0 and θ_1 are the angles of incidence and refraction, respectively. The angle of refraction is the angle of the light beam in the material, measured from the surface normal. For a nonabsorbing material, it can be obtained in terms of the refractive index n_1 of the material from Snell's Law:

$$\frac{\sin\theta_0}{\sin\theta_1} = \frac{n_1}{n_0} \qquad [11]$$

where n_0 and n_1 are the refractive indexes of the incident medium (usually air with $n_0 = 1$) and the material. Sometimes the refractive index of the material is expressed as a ratio measured relative to the refractive index of the incident medium: $n = n_1/n_0$. The reflectances of absorbing materials are similar to eqns [9]–[11] but involve complex refractive indexes and angles of refraction.

Figure 6 shows curves for R_s and R_p as a function of angle of incidence for four nonabsorbing materials that have different refractive indexes. In all cases the reflectance is higher for the *s* component than for the *p* component except at 0° and 90° angles of incidence where they are the same. At the so-called Brewster angle, θ_B, $R_p = 0$, $\tan\theta_B = n_1/n_0$, and incident unpolarized light is now completely linearly polarized perpendicular to the plane of incidence (s-polarized light). Note that high refractive index materials produce more intense polarized beams (i.e., have higher reflectances) than low refractive index materials.

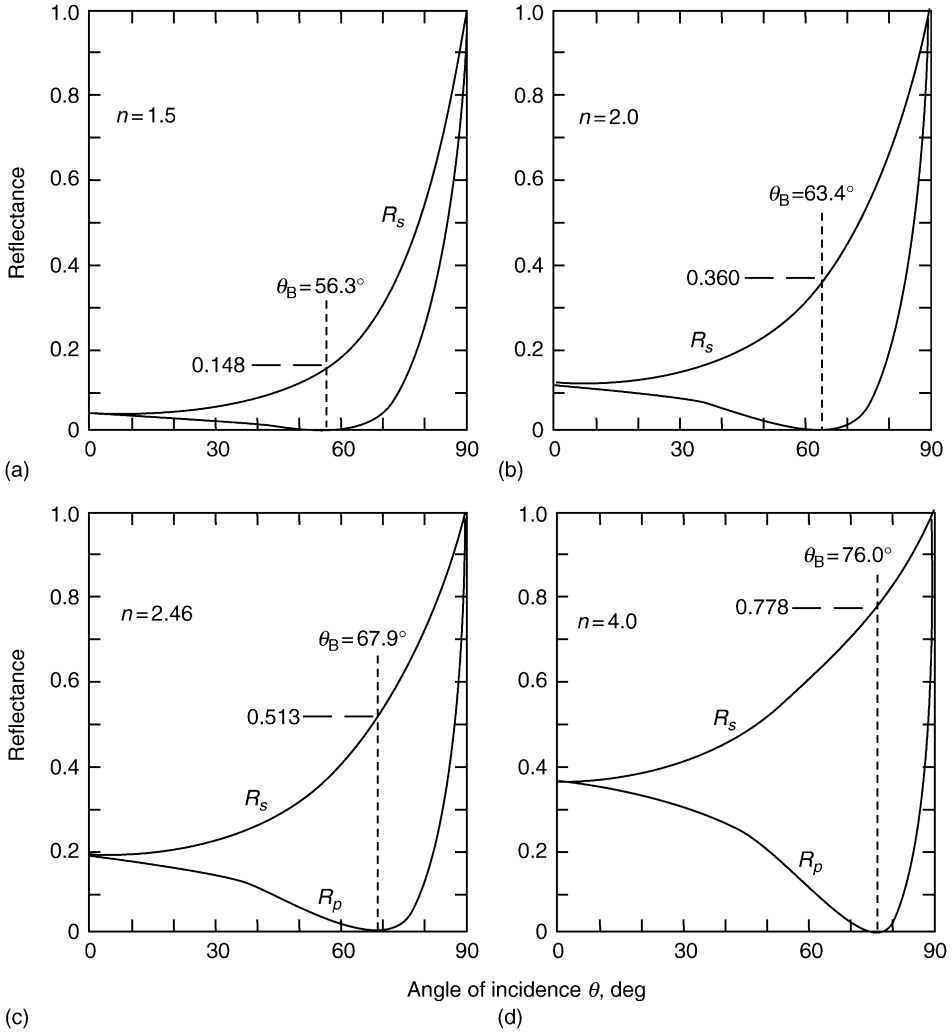

Figure 6 Reflectance of light polarized parallel R_p and perpendicular R_s to the plane of incidence from materials of different refractive index *n* as a function of angle of incidence: (a) $n = 1.5$ (alkali halides in the ultraviolet, glass (approximately) in the visible, and sheet plastics in the infrared), (b) $n = 2.0$ (AgCl in the infrared), (c) $n = 2.46$ (Se in the infrared), and (d) $n = 4.0$ (Ge in the infrared). The Brewster angle θ_B (at which R_p goes to 0) and the magnitude of R_s at θ_B are also indicated. (Reproduced with permission from Bennett JM (1995) Polarization. In: Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. I, chap. 5. New York: McGraw-Hill, Inc.)

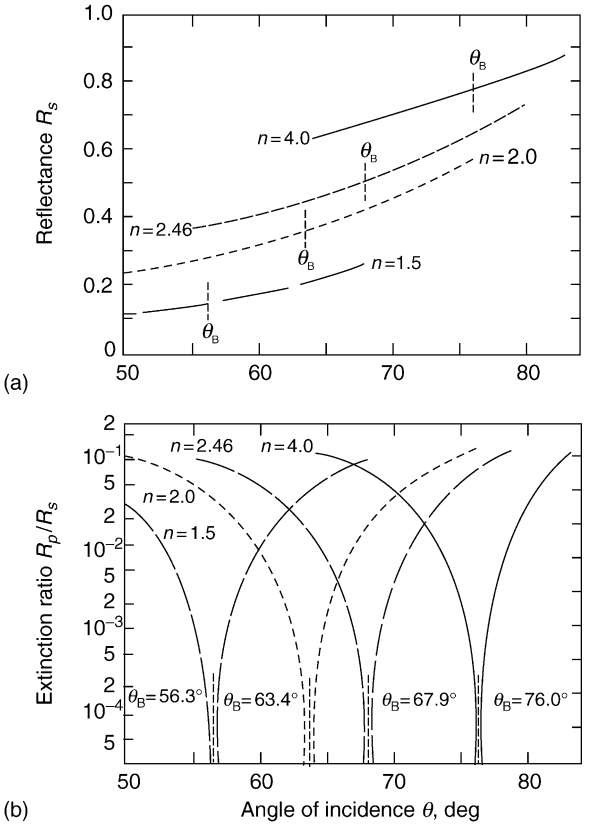

Figure 7 (a) Reflectance R_s and (b) extinction ratio R_p/R_s for materials of different refractive index at angles near the Brewster angle θ_B. A single surface of the material is assumed. (Reproduced with permission from Bennett JM (1995) Polarization. In: Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. I, chap. 5. New York: McGraw-Hill, Inc.)

Figure 7 shows the reflectances and extinction ratios for materials having different refractive indexes. Each curve is for a single reflection. Since plates have two surfaces, there will be two reflections from an actual reflection polarizer so the reflectance and extinction ratios will increase. If the plates are thick, the reflection from the back surface of the plate will be displaced from the reflection from the front surface of the plate. A reflection polarizer is normally used close to the Brewster angle because a high degree of polarization (i.e., a very small extinction ratio) is desired. Because the extinction ratio changes rapidly for angles of incidence close to the Brewster angle, the incident beam must be well collimated to obtain a high degree of polarization. A main disadvantage of reflection polarizers is that the reflected beam is no longer parallel to the incident beam and two additional reflections are required to align the beam.

Light transmitted through a plate will only be partially linearly polarized at any angle of incidence including the Brewster angle because both s- and p-components are partially transmitted. Transmission polarizers are thus made of several plates to increase the degree of polarization. Figure 8 shows the transmittance and extinction ratio for a stack of four plane parallel plates assuming multiple incoherent reflections within each plate and no reflections between plates. At the Brewster angle the p-transmittance is theoretically 1 (assuming that there is no absorption within the material) but the extinction ratio greatly depends on the refractive index of the material. A stack of low refractive index plates ($n = 1.5$) has a poor extinction ratio, while a pile of high refractive index plates ($n = 4.0$) has a much better extinction ratio. The plates are often inclined at small angles to each other so the light multiply reflected between plates (which decreases the polarization) is removed from the transmitted beam. The sides of each plate are plane parallel to increase the polarization, but the plates are too thick for the amplitudes of the multiple internally reflected beams to add or subtract. If the amplitudes of the beams could be added, there would be interference effects and the transmittance would vary with the thickness of each plate and with the wavelength. These are so-called interference polarizers and are mentioned below.

Transmission polarizers do not have the angle deviation problem of the reflection polarizers, but the transmitted beam may be slightly displaced parallel to the incident beam if the plates are thick. The main problem with transmission polarizers is that the light is not completely polarized even with several plates in a stack. If the plates are slightly absorbing, the transmission of the polarizer is reduced.

Miscellaneous Types

There are numerous other types of polarizers that mostly use thin films. Interference effects in thin films can increase the polarization efficiency at certain wavelengths depending on the thicknesses of the films and the design of the multilayer coating. Many of the applications involve non-normal incidence designs. For example, a single high refractive index film or a multilayer coating evaporated onto a low refractive index substrate increases the degree of polarization of reflection and transmission polarizers. Polarizing beamsplitters also use multilayer dielectric coatings. Free-standing films of different thicknesses were formerly used for infrared polarizers before wire grid polarizers became available.

Dichroic absorbers have been made from two-phase lamelar eutectics of thin needles of a conducting material embedded in a transparent matrix. Thin sheets of pyrolytic graphite material also act

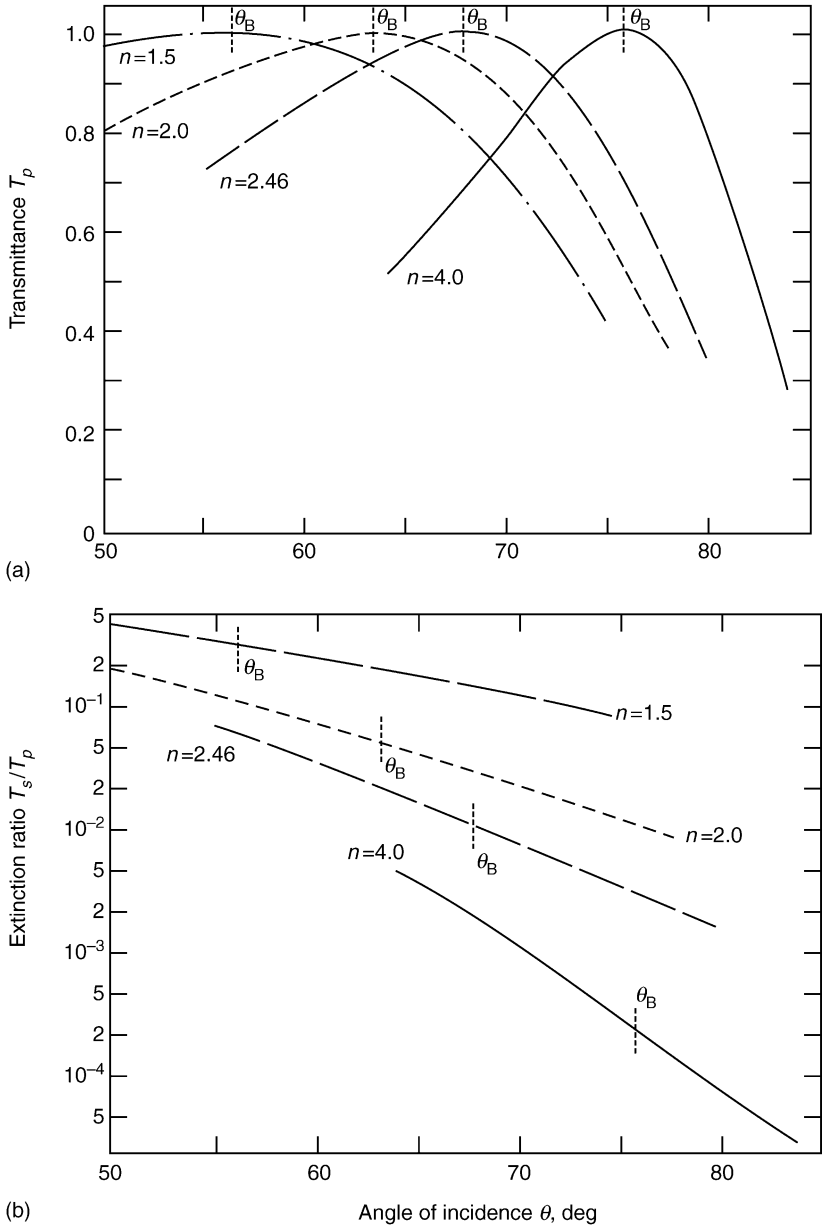

Figure 8 (a) Transmittance and (b) extinction ratio of four plane-parallel plates of refractive index n as a function of angle of incidence, for angles near the Brewster angle. Assumptions are multiple reflections but no interference within each plate and no reflections between plates. (Reproduced with permission from Bennett JM (1995) Polarization. In Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. I, chap. 5. New York: McGraw-Hill, Inc.)

as dichroic absorbers. There are also numerous miniature polarizer designs for fiber optics and nanotechnology applications.

Retarders or Retardation Plates

Retarders, or retardation plates, are devices that can change linearly polarized light into circularly or elliptically polarized light. They can also rotate the plane of polarization of linearly polarized light. A retardation plate is made from a uniaxial crystal that has an optic axis (as discussed above); the light travels in a direction perpendicular to the optic axis, as described below and shown in Figure 9. The ordinary and extraordinary rays travel at different velocities through the crystal depending on their refractive indexes: $n = c/v$, where c is the velocity of light in a vacuum and v is the velocity of light in the material. The larger the refractive index, the slower is the velocity of light in the material. The ordinary ray

with a refractive index n_o and the extraordinary ray with a refractive index n_e have mutually perpendicular vibration directions. If the ray has a vibration direction at another azimuth in the crystal, the refractive index is intermediate between n_o and n_e. For a positive uniaxial crystal $n_e > n_o$ so the extraordinary ray travels slower than the ordinary ray through the crystal. Thus, the designation 'fast axis' is often used for the ordinary ray and 'slow axis' is used for the extraordinary ray, as shown in Figure 9. In a negative uniaxial crystal, $n_e < n_o$, i.e., the velocities along the two axes are reversed.

Because there is a velocity difference between the ordinary and extraordinary rays traveling through a uniaxial crystal, they get out of phase. Depending on their velocities and the optical thickness of the material (the refractive index times the physical thickness), the addition of their amplitudes results in a wave whose vibration direction is either: (a) perpendicular to the original vibration direction; (b) rotates in a circle (right or left circularly polarized light); or (c) rotates in an ellipse (right or left elliptically polarized light). The path difference N between two rays in the crystal, measured in terms of the wavelength of the light, is $N\lambda = \pm d(n_e - n_o)$, where d is the physical thickness of the material. The corresponding phase difference δ between the two rays is $\delta = 2\pi N = \pm(2\pi d/\lambda)(n_e - n_o)$. The quantity N is important because if beams of light vibrating along the fast and slow axes of a crystal get out of step by one quarter of the wavelength of the light, the device is called a quarter wave (or $\lambda/4$) retardation plate, or simply a quarter-wave plate. There are also half-wave ($\lambda/2$) plates that rotate the plane of polarization, and full-wave (λ) plates that rotate the plane of polarization through 180°. If light passes through a full-wave plate, theoretically it is indistinguishable from the original beam. However, materials are normally temperature sensitive so that as the temperature changes, the retardation is no longer exactly one wave, but may be slightly less than or greater than one wavelength. Other thicknesses of retardation plates produce elliptically polarized light.

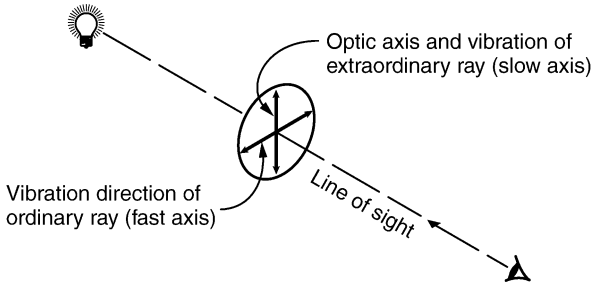

Figure 9 Light incident normally on the front surface of a retardation plate showing the vibration directions of the ordinary and extraordinary rays. In a positive uniaxial crystal, the fast and slow axes are as indicated in parentheses; in a negative uniaxial crystal, the two axes are interchanged. (Adapted with permission from Bennett JM (1995) Polarization. In Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. I, chap. 5. New York: McGraw-Hill, Inc.)

Figure 10 shows what happens to a beam of linearly polarized light when the axis of vibration is at 45° to the fast and slow axes of a positive

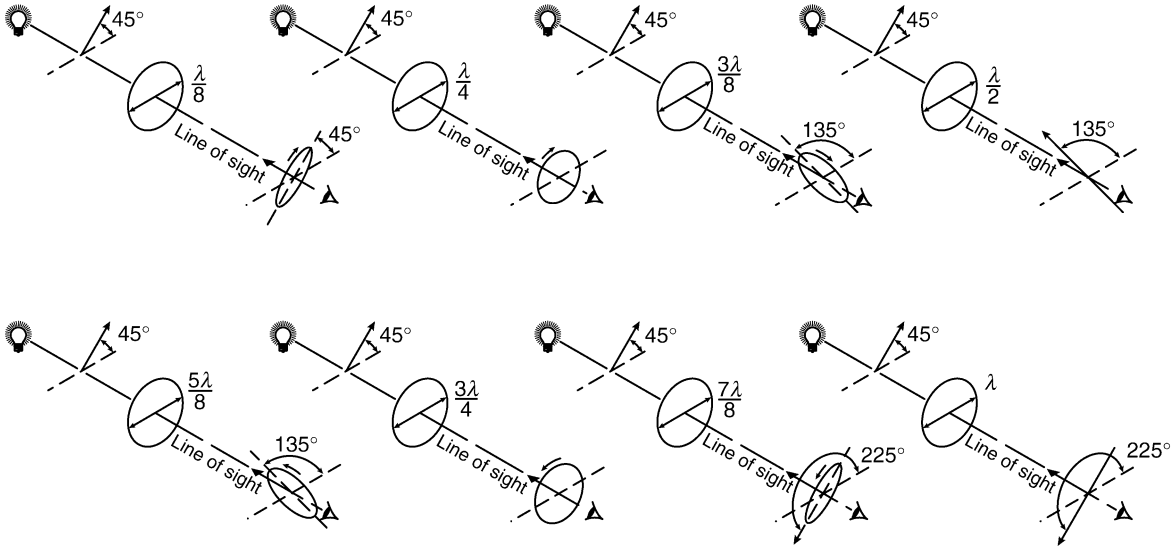

Figure 10 State of polarization of a light wave after passing through a crystal plate whose retardation is indicated in fractions of a wavelength (phase retardation $2\pi/\lambda$ times these values) and whose fast axis is indicated by the double arrow. In all cases the incident light is linearly polarized at an azimuth of 45° to the direction of the fast axis. (Adapted with permission from Bennett JM (1995) Polarization. In: Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. I, chap. 5. New York: McGraw-Hill, Inc.)

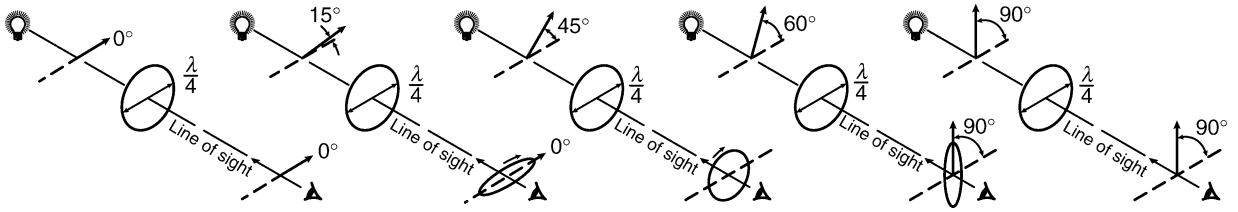

Figure 11 State of polarization of a light wave after passing through a $\lambda/4$ plate (whose fast axis is indicated by the double arrow) for different azimuths of the incident linearly polarized beam. (Adapted with permission from Bennett JM (1995) Polarization. In Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. I, chap. 5. New York: McGraw-Hill, Inc.)

uniaxial crystal. The fast axis is in the horizontal direction, the same as in Figure 9.

The main purpose of a quarter-wave plate is to change linearly polarized light into circularly polarized light. However, as Figure 11 shows, the state of polarization of the light will be quite different depending on the orientation of the plane of polarization of the incident beam relative to the fast axis of the quarter-wave plate.

A half-wave plate is used to rotate the plane of polarization of a linearly polarized beam. The plane of polarization is always rotated through an angle that is twice the angle the initial plane of polarization makes with the fast axis of the uniaxial crystal. A linearly polarized beam always remains linearly polarized.

Retardation plates are often made of mica, stretched polyvinyl alcohol, or crystal quartz, although they can also be made of other stretched plastics, sapphire, magnesium fluoride, and other materials.

Variable Retardation Plates and Compensators

Variable retardation plates are devices whose retardation can be varied in a variety of ways. They can be used to modulate or vary the phase of a beam of linearly polarized light or to analyze a beam of unknown polarization (often elliptically polarized light) such as might be produced by transmission through a birefringent material or by reflection from a metal or film-covered surface. The term compensator is often applied to a variable retardation plate since it can be used to compensate for the phase retardation produced by a material. Common types of compensators include the Babinet and Soleil compensators, in which the total thickness of a birefringent material in the light path is changed, the Sénarmont compensator which consists of a fixed quarter-wave plate and rotatable analyzer to compensate for varying amounts of ellipticity in a light beam, and tilting-plate compensators, which change the thickness of birefringent material in the light beam by changing the angle of incidence. Electro-optic and piezo-optic modulators can also be used as high-frequency variable retardation plates since their birefringence can be changed by varying the electric field or pressure (see next section).

The Babinet compensator, shown schematically in Figure 12 consists of two crystal quartz wedges, each with its axis in the plane of the face but with the axes at right angles to each other. One wedge is stationary, and the other can be moved in the direction indicated by the arrow, so that the total amount of quartz through which the light passes can be varied. The total retardation is proportional to the difference in thickness between the two wedges. This type of compensator was used extensively when the light source was a vertical slit and visual measurements were made of the state of polarization of a beam. However the bands representing different phase retardations were too narrow to be used effectively with a photoelectric detector, so the Babinet compensator was replaced by a Soleil compensator (Figure 13). This device, sometimes called a Babinet–Soleil compensator, is similar to the Babinet compensator except that the field of view has a uniform tint if the compensator is constructed correctly. This is because the ratio of the thicknesses of the two crystal quartz blocks (a movable wedge and a fixed wedge attached to a plate with the two axes perpendicular to each other) is the same over the entire field. The Soleil compensator will produce light of varying ellipticity depending on the position of the movable wedge. It is used in the same way as a Babinet compensator with the uniformly dark field of the Soleil compensator corresponding to the black zero-retardation band in the Babinet compensator.

It is sometimes necessary to accurately measure the azimuth of a beam of linearly polarized light using a photoelectric detector with a rotatable analyzer (i.e., a polarizer) directly in front it. The obvious method is to rotate the analyzer until the detector signal is a minimum and then read the analyzer angle, which equals the extinction angle (perpendicular to the azimuth of the linearly polarized beam). However, the

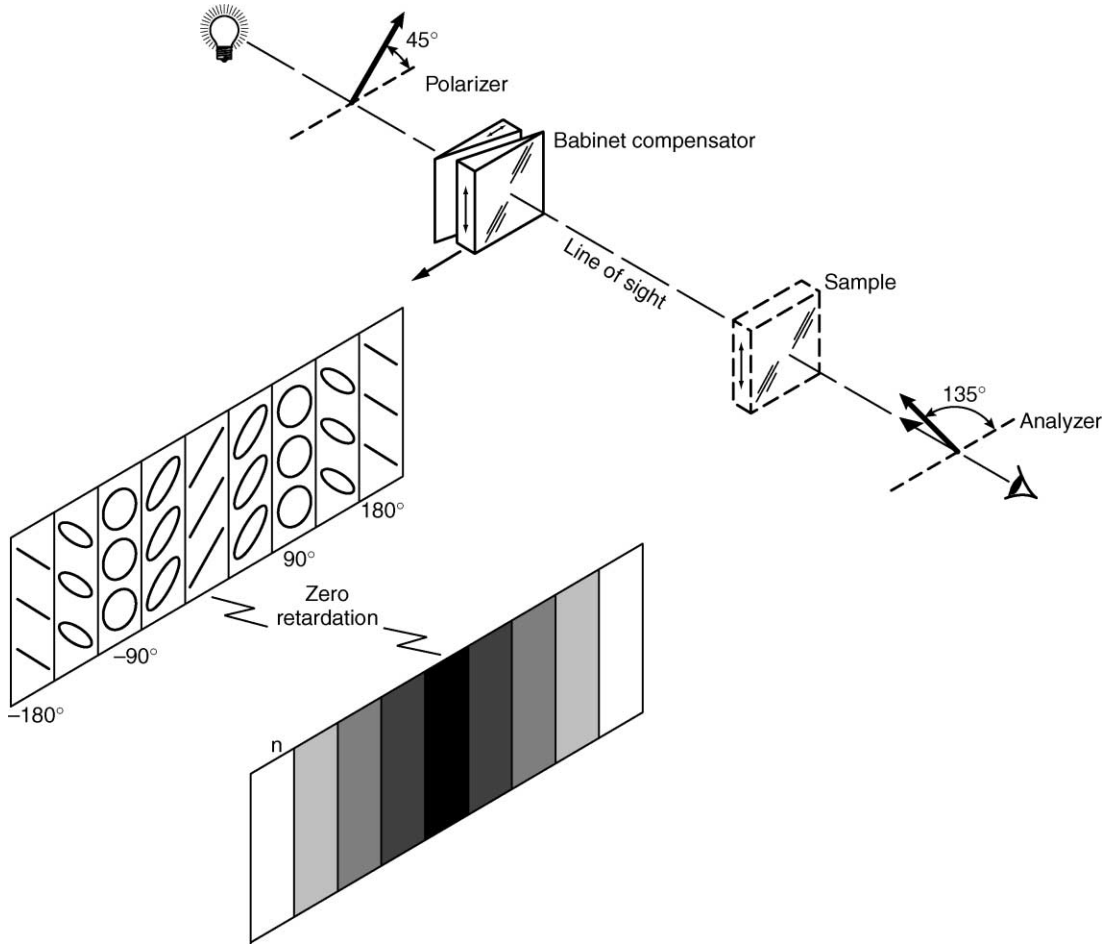

Figure 12 Arrangement of a Babinet compensator, polarizer, and analyzer for measuring the retardation of a sample. The appearance of the field after the light has passed through the compensator is shown to the left of the sample position. Retardations are indicated for alternate regions. After the beam passes through the analyzer, the field is crossed by a series of dark bands, one of which is shown to the left of the analyzer. (Adapted with permission from Bennett JM (1995) Polarizers. In: Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. II, chap. 3. New York: McGraw-Hill, Inc.)

angle can be determined more precisely if the analyzer is offset by a small angle from the extinction angle and the transmittance noted. Then the analyzer is offset by a small angle on the other side of the extinction angle at the angle where the transmittance is the same. One half the difference between these two azimuthal angles gives a more accurate value of the extinction angle than can be obtained by measuring it directly.

Before the days of photoelectric detectors, half-shade devices were extensively used to determine the azimuth of a linearly polarized beam. The device consisted of two polarizers with their axes inclined at a small angle to each other. As the device was rotated, one part of the field became darker and the other part became lighter. At the match position, both parts of the field appeared equally bright. There were a variety of these devices as well as ellipticity half-shade devices that could detect very small amounts of ellipticity in a nominally linearly polarized beam and hence could verify when a compensator had completely converted elliptically polarized light into linearly polarized light.

Electro-Optic, Magneto-Optic, and Piezo-Optic Devices

The state of polarization of light can be rapidly altered by passing it through a material that has electro-optic, magneto-optic or piezo-optic properties. The voltage, magnetic field, or pressure are varied to make the material birefringent (see above). Some materials are isotropic without the applied field, i.e., the refractive index is the same in all directions. Other materials have an optic axis

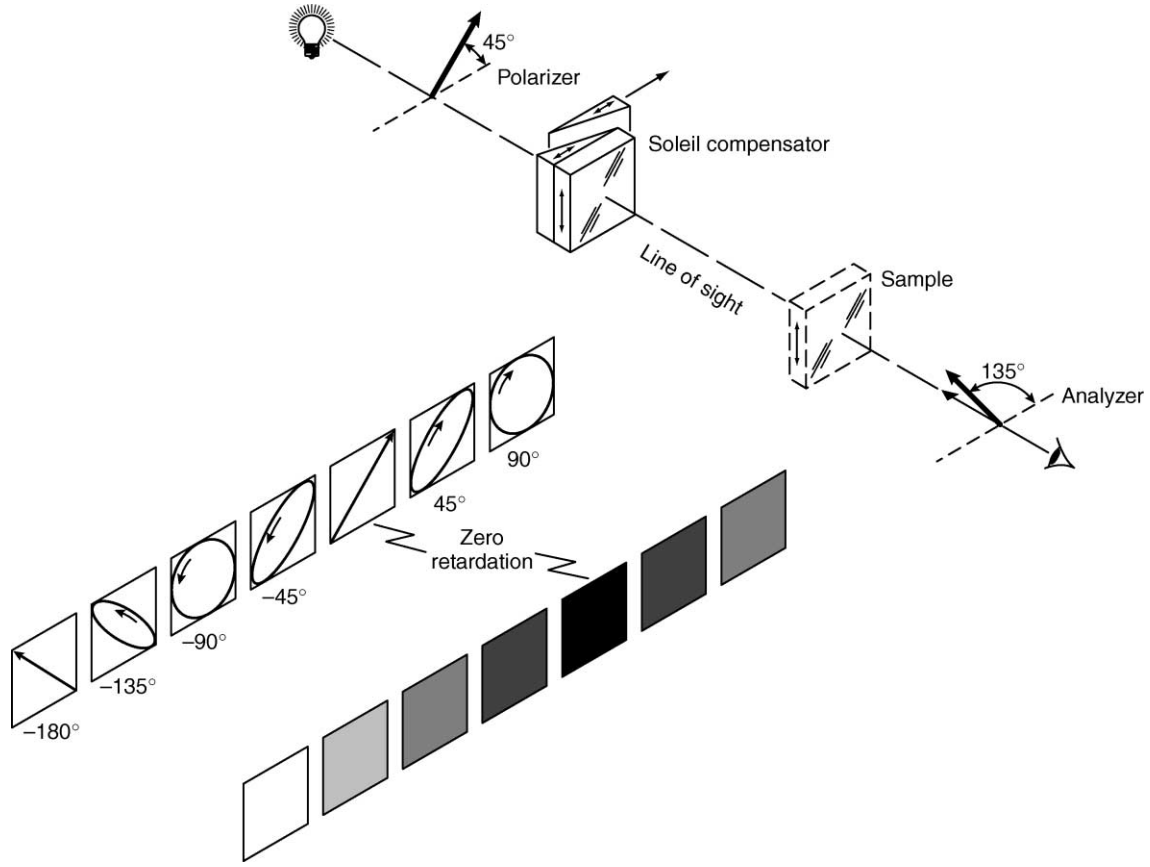

Figure 13 Arrangement of a Soleil compensator, polarizer, and analyzer for measuring the retardation of a sample. The appearance of the field after the light has passed through the compensator is shown to the left of the sample position. After the beam passes through the analyzer, the field appears as one of the shades of gray shown to the left of the analyzer. (Adapted with permission from Bennett JM (1995) Polarizers. In: Bass M (ed.) *Handbook of Optics*, 2nd edn, vol. II, chap. 3. New York: McGraw-Hill, Inc.)

(uniaxial materials) or two optic axes (biaxial materials). In these cases, the applied field creates further asymmetries in the material.

The most common electro-optic, magneto-optic and piezo-optic effects are the Pockel's effect (depending on the electric field), the Kerr effect (depending on the square of the electric field), the Faraday effect (depending on the magnetic field), the Cotton–Mouton and Voigt effects (depending on the square of the magnetic field), and stress birefringence or the photoelastic effect (depending on pressure changes). These effects are shown in Table 1 along with order of magnitude strengths needed to produce changes in the refractive index, and materials that most strongly exhibit the effects. The mathematical descriptions of the effects involve tensors and are too involved to present here. However, simple physical descriptions will be given.

If a varying electric field acts on an electro-optic material, electrons, ions, or permanent dipoles in the material are made to reorient, inducing an electric polarization. The induced polarization creates birefringence that modifies the optical polarization of a light beam passing through the material. The electric field strength determines how the polarization is changed (see Figure 10).

Linearly polarized light passing through a magneto-optic material will be rotated in a direction parallel to the direction of the applied magnetic field. This phenomenon, called the Faraday effect, or Faraday rotation, is similar to what happens in optically active materials (see the next paragraph) except that the Faraday effect depends on the direction of the magnetic field, but not on the direction the light is traveling.

There are naturally optically active materials such as camphor, nicotine, sugar solutions, and crystal quartz that can rotate the plane of linearly polarized light passing through the material. For example, the Si–O bonds in crystal quartz form a helical path around the optic axis. This crystal structure interacts with an incoming linearly polarized beam traveling parallel to the optic axis and rotates it in a clockwise direction. A 1 mm-thick piece of quartz will rotate a

linearly polarized beam by 21.7°. Other materials have asymmetric structures that have mirror images. A mirror image structure cannot be obtained by simply rotating the group of atoms in space. These materials are also optically active. The amount of rotation produced by an optically active material is proportional to the thickness (optical density) of the material that the light passes through. Dextrose (a form of glucose) and levulose (also known as fructose) rotate the plane of linearly polarized light in clockwise and counterclockwise directions, respectively. Many other organic molecules have D- (right handed, dextro-rotary) and L- (left handed, levo-rotary) mirror image forms.

An isotropic material can become anisotropic when stress or an induced strain is applied because of an elasto-optic interaction known as stress birefringence, or the photoelastic effect. This effect is usually bad because it reduces the performance of optical components and devices by introducing phase distortions caused by improper mounting or unequal thermal expansion between the mounts and components. Another source of distortion is strain that has been frozen into optical components during manufacture. French curves are excellent examples that show colored strain birefringence patterns when viewed between crossed polarizers. In one application, strain birefringence has been used constructively to produce a variable phase retarder made from crystal quartz and fused silica. A block of electro-optic crystal quartz, is cemented to a block of isotropic fused silica. When a variable electric field is applied to the crystal quartz, its length changes at the resonant frequency of the block. This produces strain in the fused silica block which in turn produces a variable retardation of light passing through the strained fused silica. Depending on the magnitude of the varying electric field, the device can act like a variable quarter-wave plate, a variable half-wave plate, or have other applications.

Matrix Methods for Computing Polarization

An optical system containing various polarizing and retarding devices can be modeled using matrices. In general, there is an incident beam (in matrix form), that has some state of polarization. It interacts with a device called an instrument (also in matrix form) that alters the state of polarization, so that the exiting beam (a third matrix, the product of the first and second matrices) has another state of polarization. There can be more than one instrument matrix acting on the same incident matrix to produce the final matrix. The two most common matrix methods are the Mueller calculus and the Jones calculus.

There is also a visual representation of this process, a Poincaré sphere, on which vectors represent different states of polarization. The polarization instrument moves the vector representing the incident polarization around the sphere in a prescribed manner. The vectors are called Stokes vectors and are used in the Mueller calculus. The various states of polarization are represented on the Poincaré sphere as follows: The equator represents various forms of linear polarization, the poles represent right- and left-circular polarization, and other points on the sphere represent elliptically polarized light. Every point on the sphere corresponds to a different polarization form. The radius of the sphere represents the incident irradiance of the light beam (which is usually assumed to be unity). The effects of various polarization instruments are determined by displacements on the sphere. Partially polarized light or absorption may be dealt with approximately by ignoring the irradiance factor, since the state of polarization is generally the quantity desired. The Poincaré sphere is most useful for visualizing problems involving nonabsorbing materials, various polarization instruments including polarizers, retarders, compensators, half-shade devices, and depolarizers, and has also been applied

to ellipsometric problems and stress-optical measurements.

The Poincaré sphere is used with Stokes vectors, which are often designated S_0, S_1, S_2, and S_3. S_0 is the incident irradiance of the light beam, corresponding to the radius of the Poincaré sphere. S_1 is the difference in irradiances between the horizontal and vertical polarization components of the beam; for example, when S_1 is positive, the preference is for horizontal polarization. S_2 indicates preference for $+45°$ or $-45°$ polarization depending on whether it is positive or negative, and S_3 gives the preference for right or left circular polarization. Thus, the Stokes vectors S_1, S_2, and S_3 are simply the three Cartesian coordinates of a point on the Poincaré sphere. S_1 and S_2 are perpendicular to each other in the equatorial plane, and S_3 points toward the north pole of the sphere. Any state of polarization of a light beam can be specified by these three vectors. The irradiance vector S_0 is related to the other three by the relation $S_0^2 = S_1^2 + S_2^2 + S_3^2$ when the beam is completely polarized. If the beam is partially polarized, $S_0^2 > S_1^2 + S_2^2 + S_3^2$.

In the Mueller calculus, the incident beam is represented by the four-component Stokes vector, written as a column vector. This vector has all real elements and gives information about irradiance properties of the beam. Thus it is not able to handle problems involving phase changes or combinations of two beams that are coherent. The instrument matrix is a 4×4 matrix with all real elements.

In the Jones calculus, the Jones vector representing the incident beam is a two-component column vector that generally has complex elements. It contains information about the *amplitude* properties of the beam and hence is well suited for handling problems involving the phases of light waves. However, it cannot handle problems involving depolarization, as the Mueller calculus can. The Jones instrument matrix is a 2×2 matrix whose elements are generally complex. The Jones calculus is well suited to problems involving a large number of similar devices arranged in series in a regular manner and makes it possible to obtain a result expressed explicitly in terms of the number of such devices. The Jones instrument matrix of a train of transparent or absorbing nondepolarizing polarizers and retarders contains no redundant information. The matrix contains four elements, each of which has two parts, so that there are a total of eight constants, none of which is a function of any other. The Mueller instrument matrix of such a train contains much redundancy; there are 16 constants but only 7 of them are independent. More information about the Poincaré sphere and the Mueller and Jones calculus is available in other references.

Introduction

Hooke postulated, in the seventeenth century, that light waves must be transverse but his idea was forgotten. Young and Fresnel put forward the same idea in the nineteenth century and accompanied their postulation with a theoretical description of light based on transverse waves. Forty years later, Maxwell proved that light must be a transverse wave and that **E** and **H**, for a plane wave in an isotropic medium with no free charge and no currents, are mutually perpendicular and lie in a plane normal to the direction of propagation, **k**.

Convention requires that we use the electric vector to label the direction of the electromagnetic wave's polarization. The direction of the displacement vector is called the direction of polarization and the plane containing the direction of polarization and the propagation vector is called the plane of polarization. The selection of the electric field is not completely arbitrary, except in relativistic situations, when $v \approx c$, the interaction of the electromagnetic wave with matter will be dominated by the electric field.

Assume that a plane wave is propagating in the z-direction. In complex notation, the plane wave is given by

$$\tilde{\mathbf{E}} = \mathbf{E}_0\, e^{i(\omega t - \mathbf{k}\cdot\mathbf{r} + \phi)} = \mathbf{E}_0\, e^{i(\omega t - kz + \phi)} \qquad [1]$$

The procedure used to decompose an arbitrary polarization into components parallel to two axes of a Cartesian coordinate system, is a technique used extensively in vector algebra to simplify mathematical calculations. According to the mathematical formalism associated with this technique, the polarization is described in terms of a set of basis vectors, $\mathbf{e}_i$. An arbitrary polarization would be expressed as

$$\mathbf{E} = \sum_{i=1}^{2} a_i \mathbf{e}_i \qquad [2]$$

The set of basis vectors, $\mathbf{e}_i$, are orthonormal, i.e.:

$$\mathbf{e}_i \mathbf{e}_j^* = \delta_{ij} = \begin{Bmatrix} 1 & i = j \\ 0 & i \neq j \end{Bmatrix} \qquad [3]$$

where we have assumed that the basis vectors could be complex. We mention this mathematical formalism because an identical formalism is encountered in a description of spin.

In a Cartesian coordinate system, the $\mathbf{e}_i$'s are the unit vectors **i**, **j**, **k**. The summation in eqn [2] extends over only two terms because the electromagnetic wave is transverse, confining **E** to a plane normal to the direction of propagation (according to the coordinate convention we have selected, the **E** field is in the x, y plane).

Polarization Ellipse

Following the formalism of eqn [2], a polarized wave can be written in terms of the x and y components of $\mathbf{E}_0$

$$\tilde{\mathbf{E}} = \mathbf{E}_{0x}\, e^{i(\omega t - kz + \phi_1)}\hat{\mathbf{i}} + \mathbf{E}_{0y}\, e^{i(\omega t - kz + \phi_2)}\hat{\mathbf{j}} \qquad [4]$$

We will use only the real part of **E** for manipulation, to prevent errors. We divide each component of the electric field by its maximum value, so that the problem is reduced to one of the following two sinusoidal varying unit vectors:

$$\begin{aligned} \frac{E_x}{E_{0x}} &= \cos(\omega t - kz + \phi_1) \\ &= \cos(\omega t - kz)\cos\phi_1 - \sin(\omega t - kz)\sin\phi_1 \\ \frac{E_y}{E_{0y}} &= \cos(\omega t - kz)\cos\phi_2 - \sin(\omega t - kz)\sin\phi_2 \end{aligned} \qquad [5]$$

When these unit vectors are added together, the resulting equation will describe the path taken by the tip of the resultant vector. The path will create a Lissajous figure.

To obtain the equation for the Lissajous figure, we eliminate the dependence of the unit vectors on $(\omega t - kz)$. First, multiply the equations by $\sin\phi_2$ and $\sin\phi_1$, respectively and then subtract the resulting equations. Second, multiply the two equations by $\cos\phi_2$ and $\cos\phi_1$, respectively and then subtract the new equations. These two operations yield the following pair of equations:

$$\begin{aligned} &\frac{E_x}{E_{0x}}\sin\phi_2 - \frac{E_y}{E_{0y}}\sin\phi_1 \\ &\quad = \cos(\omega t - kz)[\cos\phi_1 \sin\phi_2 - \sin\phi_1 \cos\phi_2] \end{aligned} \qquad [6]$$

$$\frac{E_x}{E_{0x}}\cos\phi_2 - \frac{E_y}{E_{0y}}\cos\phi_1 = \sin(\omega t - kz)[\cos\phi_1 \sin\phi_2 - \sin\phi_1 \cos\phi_2] \quad [7]$$

The term in brackets can be simplified using the trig identity

$$\sin\delta = \sin(\phi_2 - \phi_1) = \cos\phi_1 \sin\phi_2 - \sin\phi_1 \cos\phi_2 \quad [8]$$

After replacing the term in brackets by sin δ, the two equations are squared and added yielding the equation for the Lissajous figure:

$$\left(\frac{E_x}{E_{0x}}\right)^2 + \left(\frac{E_y}{E_{0y}}\right)^2 - \left(\frac{2E_xE_y}{E_{0x}E_{0y}}\right)\cos\delta = \sin^2\delta \quad [9]$$

The trig identity

$$\cos\delta = \cos(\phi_2 - \phi_1) = \cos\phi_1 \cos\phi_2 + \sin\phi_1 \sin\phi_2$$

was also used to further simplify eqn [9].

Equation [9] has the same form as the equation of a conic

$$Ax^2 + Bxy + Cy^2 + Dx + Ey + F = 0$$

Geometry defines the conic as an ellipse because, from eqn [9]

$$B^2 - 4AC = \frac{4}{E_{0x}^2E_{0y}^2}(\cos^2\delta - 1) < 0$$

This ellipse is called the polarization ellipse. The orientation of the ellipse, with respect to the x-axis, is

$$\tan 2\theta = \frac{B}{A - C} = \frac{2E_{0x}E_{0y}\cos\delta}{E_{0x}^2 - E_{0y}^2} \quad [10]$$

The tip of the resultant electric field vector obtained from eqn [4] traces out the polarization ellipse in the plane normal to **k**, as predicted by eqn [9]. The ratio of the length of the minor to the major axis of the ellipse is equal to the ellipticity, φ, i.e., the amount of deviation of the ellipse from a circle

$$\tan\varphi = \pm\left(\frac{E_m}{E_M}\right) = \frac{E_{0x}\sin\phi_1 \sin\theta - E_{0y}\sin\phi_2\cos\theta}{E_{0x}\cos\phi_1\cos\theta + E_{0y}\cos\phi_2\sin\theta} \quad [11]$$

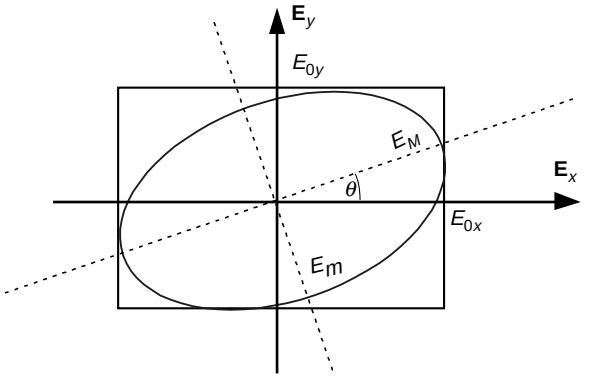

Figure 1 General form of the ellipse described by eqn [9]. Reproduced with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley and Sons.

In particle physics, the light would be said to have a negative helicity if it rotated in a clockwise direction. If we look at the source, the electric vector seems to follow the threads of a left-handed screw, agreeing with the nomenclature that left-handed quantities are negative. However, in optics the light that rotates clockwise, as we view it traveling toward us from the source, is said to be right-circularly polarized. The counterclockwise rotating light is left-circularly polarized. The association of right-circularly polarized light, with 'right-handedness' in optics, came about by looking at the path of the electric vector in space at a fixed time, then $\tan\psi = \tan(\phi - kz)$ (Figure 1).

Stokes Parameters

In the formalism associated with eqn [2], the expansion coefficients, a_i, can be used to form a 2–2 matrix which, in statistical mechanics, is called the density matrix and in optics, the coherency matrix (Table 1). The elements of the matrix are formed by the rule

$$\rho_{ij} = \mathbf{a}_i\mathbf{a}_j^* \quad [12]$$

The matrix is Hermitian, so that $\rho_{ij} = \rho_{ji}^*$. We will not develop the theory of polarization using the coherency matrix, but simply use the coherency matrix to justify the need for four independent measurements to characterize polarization. There is no unique set of measurements required by the theory, but normally measurements made are of the Stoke's parameters which are directly related to the parameters of the polarization ellipse of eqn [9].

The Stokes parameters of a light wave are measurable quantities, defined as:

$s_0 \Rightarrow$ Total flux density
$s_1 \Rightarrow$ Difference between flux density transmitted by a

Table 1 Typical Stokes vectors

Horizontal polarization	$\begin{bmatrix}1\\1\\0\\0\end{bmatrix}$	Vertical polarization	$\begin{bmatrix}1\\-1\\0\\0\end{bmatrix}$
$+45°$ polarization	$\begin{bmatrix}1\\0\\1\\0\end{bmatrix}$	$-45°$ polarization	$\begin{bmatrix}1\\0\\-1\\0\end{bmatrix}$
Right circular polarization	$\begin{bmatrix}1\\0\\0\\1\end{bmatrix}$	Left circular polarization	$\begin{bmatrix}1\\0\\0\\-1\end{bmatrix}$

linear polarizer oriented parallel to the x-axis and one oriented parallel to the y-axis. The x and y-axes are usually selected to be parallel to the horizontal and vertical directions in the laboratory.

$s_2 \Rightarrow$ Difference between flux density transmitted by a linear polarizer oriented at 45° to the x-axis and one oriented at 135°.

$s_3 \Rightarrow$ Difference between flux density transmitted by a right-circular polarizer and a left-circular polarizer.

If the Stokes parameters are to characterize the polarization of a wave, they must be related to the parameters of the polarization ellipse. It is therefore important to establish that the Stokes parameters are variables of the polarization ellipse (eqn [9]).

In its current form, eqn [9] contains no measurable quantities and thus must be modified if it is to be associated with the Stokes parameters. The time average of the Poynting vector is the quantity observed when measurements are made of light waves. We must, therefore, find the time average of eqn [9] if we wish to relate its parameters to observable quantities.

The time average eqn [9] can now be written as

$$\frac{\langle E_x^2\rangle}{E_{0x}^2} + \frac{\langle E_y^2\rangle}{E_{0y}^2} - 2\frac{\langle E_x E_y\rangle}{E_{0x}E_{0y}}\cos\delta = \sin^2\delta \qquad [13]$$

where time average is denoted by $\langle\ \rangle$

$$\langle E_x^2\rangle = \frac{1}{T}\int_{t_0}^{t_0+T} E_{0x}^2[\cos(\omega t - kz)\cos\phi_1 - \sin(\omega t - kz)\sin\phi_1]^2 dt \qquad [14]$$

With the time averages, eqn [13] can be written as

$$(E_{0x}^2 + E_{0y}^2)^2 - (E_{0x}^2 - E_{0y}^2)^2 - (2E_{0x}E_{0y}\cos\delta)^2 = (2E_{0x}E_{0y}\sin\delta)^2 \qquad [15]$$

Each term in this equation can be identified with a Stokes parameter:

$$\begin{aligned} s_0 &= \langle E_{0x}^2\rangle + \langle E_{0y}^2\rangle \qquad s_1 = \langle E_{0x}^2\rangle - \langle E_{0y}^2\rangle \\ s_2 &= \langle 2E_{0x}E_{0y}\cos\delta\rangle \quad s_3 = \langle 2E_{0x}E_{0y}\sin\delta\rangle \end{aligned} \qquad [16]$$

Equation [15] can now be written as

$$s_0^2 - s_1^2 - s_2^2 = s_3^2 \qquad [17]$$

For a polarized wave, only three of the Stokes parameters are independent. This agrees with the requirement placed upon elements of the Hermitian, coherency matrix, introduced above.

With this demonstration of the connection between the Stokes parameters and the polarization ellipse, the Stokes parameters can be written in terms of the parameters of the polarization ellipse.

$$\begin{aligned} s_1 &= s_0\cos 2\varphi\cos 2\theta \\ s_2 &= s_0\cos 2\varphi\sin 2\theta \\ s_3 &= s_0\sin 2\varphi \end{aligned} \qquad [18]$$

Mueller Calculus

Mueller pointed out that the Stokes parameters can be thought of as elements of a column matrix or a 4-vector (Table 2)

$$\mathcal{S} = \begin{pmatrix} s_0 \\ s_1 \\ s_2 \\ s_3 \end{pmatrix} \qquad [19]$$

Each element of the Stokes vector represents a measurable intensity. The vector can represent not only polarized 1ight, but unpolarized or partially polarized light.

In 1929, Soleillet discovered that an optical device performed a linear transformation on the input wave and, in 1942, Perrin put this fact into a matrix formalism involving the Stokes vectors:

$$\mathcal{S}_1 = \mathcal{M}\cdot\mathcal{S}_0 \qquad [20]$$

Mueller used experimentally derived 4×4 matrices, the $\mathcal{M}$ in eqn [20], to describe the effect of an optical device on a light wave's polarization. The $\mathcal{S}$'s in eqn [20] are column matrices whose elements

Table 2 Mueller matrices for polarizers

Linear	Horizontal	$\frac{1}{2}\begin{bmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$
	Vertical	$\frac{1}{2}\begin{bmatrix} 1 & -1 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$
	$+45°$	$\frac{1}{2}\begin{bmatrix} 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$
	$-45°$	$\frac{1}{2}\begin{bmatrix} 1 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$
Circular	Right	$\frac{1}{2}\begin{bmatrix} 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 \end{bmatrix}$
	Left	$\frac{1}{2}\begin{bmatrix} 1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & 1 \end{bmatrix}$

Table 3 Mueller matrices for retarders

Retarder	*Transmission axis*	*Mueller matrix*
Quarter-wave plate	Horizontal	$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -1 & 0 \end{bmatrix}$
	Vertical	$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{bmatrix}$
	$+45°$	$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix}$
	$-45°$	$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 \end{bmatrix}$
Half-wave plate	0° or 90°	$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{bmatrix}$
	$\pm 45°$	$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \end{bmatrix}$

are the Stokes parameters (eqn [16]). The matrices are based upon an assumed linear relationship between the incident and transmitted beams (Table 3).

The analysis of the effect of a number of polarizers and retarders is made easier by the use of the Mueller–Stokes matrix calculus, coupled with the use of the Stokes vectors. To determine the Mueller matrices, one must measure the effect a device has on unpolarized, horizontally polarized, linearly polarized at $+45°$, and right-circularly polarized light. It is then an algebraic exercise to generate the elements of the matrix. A few optical devices and their Mueller matrix are listed in Tables 2 and 3.

The Mueller matrix contains 16 parameters but there are only seven independent parameters. The matrix contains no information about absolute phase but it handles partially polarized and unpolarized light without modification (Table 4).

Jones Vector

There is one other representation of polarized light, complementary to the Stokes vector, developed by Clark Jones in 1941 and called the Jones vector. It is superior to the Stokes vector in that it handles light of a known phase and amplitude with a reduced number of parameters. However, it is inferior to the Stokes vector in that, unlike the Stokes representation, which is experimentally determined, the Jones representation cannot handle unpolarized or partially polarized light. The Jones vector is a theoretical

construct that can only describe light with a well-defined phase and frequency. The density matrix formalism can be used to correct the shortcomings of the Jones vector, but then the simplicity of the Jones representation is lost.

Assuming the coordinate system is such that the electromagnetic wave is propagating along the z-axis, it was shown earlier that any polarization could be decomposed into two orthogonal $\mathbf{E}$ vectors, i.e., parallel to the x and y directions. The Jones vector is defined as a two-row, column matrix consisting of the complex components in the x and y direction:

$$\mathbf{E} = \begin{bmatrix} E_{0x}\, e^{i(\omega t - \mathbf{k}\cdot\mathbf{r} + \phi_1)} \\ E_{0y}\, e^{i(\omega t - \mathbf{k}\cdot\mathbf{r} + \phi_2)} \end{bmatrix} \qquad [21]$$

Table 4 Jones vectors

Horizontal polarization	$\begin{bmatrix} 1 \\ 0 \end{bmatrix}$	Vertical polarization	$\begin{bmatrix} 0 \\ 1 \end{bmatrix}$
$+45°$ polarization	$\frac{1}{\sqrt{2}}\begin{bmatrix} 1 \\ 1 \end{bmatrix}$	$-45°$ polarization	$\frac{1}{\sqrt{2}}\begin{bmatrix} 1 \\ -1 \end{bmatrix}$
Right circular polarization	$\frac{1}{\sqrt{2}}\begin{bmatrix} 1 \\ i \end{bmatrix}$	Left circular polarization	$\frac{1}{\sqrt{2}}\begin{bmatrix} 1 \\ -i \end{bmatrix}$

If absolute phase is not an issue, then we may normalize the vector by dividing by that number (real or complex) that simplifies the components but keeps the sum of the square of the components equal to one. For example, assume that $E_{0x} = E_{0y}$, then

$$\mathbf{E} = E_{0x}\, e^{i(\omega t - \mathbf{k}\cdot\mathbf{r} + \phi_1)} \begin{bmatrix} 1 \\ e^{i\delta} \end{bmatrix} \qquad [22]$$

The normalized vector would be the terms contained within the bracket, each divided by $\frac{1}{\sqrt{2}}$.

The general form of the Jones vector is

$$\mathbf{E} = \begin{bmatrix} \mathbf{A} \\ \mathbf{B} \end{bmatrix} \qquad \mathbf{E}^* = [\mathbf{A}^*\mathbf{B}^*] \qquad [23]$$

Some examples of Jones vectors are shown in Table 4.

Jones Calculus

The Jones calculus is complementary to the Mueller calculus and operates on the Jones vector, (eqn [23]), similar to the way the Mueller matrix operates on the Stokes vector (Table 5).

The Jones matrix contains eight independent parameters with no redundancy, making it simpler than the Mueller calculus. However, the Jones calculus only applies to polarized light. The Jones calculus can be extended, using the density matrix formalism to allow manipulation of unpolarized

Table 5 Jones matrices for retarders

Retarder	*Transmission axis*	*Jones matrix*
	Horizontal	$\begin{bmatrix} e^{i\pi/4} & 0 \\ 0 & e^{-i\pi/4} \end{bmatrix}$
	Vertical	$\begin{bmatrix} e^{-i\pi/4} & 0 \\ 0 & e^{i\pi/4} \end{bmatrix}$
	$+45°$	$\frac{1}{2}\begin{bmatrix} 1 & i \\ i & 1 \end{bmatrix}$
Quarter-wave plate	$-45°$	$\frac{1}{2}\begin{bmatrix} 1 & -i \\ -i & 1 \end{bmatrix}$
Half-wave plate	$0°$ or $90°$	$\begin{bmatrix} 1 & 0 \\ 1 & -1 \end{bmatrix}$
	$\pm 45°$	$\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$

Table 6 Jones matrices for polarizers

Polarizer	*Transmission axis*	*Jones matrix*
Linear	Horizontal	$\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}$
	Vertical	$\begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}$
	$+45°$	$\frac{1}{2}\begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$
	$-45°$	$\frac{1}{2}\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}$
Circular	Right	$\frac{1}{2}\begin{bmatrix} 1 & -i \\ i & 1 \end{bmatrix}$
	Left	$\frac{1}{2}\begin{bmatrix} 1 & i \\ -i & 1 \end{bmatrix}$

light, but with a loss of simplicity. The matrix equation for Jones calculus is

$$\mathbf{E}_{\text{out}} = \mathcal{W}\mathbf{E}_{\text{in}} \qquad [24]$$

A few optical devices and their Jones matrices, $\mathcal{W}$, are listed in Tables 5 and 6.

For every matrix in Jones calculus, there is a matrix in Mueller calculus, but the converse is not true. For example, it is possible to construct a depolarizer, by using a thick piece of opal glass in the visible or by using gold covered sandpaper in the infrared. Such a device can be described in Mueller calculus, but there is no matrix for such a device in Jones calculus (Tables 5 and 6).

Quantum Theory of the Electromagnetic Field

The quantization of the free electromagnetic field is explained by analogy with the quantization of a collection of harmonic oscillators.

Brief History

The first step in the formulation of the quantum theory of the electromagnetic field (EMF) was the 'quantum hypothesis' put forward in 1900 by Planck. According to this hypothesis the exchange of energy between the EMF and the cavity walls occurs in portions $h\nu$, where h – the quantum of action – is a new fundamental constant (the Planck constant) and ν is the frequency of the material oscillator in the wall. With the help of this hypothesis Planck explained the spectrum of the electromagnetic radiation in thermodynamic equilibrium with the cavity walls. The second step was made in 1905 by Einstein, who postulated that the quantum hypothesis of Planck should be applied directly to the EMF. The assumption that the energy of the electromagnetic radiation is carried by light quanta (named photons by Lewis in 1926), each of energy $h\nu$, enabled Einstein to explain the puzzling properties of the photoelectric effect, namely, the gross disparity between the tiny classical energy flux delivered to an electron and the amount of energy needed to eject the photo-electron from the metal. After the formulation of quantum mechanics, it became possible to complete the quantum theory of the EMF (Dirac 1927) by applying the general rules of quantization to the classical Maxwell theory. However, this theory ran into difficulties when it was applied to the interaction of the EMF with charged matter.

The lightest carriers of the electric charge are the electrons and their dynamics determines to a very large extent the electromagnetic properties of ordinary matter. The main principles of quantum electrodynamics (QED) – the theory unifying the quantum theory of the EMF and the relativistic theory of electrons (Dirac 1928) – have been set forth by Heisenberg and Pauli already in 1929 but the proper tool (renormalization theory) to perform highly accurate calculations was developed by Feynman and Schwinger in 1949. In 1967 QED was unified by Weinberg and Salam with the theory of weak interactions. Later, after the unification with the theory of strong interactions, QED became part of the so called 'standard model' – the present day theory of elementary ingredients of matter: quarks, leptons, gluons, intermediate bosons, and photons. Therefore, the modern quantum theory of the EMF is not a self-contained theory but part of a much more encompassing theory. Often it requires some input from a more general theory or from phenomenology. However, the quantum theory of the EMF with only a very

crude description of its coupling to the rest of the world (for example, in the form of boundary conditions or constitutive relations) is still not only a good starting point to a more elaborate theory but also a source of important information about the behavior of photons under realistic conditions. The main reason why treating photons as free particles gives a reasonably good approximation is the smallness of the Sommerfeld fine structure constant $\alpha = e^2/4\pi\varepsilon_0\hbar c \approx 1/137$ that measures the strength of the electromagnetic interactions between photons and charged particles.

Electromagnetic Field as a Collection of Harmonic Oscillators

In order to apply the same quantization procedure as in quantum mechanics, it is useful to formulate classical electrodynamics in a way that exhibits its close relationship with mechanical systems. Many properties of the electromagnetic field may be described and understood in the simplest case of the free field. Therefore, in this article we restrict ourselves to the quantum description of the free EMF.

It was discovered by Rayleigh and Jeans that the electromagnetic field may be viewed as a collection of harmonic oscillators. This analogy enables one to apply well-established methods of simple quantum mechanics to describe the much more complicated problem of the quantum field. The dynamics of a single, one-dimensional harmonic oscillator is governed by the Hamiltonian:

$$H(p,q) = \frac{p^2}{2m} + \frac{m\omega^2 q^2}{2}$$

The equations of motion for the position and momentum of a harmonic oscillator have the same form in classical and in quantum theory:

$$\frac{\mathrm{d}q(t)}{\mathrm{d}t} = \frac{p(t)}{m}, \qquad \frac{\mathrm{d}p(t)}{\mathrm{d}t} = -m\omega^2 q(t)$$

The solutions of these equations describe harmonic oscillations with the frequency ω

$$q(t) = q_0\cos(\omega t) + (p_0/m\omega)\sin(\omega t)$$

$$p(t) = -m\omega q_0\sin(\omega t) + p_0\cos(\omega t)$$

A complete description of a multidimensional harmonic oscillator may be obtained in terms of normal modes. The transformation to normal modes leads to a decomposition of the Hamiltonian of the system into the sum, one term for each mode,

$$H = \sum_k \left(\frac{p_k^2}{2m} + \frac{m\omega_k^2 q_k^2}{2}\right)$$

Thus, each mode may be viewed as a separate system – a one-dimensional harmonic oscillator with characteristic frequency ω_k – noninteracting with the remaining oscillators.

The Maxwell equations for the free EMF read

$$\partial_t \mathbf{B}(\mathbf{r},t) = -\nabla\times\mathbf{D}(\mathbf{r},t)/\varepsilon,\ \nabla\cdot\mathbf{B}(\mathbf{r},t) = 0$$

$$\partial_t \mathbf{D}(\mathbf{r},t) = \nabla\times\mathbf{B}(\mathbf{r},t)/\mu,\ \nabla\cdot\mathbf{D}(\mathbf{r},t) = 0$$

In the vacuum, the constants ε and μ must be replaced by ε_0 and μ_0. The Maxwell equations lead to the wave equation for the vector $\mathbf{D}(\mathbf{r},t)$

$$\left(\frac{1}{c^2}\partial_t^2 - \Delta\right)\mathbf{D}(\mathbf{r},t) = 0$$

and to the same equation for the vector $\mathbf{B}(\mathbf{r},t)$. The solution of this equation obtained by the separation of variables has the form

$$\mathbf{D}(\mathbf{r},t) = a(t)\mathbf{u}(\mathbf{r})$$

where $a(t)$ satisfies the harmonic equation

$$\frac{\mathrm{d}^2}{\mathrm{d}t^2}a(t) + \omega^2 a(t) = 0$$

and $\mathbf{u}(\mathbf{r})$ satisfies the Helmholtz equation

$$(\Delta + (\omega/c)^2)\mathbf{u}(\mathbf{r}) = 0$$

Without going into mathematical details we shall assume that there exist a complete set of vector functions $\mathbf{u}_k(\mathbf{r})$, called the mode functions, satisfying the Helmholtz equations

$$(\Delta + (\omega_k/c)^2)\mathbf{u}_k(\mathbf{r}) = 0$$

the divergence condition $\nabla\cdot\mathbf{u}_k(\mathbf{r}) = 0$, the orthonormality conditions

$$\int \mathrm{d}^3 r\,\mathbf{u}_k(\mathbf{r})\cdot\mathbf{u}_l(\mathbf{r}) = \delta_{kl}$$

and also the appropriate boundary conditions. In most cases of physical interest such a set does exist.

Given the set of mode functions $\mathbf{u}_k(\mathbf{r})$ one may expand the vector field $\mathbf{D}(\mathbf{r},t)$ at each t into the series

$$\mathbf{D}(\mathbf{r},t) = -\sum_k p_k(t)\mathbf{u}_k(\mathbf{r})$$

The minus sign is purely conventional; it makes the correspondence with the harmonic oscillator a closer one. The same procedure may be repeated for the

vector $\mathbf{B}$ with a different complete set of functions $\mathbf{v}_k(\mathbf{r})$, resulting in the decomposition

$$\mathbf{B}(\mathbf{r},t)=\sum_k q_k(t)\mathbf{v}_k(\mathbf{r})$$

The Maxwell equations are satisfied if the coefficient functions $p_k(t)$ and $q_k(t)$ obey the equations of motion for harmonic oscillators

$$\frac{\mathrm{d}q_k(t)}{\mathrm{d}t}=\frac{p_k(t)}{\varepsilon},\quad \frac{\mathrm{d}p_k(t)}{\mathrm{d}t}=-\varepsilon\omega^2 q_k(t) \qquad [1]$$

and the functions $\mathbf{v}_k(\mathbf{r})$ are related to $\mathbf{u}_k(\mathbf{r})$ by the formulas

$$\mathbf{v}_k(\mathbf{r})=\nabla\times\mathbf{u}_k(\mathbf{r})$$

Note that the electric constant ε plays the same role as the mass for a mechanical oscillator. The calculation of the Hamiltonian, the total field energy,

$$H=\int \mathrm{d}^3r\left(\frac{\mathbf{D}^2}{2\varepsilon}+\frac{\mathbf{B}^2}{2\mu}\right)$$

completes the reduction of the electromagnetic field to a collection of harmonic oscillators. Upon inserting the representation of the field vectors in terms of the complete set of functions $\mathbf{u}_k(\mathbf{r})$ into the integral, one obtains the following formula

$$H=\sum_k\left(\frac{p_k^2}{2\varepsilon}+\frac{\varepsilon\omega_k^2q_k^2}{2}\right)$$

which differs from its mechanical counterpart only by the replacement $m\to\varepsilon$. The time dependence has been omitted here because the Hamiltonian is a constant of motion.

Mode Functions

The simplest example of a complete set of mode functions is that obtained for a rectangular metallic cavity. In this case the functions $\mathbf{u}_k(\mathbf{r})$ may be expressed in terms of trigonometric functions. In order to write them down, it is convenient to replace one label k by a collection of three numbers $\boldsymbol{\kappa}=\{\kappa_x,\kappa_y,\kappa_z\}$ and an additional index λ taking on the values 1 and 2. The mode functions $\mathbf{u}_{\boldsymbol{\kappa}\lambda}(\mathbf{r})$ satisfying the proper boundary conditions have the following components

$$\mathbf{u}_{\boldsymbol{\kappa}\lambda}(\mathbf{r})=N\begin{pmatrix}a_x^{(\lambda)}\cos(\kappa_x x)\sin(\kappa_y y)\sin(\kappa_z z)\\ a_y^{(\lambda)}\sin(\kappa_x x)\cos(\kappa_y y)\sin(\kappa_z z)\\ a_z^{(\lambda)}\sin(\kappa_x x)\sin(\kappa_y y)\cos(\kappa_z z)\end{pmatrix}$$

where $N=\sqrt{8/(L_xL_yL_z)}$, the coefficients $\{\kappa_x,\kappa_y,\kappa_z\}$ have the form $\{\kappa_x,\kappa_y,\kappa_z\}=\{\pi n_x/L_x,\pi n_y/L_y,\pi n_z/L_z\}$ and all the n's are natural numbers. The components of both vectors $\mathbf{a}^{(\lambda)}$ are subjected to the conditions $\boldsymbol{\kappa}\cdot\mathbf{a}^{(\lambda)}=0$ (vanishing divergence) and orthonormalization $\mathbf{a}^{(\lambda)}\cdot\mathbf{a}^{(\lambda')}=\delta_{\lambda\lambda'}$. For each set $\{\kappa_x,\kappa_y,\kappa_z\}$ one must choose two independent solutions of these conditions $\mathbf{a}^{(1)}$ and $\mathbf{a}^{(2)}$. These two vectors define two states of linear polarization. The mode function $\mathbf{u}_{\boldsymbol{\kappa}\lambda}(\mathbf{r})$ is a solution of the Helmholtz equation for the value of ω/c equal to the length of the vector $\boldsymbol{\kappa}$. The expansion of the EMF vectors into the mode functions in a rectangular cavity has the form

$$\mathbf{D}(\mathbf{r},t)=-\sum_{\boldsymbol{\kappa}\lambda}p_{\boldsymbol{\kappa}\lambda}(t)\mathbf{u}_{\boldsymbol{\kappa}\lambda}(\mathbf{r})$$

$$\mathbf{B}(\mathbf{r},t)=\sum_{\boldsymbol{\kappa}\lambda}q_{\boldsymbol{\kappa}\lambda}(t)\nabla\times\mathbf{u}_{\boldsymbol{\kappa}\lambda}(\mathbf{r})$$

where the summation extends over all allowed values of $\boldsymbol{\kappa}$ and two values of λ. One may explicitly write down mode functions also for a cylindrical and for a spherical cavity. They involve Bessel functions and are obtained by solving the Helmholtz equation in cylindrical and spherical coordinates, respectively.

One often uses another set of mode functions that does not correspond to any physical boundary conditions but is very helpful in the theoretical analysis. It is obtained by imposing the so-called periodic boundary conditions that were first introduced by Born in the study of crystal lattices. The periodic boundary conditions require that the electromagnetic field is periodic in space; it does not change when the coordinates are displaced by the 'period of the lattice' in all three directions. Assuming, for simplicity, that this period is the same, equal to L, in all directions, one obtains the following conditions for the mode functions

$$\mathbf{u}_k(\mathbf{r})=\mathbf{u}_k(\mathbf{r}+L\mathbf{i}_x)=\mathbf{u}_k(\mathbf{r}+L\mathbf{i}_y)=\mathbf{u}_k(\mathbf{r}+L\mathbf{i}_z)$$

where $\mathbf{i}_i$ are the unit vectors in the directions of the coordinate axes. The complete set of solutions of the Helmholtz equation satisfying the periodic boundary conditions is labeled by the wavevector $\mathbf{k}=\{2\pi n_x/L,2\pi n_y/L,2\pi n_z/L\}$, where all the n's are arbitrary integers, and by the polarization index λ. The value of ω/c in the Helmholtz equation is equal in this case to the length of the vector k. Each member of the set $\mathbf{u}_{\mathbf{k}\lambda}$ has the form

$$\mathbf{u}_{\mathbf{k}\lambda}(\mathbf{r})=\frac{1}{\sqrt{V}}\mathbf{e}_{\mathbf{k}\lambda}\exp(\mathrm{i}\mathbf{k}\cdot\mathbf{r}) \qquad [2]$$

where $V = L^3$. The polarization vectors $\mathbf{e}_{\mathbf{k}\lambda}$ must be orthogonal to the wave vector $\mathbf{k}$. It is convenient to impose the unitary orthonormality conditions $\mathbf{e}_{\mathbf{k}\lambda} \cdot \mathbf{e}^*_{\mathbf{k}\lambda'} = \delta_{\lambda\lambda'}$ and also to assume that $\mathbf{e}^*_{\mathbf{k}\lambda} = \mathbf{e}_{-\mathbf{k}\lambda}$. The expansion of the EMF vectors into the mode functions obeying the periodic boundary conditions has the form

$$\mathbf{D}(\mathbf{r},t) = -\frac{1}{\sqrt{V}} \sum_{\mathbf{k}\lambda} P_{\mathbf{k}\lambda}(t)\mathbf{e}_{\mathbf{k}\lambda} e^{i\mathbf{k}\cdot\mathbf{r}}$$

$$\mathbf{B}(\mathbf{r},t) = \frac{1}{\sqrt{V}} \sum_{\mathbf{k}\lambda} Q_{\mathbf{k}\lambda}(t) i\mathbf{k} \times \mathbf{e}_{\mathbf{k}\lambda} e^{i\mathbf{k}\cdot\mathbf{r}} \qquad [3]$$

where the sum extends again over all allowed values of the vectors $\mathbf{k}$ and over two values of λ. The expansion coefficients $P_{\mathbf{k}\lambda}$ and $Q_{\mathbf{k}\lambda}$ are now complex. In order to guarantee that the field vectors are real, they must obey the conditions

$$P^*_{\mathbf{k}\lambda} = P_{-\mathbf{k}\lambda},\ Q^*_{\mathbf{k}\lambda} = Q_{-\mathbf{k}\lambda}$$

These conditions are satisfied if $P_{\mathbf{k}\lambda}$ and $Q_{\mathbf{k}\lambda}$ are parametrized by the real (but otherwise arbitrary) variables $p_{\mathbf{k}\lambda}$ and $q_{\mathbf{k}\lambda}$

$$P_{\mathbf{k}\lambda} = \frac{p_{\mathbf{k}\lambda} + p_{-\mathbf{k}\lambda}}{2} + \frac{\varepsilon\omega_{\mathbf{k}}(q_{\mathbf{k}\lambda} - q_{-\mathbf{k}\lambda})}{2i}$$

$$Q_{\mathbf{k}\lambda} = \frac{q_{\mathbf{k}\lambda} + q_{-\mathbf{k}\lambda}}{2} + \frac{i(p_{\mathbf{k}\lambda} - p_{-\mathbf{k}\lambda})}{2\varepsilon\omega_{\mathbf{k}}}$$

The energy of the EMF splits again into a sum of independent contributions from all the modes

$$H = \sum_{\mathbf{k}\lambda} \omega_{\mathbf{k}} \left(\frac{p_{\mathbf{k}\lambda} p_{\mathbf{k}\lambda}}{2\varepsilon\omega_{\mathbf{k}}} + \frac{\varepsilon\omega_{\mathbf{k}} q_{\mathbf{k}\lambda} q_{\mathbf{k}\lambda}}{2} \right)$$

An important property of the periodic mode functions [2] is that not only the Hamiltonian but also the total momentum of the field splits into a sum of independent contributions. The total momentum $\mathbf{P}$ of the EMF is

$$\mathbf{P} = \int d^3r\, \mathbf{D} \times \mathbf{B}$$

Upon substituting into this expression the expansions [3] of the field vectors, one obtains, with the use of the orthonormality conditions,

$$\mathbf{P} = \sum_{\mathbf{k}\lambda} \mathbf{k} \left(\frac{p_{\mathbf{k}\lambda} p_{\mathbf{k}\lambda}}{2\varepsilon\omega_{\mathbf{k}}} + \frac{\varepsilon\omega_{\mathbf{k}} q_{\mathbf{k}\lambda} q_{\mathbf{k}\lambda}}{2} \right)$$

Canonical Quantization

The canonical quantization in quantum mechanics consists in replacing the c-numbers representing the classical canonical variables q_k and p_k by the operators $\hat{q}_k$ and $\hat{p}_k$. These operators are assumed to obey the canonical commutation relations

$$[\hat{q}_k, \hat{p}_l] = i\hbar\delta_{kl} \qquad [4]$$

The canonical quantization of the EMF may proceed along the same lines as in quantum mechanics. All the variables q_k and p_k appearing in the decomposition into normal modes are replaced by the operators. When this is done, the field vectors $\mathbf{B}$ and $\mathbf{D}$ become the field operators $\hat{\mathbf{B}}$ and $\hat{\mathbf{D}}$ and the expression for the energy of the field becomes the Hamiltonian operator $\hat{H}$

$$\hat{H} = \sum_k \frac{\hat{p}_k^2}{2\varepsilon} + \frac{\varepsilon\omega_k^2 \hat{q}_k^2}{2}$$

The only difference between quantum mechanics and quantum field theory is that in the second case the number of canonical variables is infinite but this may cause complications only when one wants to give the quantum theory of the EMF a firm mathematical foundation. In physical applications one may think of the number of field oscillators as being very large but finite.

Time evolution of a quantum system is described by associating the time dependence either with the operators (the Heisenberg picture) or with the state vectors (the Schrödinger picture). In both pictures the time dependence is governed by the system Hamiltonian. In the Heisenberg picture the time dependence of the operators is given by the commutators with $\hat{H}$

$$\frac{d\hat{q}_k(t)}{dt} = \frac{1}{i\hbar}[\hat{q}_k(t), \hat{H}] = \frac{\hat{p}_k(t)}{\varepsilon}$$

$$\frac{d\hat{p}_k(t)}{dt} = \frac{1}{i\hbar}[\hat{p}_k(t), \hat{H}] = -\varepsilon\omega_k^2 \hat{q}_k(t)$$

These equations have the same form as in the classical theory (cf. eqn [1]). Therefore, in the Heisenberg picture the field operators will also obey the same equations as in the classical theory – the Maxwell equations:

$$\partial_t \hat{\mathbf{B}}(\mathbf{r},t) = -\nabla \times \hat{\mathbf{D}}(\mathbf{r},t)/\varepsilon,\ \ \nabla \cdot \hat{\mathbf{B}}(\mathbf{r},t) = 0$$

$$\partial_t \hat{\mathbf{D}}(\mathbf{r},t) = \nabla \times \hat{\mathbf{B}}(\mathbf{r},t)/\mu,\ \ \nabla \cdot \hat{\mathbf{D}}(\mathbf{r},t) = 0$$

Of course, the average values of the field operators evaluated in both pictures are the same and for every quantum state they obey the classical Maxwell equations.

The commutation relations [4] for the canonical operators and the completeness of the mode functions imply the following equal-time commutation relations for the field operators

$$[\hat{B}_i(\mathbf{r},t),\hat{D}_j(\mathbf{r}',t)] = \mathrm{i}\hbar\sum_k \varepsilon_{ijk}\partial_k\delta^{(3)}(\mathbf{r}-\mathbf{r}')$$

These relations do not depend on the choice of the mode functions. They summarize in a universal manner the canonical properties of the electromagnetic field operators.

Annihilation and Creation Operators

The canonical variables q_k and p_k are convenient for bringing home the analogy between mechanical oscillators and wave fields. However, there exists also a complementary, corpuscular aspect of the quantum theory of the EMF and that is most easily expressed in terms of photons. The best way to describe photons in quantum field theory is in terms of annihilation and creation operators. These operators were introduced by Schrödinger in the context of the quantum-mechanical harmonic oscillator but they have become really indispensable in quantum field theory. Formally, the annihilation $\hat{a}_k$ and the creation $\hat{a}_k^\dagger$ operators are defined as the following complex combinations of canonical operators

$$\begin{aligned}\hat{a}_k &= \sqrt{\frac{\varepsilon\omega}{2\hbar}}\left(\hat{q}_k + \mathrm{i}\frac{\hat{p}_k}{\varepsilon\omega}\right)\\ \hat{a}_k^\dagger &= \sqrt{\frac{\varepsilon\omega}{2\hbar}}\left(\hat{q}_k - \mathrm{i}\frac{\hat{p}_k}{\varepsilon\omega}\right)\end{aligned} \qquad [5]$$

Annihilation and creation operators are dimensionless, one is the Hermitian adjoint of the other, and they obey very simple commutation relations:

$$[\hat{a}_k,\hat{a}_l^\dagger] = \delta_{kl} \qquad [6]$$

The Hamiltonian expressed in terms of annihilation and creation operators reads

$$\hat{H} = \sum_k \hbar\omega_k\hat{a}_k^\dagger\hat{a}_k + \frac{1}{2}\sum_k \hbar\omega_k \qquad [7]$$

This Hamiltonian determines the following time dependence of the annihilation and creation operators

$$\hat{a}_k(t) = \hat{a}_k\exp(-\mathrm{i}\omega_k t),\ \hat{a}_k^\dagger(t) = \hat{a}_k^\dagger\exp(\mathrm{i}\omega_k t)$$

The field operators expressed in terms of annihilation and creation operators corresponding to the periodic boundary conditions are

$$\hat{\mathbf{D}}(\mathbf{r},t) = \mathrm{i}\sum_{\mathbf{k}\lambda}\sqrt{\frac{\hbar\varepsilon\omega_\mathbf{k}}{2V}}\hat{a}_{\mathbf{k}\lambda}\mathbf{e}_{\mathbf{k}\lambda}\mathrm{e}^{-\mathrm{i}\omega_\mathbf{k}t+\mathrm{i}\mathbf{k}\cdot\mathbf{r}} + \mathrm{H.c.}$$

$$\hat{\mathbf{B}}(\mathbf{r},t) = \mathrm{i}\sum_{\mathbf{k}\lambda}\sqrt{\frac{\hbar}{2V\varepsilon\omega_\mathbf{k}}}\hat{a}_{\mathbf{k}\lambda}\mathbf{k}\times\mathbf{e}_{\mathbf{k}\lambda}\mathrm{e}^{-\mathrm{i}\omega_\mathbf{k}t+\mathrm{i}\mathbf{k}\cdot\mathbf{r}} + \mathrm{H.c.}$$

where H.c. stands for the Hermitian conjugate of the first term. In the limiting case for infinite empty space, when $V\to\infty$, the Fourier sum becomes the Fourier integral:

$$\begin{aligned}\hat{\mathbf{D}}(\mathbf{r},t) = \mathrm{i}\sum_\lambda\int \mathrm{d}^3k\sqrt{\frac{\hbar\varepsilon\omega_\mathbf{k}}{2(2\pi)^3}}(&\hat{a}_\lambda(\mathbf{k})\mathbf{e}_{\mathbf{k}\lambda}\mathrm{e}^{-\mathrm{i}\omega_\mathbf{k}t+\mathrm{i}\mathbf{k}\cdot\mathbf{r}}\\ &-\hat{a}_\lambda^\dagger(\mathbf{k})\mathbf{e}_{\mathbf{k}\lambda}^*\mathrm{e}^{\mathrm{i}\omega_\mathbf{k}t-\mathrm{i}\mathbf{k}\cdot\mathbf{r}})\end{aligned}$$

$$\begin{aligned}\hat{\mathbf{B}}(\mathbf{r},t) = \mathrm{i}\sum_\lambda\int \mathrm{d}^3k\sqrt{\frac{\hbar}{2\varepsilon\omega_\mathbf{k}(2\pi)^3}}(&\hat{a}_\lambda(\mathbf{k})\mathbf{k}\mathbf{e}_{\mathbf{k}\lambda}\mathrm{e}^{-\mathrm{i}\omega_\mathbf{k}t+\mathrm{i}\mathbf{k}\cdot\mathbf{r}}\\ &-\hat{a}_\lambda^\dagger(\mathbf{k})\mathbf{k}\times\mathbf{e}_{\mathbf{k}\lambda}^*\mathrm{e}^{\mathrm{i}\omega_\mathbf{k}t-\mathrm{i}\mathbf{k}\cdot\mathbf{r}})\end{aligned}$$

In this case, the commutation relations involve the (three-dimensional) Dirac delta function

$$[\hat{a}_\lambda(\mathbf{k}),\hat{a}_{\lambda'}^\dagger(\mathbf{k}')] = \delta_{\lambda\lambda'}\delta^{(3)}(\mathbf{k}-\mathbf{k}') \qquad [8]$$

The field operators may also be expressed in terms of the vector potential operator $\hat{\mathbf{A}}(\mathbf{r},t)$

$$\hat{\mathbf{D}}(\mathbf{r},t) = -\varepsilon\partial_t\hat{\mathbf{A}}(\mathbf{r},t),\ \hat{\mathbf{B}}(\mathbf{r},t) = \nabla\times\hat{\mathbf{A}}(\mathbf{r},t)$$

$$\begin{aligned}\hat{\mathbf{A}}(\mathbf{r},t) = \sum_\lambda\int \mathrm{d}^3k\sqrt{\frac{\hbar}{2\varepsilon\omega_\mathbf{k}(2\pi)^3}}(&\hat{a}_\lambda(\mathbf{k})\mathbf{e}_{\mathbf{k}\lambda}\mathrm{e}^{-\mathrm{i}\omega_\mathbf{k}t+\mathrm{i}\mathbf{k}\cdot\mathbf{r}}\\ &+\hat{a}_\lambda^\dagger(\mathbf{k})\mathbf{e}_{\mathbf{k}\lambda}^*\mathrm{e}^{\mathrm{i}\omega_\mathbf{k}t-\mathrm{i}\mathbf{k}\cdot\mathbf{r}})\end{aligned}$$

The vector potential is needed for the description of the interaction with charged particles.

Space of Quantum States

The standard basis in the space of quantum states consists of the state vectors of stationary states – the eigenvectors of the Hamiltonian.

Vacuum State

The lowest energy state of the EMF – the ground state of the system – is often called the vacuum state. The state vector describing the vacuum state is denoted by $|0\rangle$. The vacuum state is the common ground state of all harmonic oscillators making up the EMF. Since the ground state of a single harmonic oscillator has the energy $\hbar\omega/2$, the energy of the ground state for an infinite number of oscillators is infinite (last term in eqn [7]). This infinity has no physical consequences because only the energy differences are observable. In the presence of obstacles (mirrors, resonators, beamsplitters, etc.), owing to the change in the mode structure, there will be a change in the energy of the new ground state relative to the energy in empty space. The energy differences between various ground states do have physical significance.

Fock Basis

It follows from the commutation relations [6] and from the form [7] of the Hamiltonian that the operator $\hat{a}_k$ decreases the energy of the EMF by the Planck quantum of energy $\hbar\omega_k$. Therefore, all operators $\hat{a}_k$ must annihilate the ground state vector, $\hat{a}_k|0\rangle = 0$, because there is no state with a lower energy. Each creation operator $\hat{a}_k^\dagger$ acting on any state vector adds one excitation with the energy $\hbar\omega_k$. These excitations of the electromagnetic field with characteristic energies $\hbar\omega_k$ are interpreted as photons. The state vectors of the form $\hat{a}_k^\dagger|0\rangle$ describe one-photon states, the state vectors of the form $\hat{a}_k^\dagger\hat{a}_l^\dagger|0\rangle$ describe two-photon states, etc. All the vectors generated from the vacuum state vector by acting with the creation operators form a basis, called the Fock basis. The general state vector of this basis is characterized by a sequence of natural numbers $\{n_1, n_2, \ldots\}$ and is generated from the vacuum state according to the formula

$$|n_1, n_2, \ldots\rangle = (n_1!n_2!\cdots)^{-1/2}(\hat{a}_1^\dagger)^{n_1}(\hat{a}_2^\dagger)^{n_2}\ldots|0\rangle \qquad [9]$$

where the prefactor is needed for normalization. The number n_k tells us how many photons of type k are present in this state. The spatial structure of a field excitation created by $\hat{a}_k^\dagger$ is described by the mode function $\mathbf{u}_k(\mathbf{r})$. Thus, this mode function plays the same role as the wavefunction $\psi(\mathbf{r})$ of a massive particle and the set of indices labeling the mode functions is the analog of quantum numbers for $\psi(\mathbf{r})$. In particular, for the mode function [2], the photons have a definite momentum $\hbar\mathbf{k}$. In a cylindrical waveguide the photons may have a definite momentum only along the axis of the cylinder. In a spherical cavity the photons may have the definite value of square of the total angular momentum and its projection on a given axis. The Fock states are highly nonclassical; all average values of the EMF in these states vanish.

All states of the EMF are either pure or mixed. Pure states are described by all linear superpositions of the basis states. In particular, by superposing photon states with a range of energies, one may form nonmonochromatic photon wavepackets. All superpositions are allowed since photons do not have any absolutely conserved quantum numbers (like, e.g., charge). Mixed states are described by the density operators. Among the mixed states the prominent role is played by the thermal state describing the EMF in equilibrium with a reservoir at temperature T.

Coherent States

The one-mode coherent states $|\alpha\rangle$ are obtained from the vacuum state by the action of the unitary displacement operator $\hat{D}(\alpha, \alpha^*)$

$$|\alpha\rangle = D(\alpha, \alpha^*)|0\rangle = \mathrm{e}^{\alpha\hat{a}^\dagger - \alpha^*\hat{a}}|0\rangle = \mathrm{e}^{-|\alpha|^2/2}\mathrm{e}^{\alpha\hat{a}^\dagger}|0\rangle$$

where $\hat{a}$ and $\hat{a}^\dagger$ are the annihilation and creation operators corresponding to a given mode. Coherent states are superpositions of an infinite number of Fock states. The multimode coherent state is generated by the product of displacement operators

$$|\alpha_1, \alpha_2, \ldots\rangle = \mathrm{e}^{\sum_k (\alpha_k\hat{a}_k^\dagger - \alpha_k^*\hat{a}_k)}|0\rangle$$

In reality, the coherent states are generated by the action of an external (strong) time-dependent electric current. In that case the coefficients α_k are the projections of the current on the mode functions. The average values of the field operators $\langle\hat{B}_i(\mathbf{r}, t)\rangle$ and $\langle\hat{D}_j(\mathbf{r}, t)\rangle$ in coherent states are the solutions of the Maxwell equations in the presence of an external electric current.

Entangled States

The states of the EMF describing photons in different modes may exhibit correlations. The simplest such state is a two-photon state of the form $|\phi\rangle = 2^{-1/2}(\hat{a}_1^\dagger\hat{a}_2^\dagger + \hat{a}_3^\dagger\hat{a}_4^\dagger)|0\rangle$. In this case, when one photon is found, say, in the state 1, the other will be found with the probability 1 in the state 2. The states that exhibit correlations between photons belonging to different modes are called the entangled states.

Correlations occur also in the classical theory, but only for statistical mixtures when there is a loss of information. In quantum theory the correlations may arise even without a loss of information, i.e., for pure states. A striking feature of entangled states is that the decomposition of such a state into a sum of Fock states is not unique. For example, the state vector $|\phi\rangle$ may also be written in the form $|\phi\rangle = 2^{-1/2}(\hat{a}^\dagger_{1'}\hat{a}^\dagger_{2'} + \hat{a}^\dagger_{3'}\hat{a}^\dagger_{4'})|0\rangle$, where $\hat{a}^\dagger_{1'} = 2^{-1/2}(\hat{a}^\dagger_1 - \hat{a}^\dagger_3)$, $\hat{a}^\dagger_{2'} = 2^{-1/2}(\hat{a}^\dagger_2 - \hat{a}^\dagger_4)$, $\hat{a}^\dagger_{3'} = 2^{-1/2}(\hat{a}^\dagger_1 + \hat{a}^\dagger_3)$, $\hat{a}^\dagger_{4'} = 2^{-1/2}(\hat{a}^\dagger_2 + \hat{a}^\dagger_4)$. Entangled states play a crucial role in quantum information theory, especially in quantum cryptography.

Quantum Fluctuations and the Uncertainty Relations

It follows from the basic principles of quantum theory that there are no states of the system for which both canonical variables q and p have sharply defined values. The limits on the quantum fluctuations (variances) of these values are determined by the uncertainty relation. The most stringent form of this relation obtained from the commutation relations [4] (for a single mode) reads

$$(\Delta q)^2(\Delta p)^2 \geq \frac{\hbar^2}{4} + \frac{\langle \delta\hat{q}\delta\hat{p} + \delta\hat{p}\delta\hat{q}\rangle^2}{4} \qquad [10]$$

where $\delta\hat{q} = \hat{q} - \langle\hat{q}\rangle$, $\delta\hat{p} = \hat{p} - \langle\hat{p}\rangle$, $(\Delta q)^2 = \langle(\delta\hat{q})^2\rangle$, and $(\Delta p)^2 = \langle(\delta\hat{p})^2\rangle$. The states for which this inequality is saturated play a distinguished role in quantum theory. Since the uncertainty relation expresses the limitations on the quantum fluctuations of q and p, the best one can do in approaching the classical regime is to achieve equality in the uncertainty relation. That is why the quantum states that saturate [10] are viewed as the counterparts of the classical states. In the quantum theory of the EMF, the uncertainty relations express the complementarity between the magnetic and electric fields. The better one knows the magnetic field, the more uncertain is the electric field, and vice versa. However, the projections of the field operators $\hat{\mathbf{B}}$ and $\hat{\mathbf{D}}$ on the same direction commute (cf. eqn [5]). Therefore, there are no limitations on the magnetic and electric field values in a given direction and only the values in different directions are subjected to the quantum uncertainty relation.

In the vacuum state the variances of q and p for each mode are

$$(\Delta q)^2 = \frac{\hbar}{2\varepsilon\omega}, (\Delta p)^2 = \frac{\hbar\varepsilon\omega}{2} \qquad [11]$$

and they saturate the uncertainty relation. These fluctuations are called the shot noise. Very often one uses dimensionless quadrature operators $\hat{X}_1 = \hat{q}\sqrt{2\varepsilon\omega/\hbar}$ and $\hat{X}_2 = \hat{p}\sqrt{2/\varepsilon\omega\hbar}$, whose fluctuations in the vacuum state are equal to 1. All coherent states have the same fluctuations as the vacuum state. They may be viewed in the phase space as the vacuum state displaced from the origin (corresponding to the vacuum state) by the mean values of q and p.

Coherent states are not the only states that saturate the uncertainty relations. The other states with this property are called the squeezed states. The fluctuations of X_1 and X_2 for squeezed states are different from 1 but their product is still equal to 1, $(\Delta X_1)^2(\Delta X_2)^2 = 1$.

Fock states have well-defined energies and numbers of photons since they are the eigenstates of the Hamiltonian. However, the phases of the EMF are maximally uncertain; they are evenly spread over the whole range from 0 to 2π. That is why the average values of the field vectors vanish in all Fock states.

Modification of the Spontaneous Transition Rate in Confined Space

In order to understand the modification of the spontaneous emission rate in an external cavity-like structure, it must be remembered that in quantum electrodynamics this rate is proportional to the density of modes of the electromagnetic field, i.e., the vacuum field fluctuations above the atomic transition frequency ω_0. As a consequence the spontaneous emission rate is increased if the atom is surrounded by a cavity tuned to the transition frequency. Conversely, the decay rate decreases when the cavity is mistuned. This fact was already recognized in the pioneering days of nuclear magnetic resonance by Purcell.

The spontaneous decay rate of the atom in the cavity, γ_c, will then be enhanced in relation to that in free space, γ_f, by a factor given by the ratio of the corresponding mode densities

$$\frac{\gamma_c}{\gamma_f} = \frac{\rho_c(\omega_0)}{\rho_f(\omega_0)} = \frac{2\pi Q}{V_c \omega_0^3} = \frac{Q\lambda_0^3}{4\pi^2 V_c}$$

where V_c is the volume of the cavity and Q is the quality factor of the cavity which expresses the 'sharpness' of the mode. For low-order cavities $V_c \approx \lambda_0^3$ this means that the spontaneous emission rate is increased by roughly a factor of Q. As mentioned already, when the cavity is detuned, the decay rate will decrease. In this case the atom cannot emit a photon, since the cavity is not able to accept it, and the energy will stay with the atom, i.e., its decay is inhibited.

To change the decay rate of an atom, in principle no resonator has to be present; any conducting surface near the radiator affects the mode density and, therefore, the spontaneous radiation rate. Parallel conducting planes can alter the emission rate somewhat but can only reduce the rate by a factor of 2 owing to the existence of modes, independent of the plate separation with an electric field perpendicular to the planes.

In order to demonstrate experimentally the modification of the spontaneous decay rate, it is not necessary to go to single-atom densities. The experiments where the spontaneous emission is inhibited can also be performed with large atom numbers. However, in the opposite case, when the increase of the spontaneous rate is observed, a large number of excited atoms may disturb the experiment by induced transitions. The first experimental work on inhibited spontaneous emission was done by Drexhage, Kuhn and Schäfer in 1974. The fluorescence of a thin dye film near a mirror was investigated. A reduction of the fluorescence decay by up to 25% was observed. Later experiments with microcavities filled with dye solutions were performed by de Martini *et al*. These experiments demonstrated that thresholdless lasing is possible in such systems.

Inhibited spontaneous emission was observed by Gabrielse and Dehmelt. In these neat experiments with a single electron stored in a Penning trap they observed that cyclotron orbits show lifetimes which are up to 10 times longer than that calculated for free space. The electrodes of the trap form a cavity which decouples the cyclotron motion from the vacuum field leading to the longer lifetime.

A new stage in experiments on cavity QED was reached when it was recognized that highly excited alkaline atoms are very suitable for these experiments. The main quantum numbers are in the range $n = 20-60$. Those so-called Rydberg atoms couple very strongly to the radiation field as will be discussed later. The transitions to neighboring states are in the microwave region. The cavities can therefore be built as low-order cavities with dimensions on the order of the wavelength of the transitions being in the mm or cm regions. The spontaneous rate of these transitions in free space is small owing to the low value of their transition frequency, therefore an enhancement is possible. Experiments with Rydberg atoms on the inhibition of spontaneous emission have been performed by Kleppner and coworkers and by Haroche and coworkers. In the latter experiment a 3.4 μm transition of the Cs atom was suppressed.

The first observation of enhanced atomic spontaneous emission in a resonant cavity was published by Haroche *et al*. This experiment was performed with Rydberg atoms of Na excited in the 23s state in a niobium superconducting cavity resonant at 340 GHz. Cavity tuning-dependent shortening of the lifetime was observed. The cooling of the cavity had the advantage of totally suppressing the black-body field. The latter effect is completely absent if optical transitions are observed, however, in this case it is more difficult to obtain low-order cavities. The first experiments on optical transitions were performed by Feld and collaborators. They succeeded

in demonstrating the enhancement of spontaneous transitions even in higher-order optical cavities.

In modern semiconductor devices both electronic and optical properties can be tailored with a high degree of precision. Therefore, electron–hole systems producing recombination radiation analogous to radiating atoms can be localized in cavity-like structures, e.g., in quantum wells. Thus optical microcavities of half or full wavelength size are obtained. Both suppression and enhancement of spontaneous emission in semiconductor microcavities were demonstrated in experiments by Yamamoto and collaborators. Yablonovitch *et al.* proposed the use of photonic band gap structures in semiconductors. In those systems spontaneous emission is forbidden in certain frequency regions owing to the special material properties.

Energy Shift in Confined Space

In the previous section we focused on changes of radiation rates of atoms near conducting walls or in cavity-like structures. Next we will discuss the more subtle phenomenon of energy shifts. While radiation rates are modified by the influence of the vacuum field on the real emission of photons the energy shifts are caused by the modification of a virtual photon interaction.

Resonant and nonresonant phenomena have to be distinguished. The resonant self-energy shift of a decaying atomic dipole in the vicinity of a conducting wall can be determined from the average polarization energy produced by the image dipole field. For distances comparable to the wavelength the near-field condition is satisfied, resulting in the z^{-3} dependence of the static dipole–dipole interaction characteristic for the van der Waals energy; under far-field conditions the distance dependence is given by z^{-1}. The polarization of the atom by the nonresonant parts of the broadband electromagnetic field causes energy shifts, of which the Lamb shift is the most prominent. In the sense of the nonrelativistic treatment by Bethe the major contribution of that shift can be described as being a result of the emission and reabsorption of virtual photons. It is plausible that just as the real emission of a photon is modified in confined space, so also is the virtual process. The latter 'real' radiation energy shift is thus a consequence of vacuum fluctuations only. It is identical with the energy shift predicted by Casimir and Polder and is analogous to the better-known result of Casimir on the force between two plane neutral conducting plates.

The question of modification of atomic energies in confined space has recently found considerable interest and many calculations of the phenomenon have been performed. Direct application to the energy shift of Rydberg atoms, which are of special interest for experimental studies, was performed by Barton in 1987. He calculated the direct electrostatic interaction with a conducting wall and the radiation induced (retarded) effects. The result is that in the case of two parallel plates the electrostatic effect is dominant when the distance L between the conducting plates is small, $L < n^3 a_0/\alpha$ (n is the principal quantum number of the Rydberg atom, a_0 the Bohr radius, and α the fine-structure constant), and the radiative effect plays the major role when large distances are used, $L > n^3 a_0 \alpha$.

Experiments to measure the van der Waals force of conducting planes have been performed by Hinds and coworkers. They could clearly demonstrate the z^{-3} dependence of the van der Waals force. The retarded effects were not detectable at large distances but at small distances from the wall a deviation from the z^{-3} dependence was found which was attributed to the retarded QED potential.

The energy shift of rubidium Rydberg atoms in confined space has been measured by Marrocco *et al.* in an experiment with extreme high-resolution using the Ramsey experiment two-field method. The atoms are excited in s-Rydberg states ($n \approx 30$) by two-photon transitions using the light of an ultrastable dye laser, the linewidth of which was less than 10 Hz. The laser intensity was enhanced in a folded cavity locked to the laser frequency. Both interaction zones necessary for the Ramsey method were enclosed in this cavity. Between the two interaction regions the atoms pass through a pair of conducting plates, the distance between which can be changed. The shift of the Ramsey interference was measured as a function of the plate distance. Using the Ramsey method has the advantage that the shift can be determined without a direct probing of the atoms in the space between the plates. A level shift on the order of about 150 Hz could be measured, in very good agreement with theory.

Maser Operation

If the rate of atoms crossing a cavity exceeds the cavity damping rate ω/Q, the photon released by each atom is stored long enough to interact with the next atom. Here ω stands for the cavity frequency and Q for the quality factor of the cavity. The atom–field coupling becomes stronger and stronger as the field builds up and evolves to a steady state. Using Rydberg atoms with a large field–atom coupling constant leads to a new kind of maser which operates with exceedingly small numbers of atoms and photons.

The photons corresponding to transitions between neighboring Rydberg atoms are in the microwave region at about 20–100 GHz. Atomic fluxes as small as a few atoms per second have generated maser action, as could be demonstrated by Walther *et al*. of the University of Munich in 1985 using a superconducting cavity. For such a low flux there is never more than a single atom in the resonator – in fact, most of the time the cavity is empty of atoms. It should also be mentioned that in the case of such a setup a single resonant photon is sufficient to saturate the maser transition.

The scheme for this one-atom maser or micromaser is shown in **Figure 1**. The setup represents the simplest system in radiation–atom interaction: a single atom is interacting with a single mode of the radiation field. This device was used to verify the complex dynamics of a single atom in a quantized field predicted by the Jaynes–Cummings model. All of the features are explicitly a consequence of the quantum nature of the electromagnetic field: the statistical and discrete nature of the photon field leads to new characteristic dynamics such as collapse and revivals in the exchange of a photon between the atom and the cavity mode. The frequency of this exchange is usually called the Rabi flopping frequency. The field in the cavity is measured through the number of atoms in the lower state of the maser transition. Due to the strong coupling between the atom and maser field both are entangled. The strong coupling can also be used to entangle subsequent atoms.

The steady-state field of the micromaser shows sub-Poisson statistics. This is in contrast to regular masers and lasers where coherent fields (Poisson statistics) are observed. The reason for nonclassical radiation being produced is that a fixed interaction time of the atoms is chosen, leading to careful control of the atom–field interaction dynamics.

Under steady-state conditions, the photon statistics $P(n)$ of the field of the micromaser are essentially determined by the pump parameter $\Theta = N_{\mathrm{ex}}^{1/2}\Omega t_{\mathrm{int}}$, denoting the angular rotation of the pseudospin vector of the interacting atom. Here, N_{ex} is the average number of atoms that enter the cavity during the decay time of the cavity τ_{cav}, Ω the vacuum Rabi flopping frequency, and t_{int} is the atom–cavity interaction time. The normalized photon number of the maser $\langle \nu \rangle = \langle n \rangle / N_{\mathrm{ex}}$ shows the following generic behavior

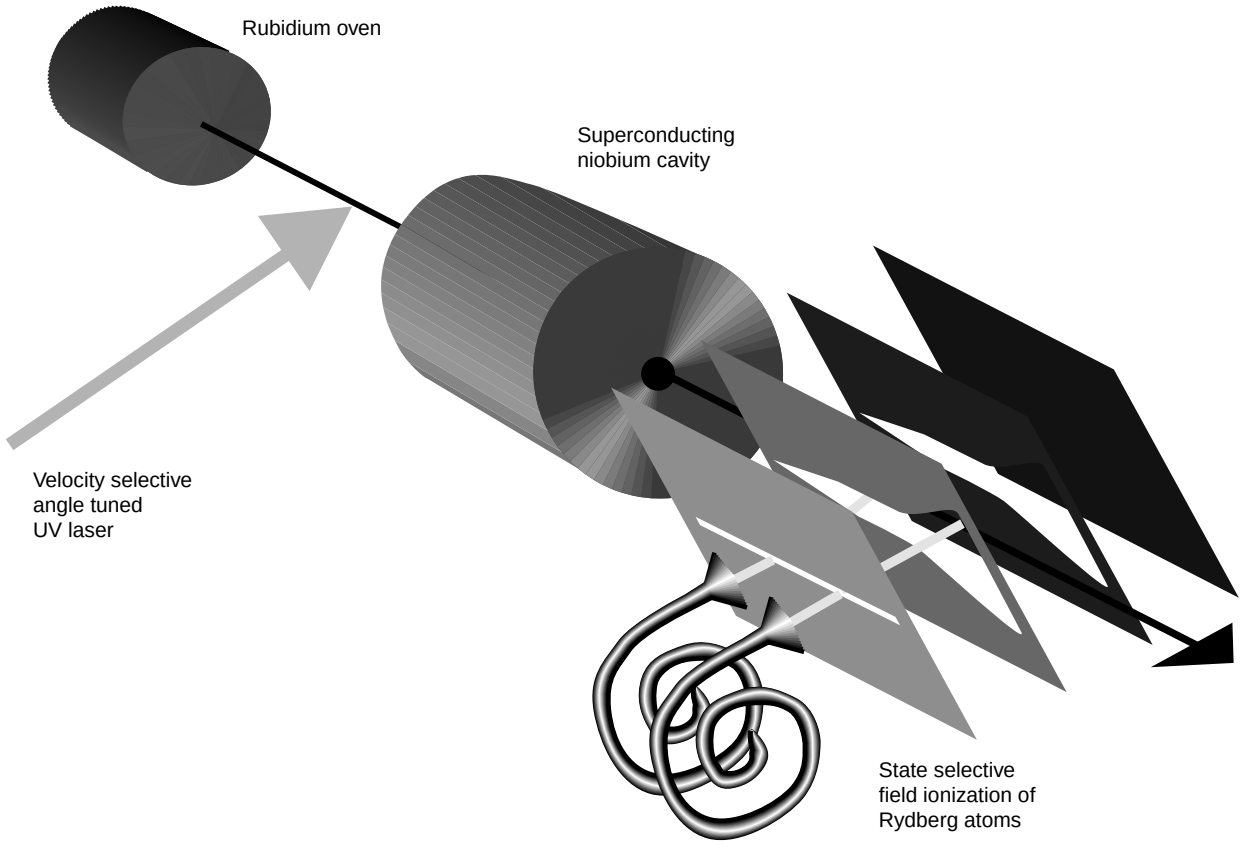

Figure 1 Micromaser setup of rubidium Rydberg atoms in the 63p state. The velocity of the atoms is controlled by exciting a velocity subgroup of atoms in the atomic beam. The atoms in the upper and lower maser levels are selectively detected by field ionization. The number of photons deposited in the cavity is determined through the number of atoms in the lower state (61d).

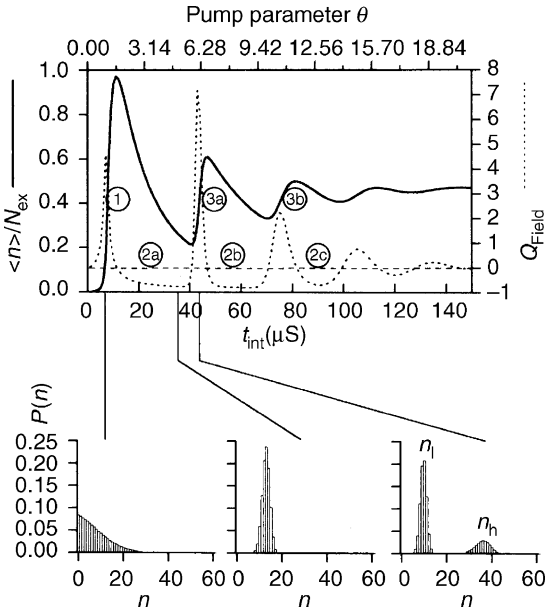

Figure 2 One-atom maser or micromaser characteristics. The upper part of the figure shows the average photon number versus interaction time (solid curve) and the photon number fluctuations represented by the Q-factor (dotted line). Both curves are determined by the photon exchange dynamics between atom and field. The pump parameter gives the angular rotation of the pseudospin vector of the interacting atom (e.g., 2π corresponds to a full rotation, i.e., the atom is again in the upper level). In the lower part of the figure the steady-state photon number distribution $P(n)$ is shown for three values of t_{int}. The distribution on the left side corresponds to the maser threshold, that on the right gives an example of the double-peaked distribution associated with the quantum jump behavior. In this situation, the atom is back in the excited state and can again emit, leading to a higher steady-state photon number n_{h}. With increasing t_{int} this part will grow and n_{l} will decrease and disappear. A new jump occurs in the region 3b.

(see Figure 2). It suddenly increases at the maser threshold value $\Theta = 1$ and reaches a maximum for $\Theta \approx 2$ (denoted by 1 in Figure 2). The behavior at threshold corresponds to the characteristics of a continuous phase transition. As Θ increases further, the normalized averaged photon number $\langle \nu \rangle / N_{\text{ex}}$ decreases to a minimum slightly below $\Theta \approx 2\pi$, and then abruptly increases to a second maximum (3a in Figure 2). This general type of behavior recurs roughly at integer multiples of 2π, but becomes less pronounced with increasing Θ. The reason for the periodic maxima of the average photon number is that for integer multiples of $\Theta = 2\pi$ the pump atoms perform an integer number of full Rabi flopping cycles, and start to flip over at a slightly larger value of Θ, thus leading to enhanced photon emission. The periodic maxima for $\Theta = 2\pi, 4\pi$, and so on may be interpreted as first-order phase transitions.

The photon statistics of the maser radiation is usually characterized by the Q-parameter introduced by Mandel:

$$Q_{\text{field}} = \left\{ \left(\langle n^2 \rangle - \langle n \rangle^2 \right) / \langle n \rangle \right\} - 1$$

It can be seen that $Q_{\text{field}} = 0$ corresponds to a Poissonian photon distribution. Q_{field} for the micromaser is plotted as a dotted line in Figure 2. The value drops below zero in the region 2a, 2b, etc. This shows the highly sub-Poissonian character of the one-atom-maser field being present over a large range of parameters.

The reason for the sub-Poissonian atomic statistics is the following. A changing flux of atoms changes the Rabi frequency via the stored photon number in the cavity. Adjusting the interaction time allows the phase of the Rabi nutation cycle to be chosen such that the probability of the atoms leaving the cavity in the upper maser level increases when the flux, and hence the photon number in the cavity, is raised. This leads to sub-Poissonian atomic statistics since the number of atoms in the lower state decreases with increasing flux and photon number in the cavity. This feedback mechanism can be neatly demonstrated when the anticorrelation of atoms leaving the cavity in the lower state is investigated. Measurements of this anticorrelation phenomenon could be made.

The fact that anticorrelation is observed shows that the atoms in the lower state are more equally spaced than expected for a Poissonian distribution of the atoms in the beam. This means, for example, that when two atoms enter the cavity close to each other, the second one performs a transition to the lower state with reduced probability.

The interaction with the cavity field thus leads to an atomic beam with atoms in the lower maser level showing number fluctuations which are up to 40% below those of a Poissonian distribution found in usual atomic beams. This is interesting because atoms in the lower level have emitted a photon to compensate for cavity losses inevitably present. Although this process is induced by dissipation giving rise to fluctuations, the atoms still obey sub-Poissonian statistics.

Generation of Number States (Fock States) of the Radiation Field

When the micromaser is operated at low temperatures, a very interesting feature is observed in the inversion of the population of the two maser levels called trapping states. They are a steady-state feature of the maser field; they occur in the micromaser as a direct consequence of field quantization in a cavity. At low cavity temperatures the number of black-body

photons, n_{th}, in the cavity mode is reduced and trapping states begin to appear; at higher temperatures they are washed out by the thermal photons. The trapping states show up when the atom–field coupling Ω and the interaction time t_{int} are chosen such that in a cavity field with n_q photons the atoms undergo an integer number k of Rabi cycles. This is summarized by the condition

$$\Omega t_{int}\sqrt{n_q + 1} = k\pi \qquad [1]$$

for the trapping state, denoted by (n_q, k). When eqn [1] is satisfied, the cavity photon number is left unchanged after interaction of an atom and hence the photon number is 'trapped'. This will occur regardless of the atomic pump rate N_{ex}. The trapping state is therefore characterized by the upper-bound photon number n_q and the number of integer multiples of full Rabi cycles k. In this situation the field is stabilized. Whenever a photon disappears, e.g., due to dissipation, the next incoming atom experiences a changed Rabi nutation frequency and emits a photon with high probability. At the trapping condition a quantum nondemolition situation is present. Through the dynamics of the Rabi nutation the field is measured, without any net change of the field.

The build-up of the cavity field can be seen in Figure 3, where the emerging atom inversion is plotted against the interaction time and pump rate. At low atomic pump rates (low N_{ex}) the maser field cannot build up and the maser exhibits Rabi oscillations due to the interaction with the vacuum field. At the positions of the trapping states, the field

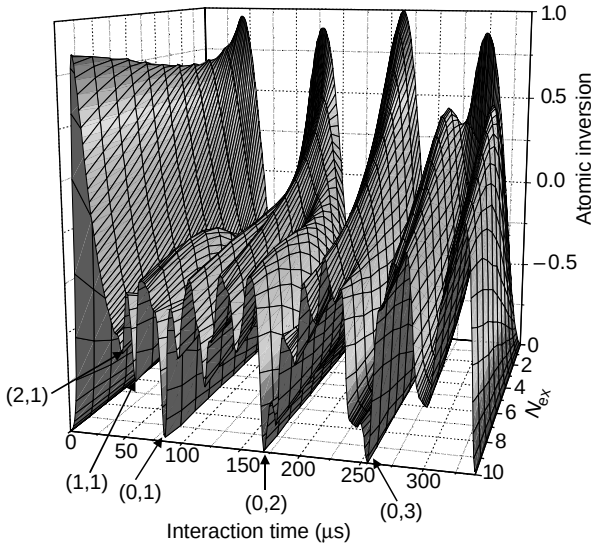

Figure 3 Behavior of the micromaser at low temperature showing the trapping states, manifested as valleys along the N_{ex} axis. For the designation of the trapping states see text.

increases until it reaches the trapping-state condition. This is manifested as a reduced emission probability and hence as a dip in the atomic inversion. Once in a trapping state, the maser will remain there regardless of the pump rate.

Under ideal conditions the micromaser field in a trapping state is a Fock state, but when the micromaser is operated in a continuous wave mode, the field state is very fragile and highly sensitive to external influences and experimental parameters. However, in contrast to continuous-wave operation, in pulsed operation trapping states are more stable and more practical and can be used over a much broader parameter range than in continuous-wave operation.

To demonstrate the principle, Figure 4 shows a simulation of a sequence of 20 pulses of the pumping atoms in which an average of seven excited atoms per pulse are present. Under the trapping condition only a single emission event occurs, producing a single lower state atom which leaves a single photon in the cavity. Since the atom–cavity system is in the trapping condition, the emission probability is reduced to zero and the photon number is stabilized. Consequently, excited state atoms following the emitting atom stay in the upper maser level. The variation of the time when an emission event occurs during the atom pulses in Figure 4 is due to the Poissonian spacing of upper-state atoms entering the cavity and the stochasticity of the quantum process.

The lower part of Figure 4 shows the photon number distribution resulting from this process. It was demonstrated experimentally by Brattke *et al.* that a single photon number state could be generated with a success rate of 85%. By improving the experimental parameters one can expect to prepare single-photon Fock states in 98% of the pulses by this method.

Other Cavity Experiments

Besides the micromaser, there are also other experiments using Rydberg atoms in cavities and the strong interaction of these atoms with cavities which lead to interesting applications. One example is an experiment by S. Haroche, J. M. Raimond *et al.*, who succeeded in realizing a Schrödinger cat state in a cavity. Studies on the decoherence of this state could be conducted. The experiments are quite important in exploring the boundaries between the quantum and classical worlds. Another example is the quantum nondemolition detection of a single photon in a cavity by S. Haroche employing the dispersion level shift of probing atoms.

There is an interesting equivalence between an atom interacting with a single-mode field and a quantum

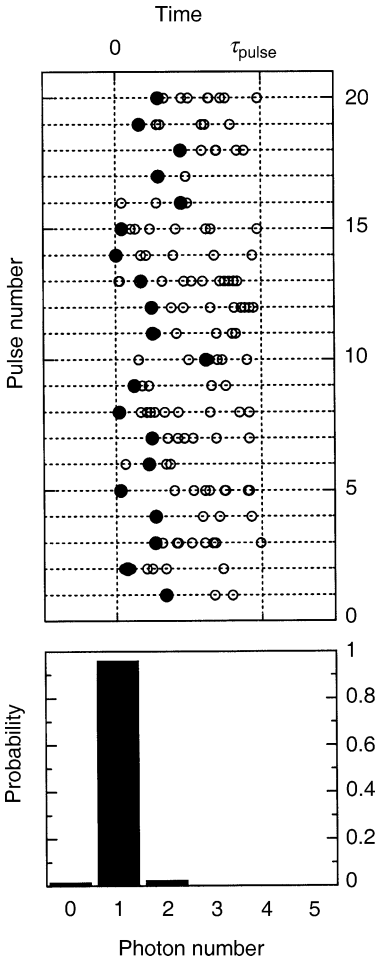

Figure 4 A simulation of a subset of 20 subsequent atom bunches generated by pulsed laser excitation with the associated probability distribution for photons in the cavity or lower-state atom production (filled circles represent lower-state atoms and open circles represent excited-state atoms). The start and end of each pulse is indicated by the vertical dotted lines marked 0 and τ_{pulse}, respectively. For details, see Battke S, Varcoe BTH and Walther H (2001) Generation of photon number states on demand via cavity, quantum electrodynamics. *Physical Review Letters* 86: 3534–3537.

particle in a harmonic potential, as was first pointed out by D. F. Walls and H. Risken; this connection results from the fact that the radiation field is quantized on the basis of the harmonic oscillator. The Jaynes–Cummings dynamics can therefore also be observed with trapped ions, as recently demonstrated in a series of beautiful experiments by D. Wineland *et al*. They also produced a Schrödinger cat state by preparing a single trapped ion in a superposition of two spatially separated wavepackets which are formed by coupling different vibrational quantum states in the excitation process.

Besides the experiments in the microwave region, a single-atom laser emitting in the visible range has also been realized by M. Feld *et al*. Furthermore, cavity quantum electrodynamic effects have been studied in the optical spectral region by J. L. Kimble *et al*.

Today's technology in microfabrication of semiconductor diode structures allows the realization of low-order cavity structures for diode lasers. In these systems the spontaneous emission is controlled in the same way as in the micromaser. Since spontaneous decay is a source of strong losses, control of this phenomenon leads to highly efficient laser systems. Quantum control of spontaneous decay thus has important consequences for technical applications. This topic will be briefly described in the next section.

Microlasers

The simplest approach to fabricating an optical microcavity is to shrink the spacing between the mirrors of a Fabry–Perot resonator to λ/n (where n stands for the refractive index) while reducing the lateral dimensions to a range of the same order of magnitude. This structure provides a single dominant longitudinal field mode that radiates into a narrow range of angles around the cavity axis.

The first optical microcavity experiments used dye molecules between high-reflectivity dielectric mirrors in the Fabry–Perot configuration. Because spontaneous emission is a major source of energy loss, speed limitations, and noise in lasers, the capability to control spontaneous emission is expected to improve laser performance. If the fraction of spontaneous emission coupled into the lasing mode is made close to one, the 'thresholdless' laser is obtained, in which the light output increases almost linearly with the pump power instead of exhibiting a sharp turn-on at the pump threshold.

Semiconductor microcavities provide high-Q Fabry–Perot cavities for both basic studies and potential applications. Molecular beam epitaxy or organometallic chemical vapor deposition techniques are used to deposit high-reflectivity mirrors consisting of alternating quarter-wavelength layers of lattice-matched semiconductors. For example, 15–20 pairs of quarter-wave layers of $Al_{0.2}Ga_{0.8}As$ and AlAs result in a reflectivity greater than 99% and Q values greater than 500. The optically active layer in such a microcavity is typically a GaAs quantum well located at the midplane of the cavity, where the field strength is maximum.

Since the microcavities have an extremely low threshold, their efficiency will also be high. Low-cost, high-density light source arrays and photonic circuits are made possible by the small size and low power consumption of such resonators. It will be possible to produce entire wafers containing millions

of microlasers with a multipole arrangement instead of having to cleave each individual semiconductor laser as at present. This improvement will lead to higher yields and lower cost per element. Another advantage of surface-emitting microcavity sources is the efficient optical coupling of their stable symmetric mode patterns into optical fibers or waveguides. These lasers are thus certain to spark a revolution in optical communication in the future.

Conclusion

This article reviewed experiments in cavity quantum electrodynamics. The experiments shed new light on our understanding of the radiation interaction of atoms. The achievable strong coupling between atoms and radiation leads to the possibility to generate entanglement between the generated radiation field and the atoms, presenting a basis for interesting applications in connection with, e.g., quantum computing and quantum information processing. Furthermore Fock states of the radiation field can be generated. The control of spontaneous decay finally leads to interesting new laser systems offering high efficiency.

Introduction

According to classical electromagnetism, propagating light fields obey Maxwell's equations under which electric and magnetic fields exchange their strength in an oscillatory manner. If a propagating field is followed at a single reference point, it is convenient to represent the electric field as a complex number $|E(t)|\exp(-i\omega t)$ where $|E(t)|$ is the magnitude of the field and the phase of the field $\exp(-i\omega t)$ oscillates in time t with the optical frequency ω. Figure 1 illustrates how the classical field is determined by one single point in the complex plane; consequently, the phase and amplitude of the field are known exactly. According to quantum mechanics, this simple picture has to be altered because the Heisenberg uncertainty relation states that complementary quantities like phase and amplitude cannot be determined precisely at the same time. As a result, the real and imaginary parts of the field can be determined only with accuracy $\Delta\mathrm{Re}[E]$ and $\Delta\mathrm{Im}[E]$, respectively, and the Heisenberg uncertainty principle determines the best possible accuracy $\Delta\mathrm{Re}[E]\,\Delta\mathrm{Im}[E] \geq 1$. To incorporate the fundamental inaccuracy, the electric field has to be defined by using complex-valued distributions or equivalently wavefunctions as shown in Figure 1. This quantization procedure leads to the Schrödinger equation for light analogous to that for particles. The field called quantum optics investigates the quantum electrodynamics (QED) features of light.

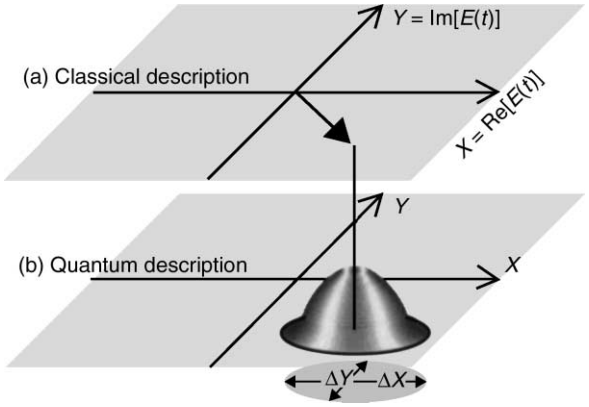

Figure 1 (a) The classically described light field $E(t)$ is a single point in the complex XY-plane; the corresponding (X, Y) vector has a definite phase and angle. (b) Quantum mechanically described light is a distribution with fluctuations ΔX and ΔY described by the shaded circle.

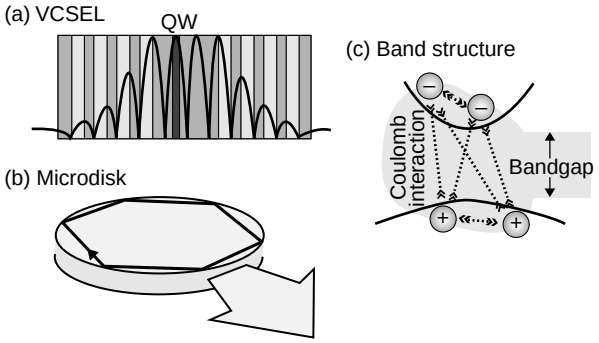

Figure 2 (a) A typical vertical-cavity surface-emitting laser (VCSEL) structure; a stack of quarter-wavelength layers with different refractive index provides a mirror such that the light intensity (solid line) is strongly confined inside the cavity. A quantum well (QW) is positioned at the field maximum. (b) In a microdisk laser, light encounters ideal total reflection when the edge of the disk is reached. The so-called whispering gallery mode emits (leaks) light from the edge. (c) A schematic illustration of semiconductor band structure, bandgap, and Coulomb interaction for an electro–hole system.

In general, light does not propagate freely in space, but it interacts strongly with the surrounding matter. For example, light can be absorbed, and its energy can be converted into excitation of the matter. As a result, the light may be slowed down, reflected, scattered, or diffracted. In order to explain the implications of the light–matter interaction in detail, one obviously has to apply a quantum mechanical description also for the matter. This approach determines the so-called eigenstates of the matter, so that the matter may occupy only certain discrete states with discrete energies. The Rydberg series of a hydrogen atom is a typical example. Similar discrete energy levels are also found for the quantized light; these levels are often referred to as photons which heuristically describe the particle properties of the light. The lowest-order light–matter interaction consists of processes where one photon is absorbed (emitted) while the matter is simultaneously excited (de-excited) from one eigenstate to another. This generic type of interaction leads to a microscopic description of the optical effects mentioned above. The magnitude of these effects depends on the strength of the interaction. By implementing different cavity configurations, the reflected light can be forced to travel across the same matter many times. As a result, the light–matter interaction is enhanced by a factor proportional to the multiple passes of the light. Thus, a cavity can be efficiently used to amplify optical phenomena. Figure 2 shows cavity configurations commonly used for semiconductors. Semiconductor cavity QED investigates quantum optical effects in semiconductor systems by enhancing them with cavity mirrors. In general, quantum optical features produce classically unexpected effects which typically stem from: (a) the discrete nature of eigenstates of light and matter; (b) the superposition principle of quantum mechanics; and (c) the Heisenberg uncertainty principle. In this article, we review both theoretical and experimental advances made so far to predict, observe, and control quantum optical effects in semiconductors with respect to effects (a)–(c).

During the last few decades, atomic quantum optics has already developed toward QED investigations, and semiconductor optics is developing rapidly into the same regime. Advanced atomic QED theories have successfully explained and guided intriguing experimental developments like laser cooling, atom condensation, and photon teleportation. However, the atomic approach can mostly be applied to describe dilute and only weakly interacting atomic gases since relatively simple models of few-level systems are used to describe the material. The elementary electronic excitations in semiconductors consist of electrons and holes (missing electrons) lifted into the conduction and valence bands, respectively. The corresponding eigenstates form continuous energy bands with the band-gap energy separation indicated in Figure 2. Since electrons and holes have opposite charges, they experience Coulomb attraction whereas bare electrons or holes repel each other. Under favorable conditions, the attractive Coulomb interaction prevails and atom-like bound electron–hole pairs (excitons) may be formed. However, since the Coulomb force has an infinite range and an electron–hole system is typically dense, excitons cannot be treated as weakly interacting quasiparticles. As a result, the atomic QED approaches cannot be used to describe quantum optics of semiconductors

in general. Thus, this article concentrates mostly on semiconductor QED theory which fully includes the interaction of charge carriers, i.e., electrons and holes, as well as quantum features of light.

The development work on quantum devices and processes is vital for advancements in several key technologies such as computers and telecommunications. The continuous decrease in component dimensions leads to a microscopic structure size (less than 1 μm); at the same time, increase in the device performance is accompanied by ultrafast operation time (faster than 1 ps). Due to these development trends, the properties of components and processes are becoming more and more quantum mechanical. Although the description of the quantum processes is complicated, the microscopic behavior offers entirely new operational functionality such as massively parallel quantum computers. These possibilities are based on the controlled manipulation of the quantum mechanical state of the light and matter. Due to rapid recent developments, optically coupled semiconductor devices have a great potential to become technologically successful and commercially viable quantum components.

Quantized States: Observation via Strong Light–Matter Interaction

In order to enhance the light–matter interaction, we choose a system where the semiconductor is placed inside a cavity in the position where the field intensity is maximum. For an empty cavity, the field intensity has a strong dependence upon frequency with a strong resonance at ω_R when the cavity length is an integer number of light wavelengths in the material. The width of the resonance is directly related to the quality of the cavity as determined by the number of back-and-forth reflections of light inside the cavity. If one chooses a vertical-cavity surface-emitting laser (VCSEL) structure, the most efficient coupling is obtained by placing a thin planar semiconductor structure at the field maximum as shown in Figure 2. If the semiconductor is planar and thin, the structure is called a quantum well because electrons and holes are confined in one direction in analogy to the standard particle-in-a-box problem of fundamental quantum mechanics. As a result, the energy levels of a quantum well are discrete in the confinement direction. If the structure is narrow enough, the system dynamics is confined to the lowest quantum-well level such that the carriers are quasi-two-dimensional due to the free in-plane motion. The optical response of such a system to a weak classical probe beam has been successfully analyzed with the so-called semiconductor Bloch equations. For the quantum-well system alone, the absorption spectrum may have a sharp resonance; this is often referred to as an excitonic resonance since it is located below the fundamental bandgap energy at a position corresponding to the exciton binding energy. Obviously, the light–matter coupling becomes large when the exciton and cavity resonances coincide. However, since these resonances are coupled, the optical response is altered; we observe a splitting into two absorption peaks instead of the original degenerate resonances. This phenomenon is commonly referred to as normal-mode coupling; in general, it is a quite common feature in quantum mechanics that degenerate states split due to an additional interaction. Figure 3 shows the first experimental observation of normal-mode coupling in semiconductors.

Since a semiconductor is a strongly interacting many-body system, several effects alter the specific character of an excitonic resonance when electrons and holes are excited. The attractive interaction between electrons and holes becomes weaker for

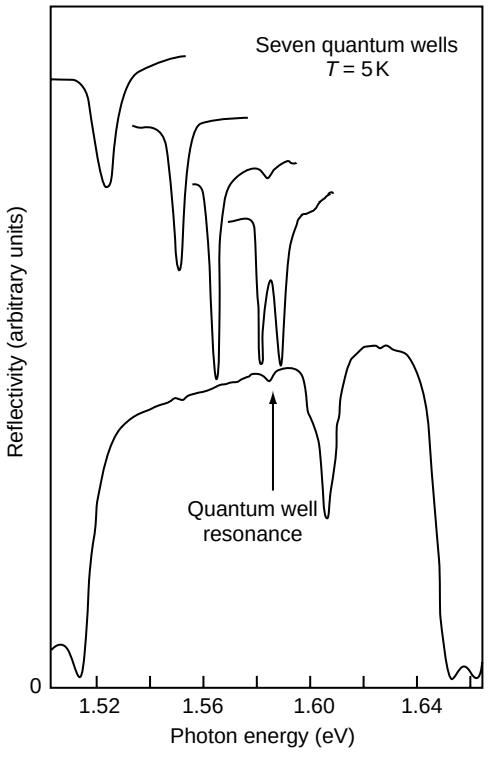

Figure 3 Probe reflectivity of a seven-quantum-well microcavity structure. The various curves correspond to the energy difference between exciton and cavity resonances. When these resonances become degenerate, the reflectivity shows two resonances corresponding to the normal-mode splitting. From Weisbuch C, Nishioka M, Ishikawa A and Arakawa Y (1992) Observation of the coupled exciton-photon mode splitting in a semiconductor quantum microcavity. *Physical Review Letters* 69: 3314. Copyright (2004) by the American Physical Society.

increased carrier density since the surrounding charges screen the bare Coulomb interaction. A particular exciton may also experience scattering from nearby electrons, holes, or other excitons via the Coulomb interaction. Furthermore, electrons and holes are Fermions, which requires that any given carrier state can only be occupied once. This poses fundamental limits on how many carriers can coexist in a specific volume; above a certain limit, additional occupation is prevented, and so-called Pauli blocking is observed. Since an exciton consists fundamentally of Fermionic constituents, eventually Pauli blocking effects become important even for excitons. Due to a combination of these many-body effects, the excitonic resonance is weakened by an increasing carrier density. Figure 4 shows a comparison between theory and experiment of the excitonic absorption spectrum for different carrier densities. For elevated densities, the exciton resonance is broadened and its height reduced. When the same investigations are repeated in a microcavity, we observe that the normal-mode peaks decrease in height but their separation is roughly unchanged for moderate densities. In general, the normal-mode spitting is proportional to the oscillator strength of the excitonic absorption, i.e., the area under the resonance. Thus, the observed constant splitting suggests an unchanged oscillator strength for moderate densities. The invariant oscillator strength was unexpected and can only be explained by using a theory which includes the Coulomb interaction of carriers microscopically. When the carrier density is increased even further, the exciton resonance is completely bleached, and the microcavity transmission has only a single peak, at the cavity mode energy; this is commonly referred to as the weak-coupling regime, in contrast to the nonperturbative strong coupling with two transmission peaks. The strong coupling regime provides several intriguing phenomena; for example, parametric amplification of emission has been demonstrated by applying simultaneously multiple light beams to the sample.

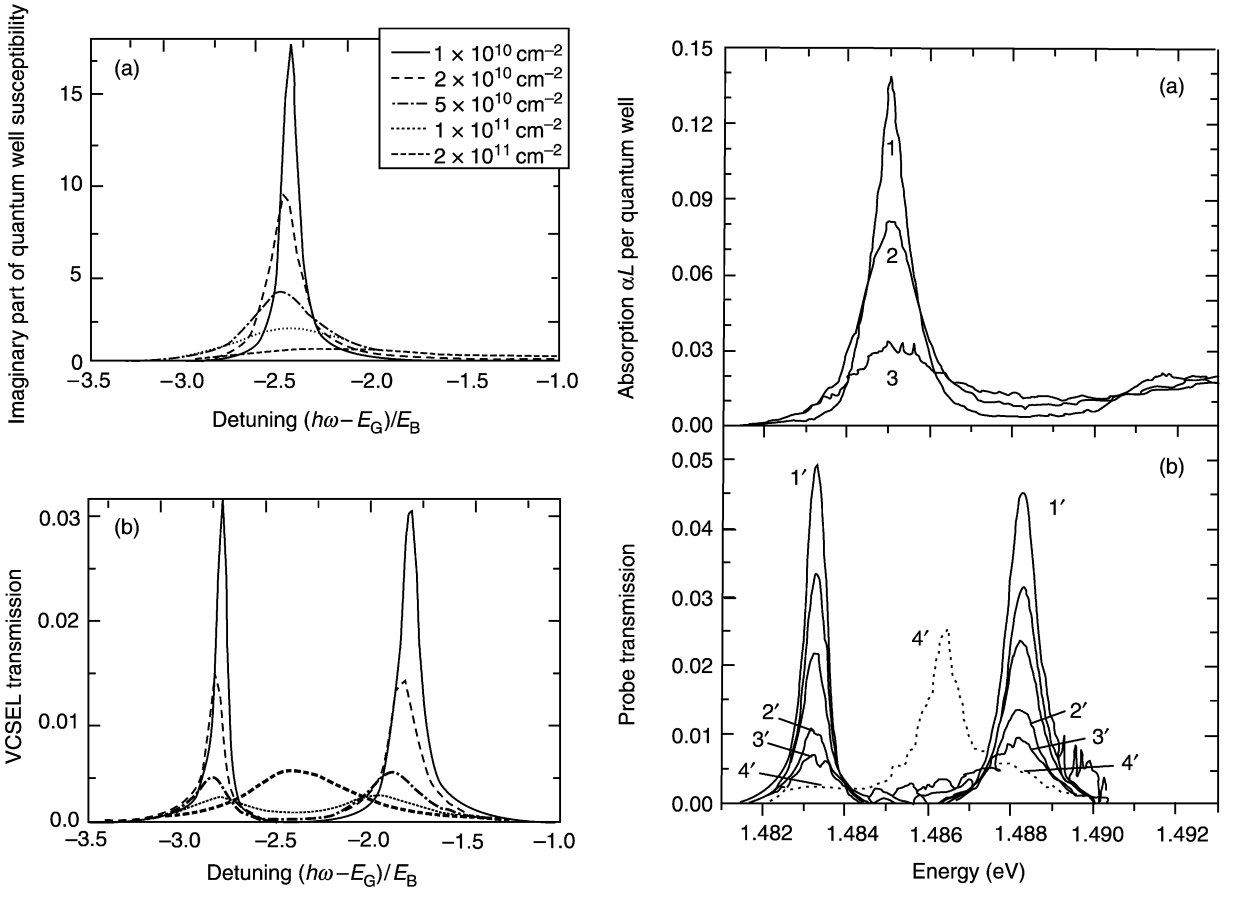

Figure 4 Left column: (a) microscopically computed bare quantum-well absorption spectrum, i.e., the imaginary part of the susceptibility, as a function of carrier density. (b) Calculated transmission of the quantum-well microcavity for corresponding densities. The ultimate cavity QED limit of normal-mode coupling follows when the light–matter interaction is so strong that even a single photon leads to splitting (genuine strong coupling). We briefly outline some aspects of the quantum statistical limit known from atomic physics. This situation can be analyzed with the so-called Jaynes–Cummings model where only two states of the atom are included together with a single light mode. In this case, the interaction between a single photon and an atom leads to a normal-mode splitting g_0. If two photons interact with one atom, the splitting increases to $2^{1/2}g_0$; more generally coupling between n photons and an atom leads to a splitting of $n^{1/2}g_0$. In the QED limit, the matter response is very nonlinear because one can detect the quantized nature of light directly from the energy splitting. This limit has already been reached in atomic cavity QED, whereas this regime is hard to approach with semiconductors because they behave more like multi-atom systems. If one has N atoms in a cavity, the first photon excites one atom, but there are N different ways of doing this, so the splitting is $N^{1/2}g_0$. If a second photon arrives, it interacts with the remaining unexcited atoms rather than the excited one, so that the splitting remains $N^{1/2}g_0$ as long as the number of photons is much smaller than N. Thus, in an N-atom system, or equivalently in semiconductors, the quantized light effects are much harder to observe than for a single atom. Currently, the normal-mode splitting in a semiconductor microcavity is explainable by the classical features of light, so that only the quantized nature of the matter is observed. In order to approach the ultimate cavity QED limit, one obviously has to reduce N and increase the light–matter coupling. In the future, this objective might be possible in quantum-dot/nanocavity systems where the semiconductor is confined in all spatial directions.

When an excited semiconductor is not under any influence of external classical light fields, it can still emit light via spontaneous emission resulting from the recombination of electron–hole pairs. The resulting light emission is called photoluminescence. Since the emission process takes place in a strongly interacting many-body system, one has to systematically include the Coulomb interaction and Fermionic features. The emission properties can be consistently described by the so-called semiconductor luminescence equations. When the microcavity photoluminescence spectrum is investigated, one observes a similar normal-mode splitting as for the transmission studies. However, this normal-mode coupling is not in the ultimate cavity QED limit even though the quantum fluctuations of the light field trigger the spontaneous emission. Nevertheless,

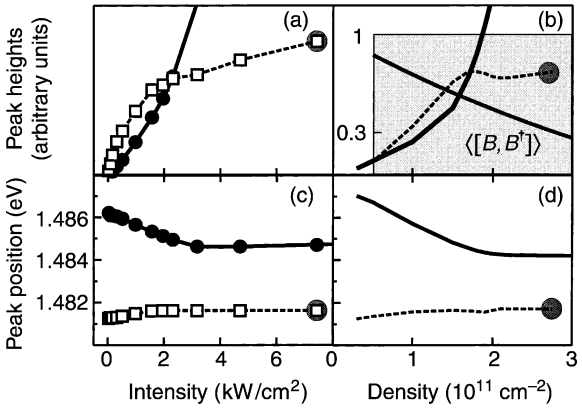

Figure 5 Measured microcavity luminescence intensities (a) and peak energies (c) versus excitation intensity for the high-energy peak (solid line) and the low-energy peak (dashed line). The results of the microscopic theory are shown in (b) and (d). From Kira M, Jahnke F, Koch SW, *et al.* (1997) Quantum theory of nonlinear semiconductor microcavity luminescence explaining "boser" experiments. *Physical Review Letters* 79: 5170. Copyright (2004) by the American Physical Society.

the luminescence shows an interesting new transition as a function of the excitation level. Figure 5 contains a comparison between theory and experiment of normal-mode peak heights and positions as a function of carrier density. For low densities, the high-energy peak is lower in height but it overtakes the low-energy peak for moderate carrier densities that are still below lasing threshold. This threshold-like overtaking was attributed to Boser action, involving exciton formation, final-state stimulation, and Bose condensation. The inset shows an estimate of just how Bosonic the excitons are, i.e., how much they actually behave as independent atoms; the value unity corresponds to the fully Bosonic situation. The nonlinear luminescence transition takes place at a density regime where the underlying Fermionic electron and hole contributions become important (commutator is roughly 0.5). A more detailed analysis with the semiconductor luminescence equations shows that Fermionic carrier nonlinearities in a detuned cavity are responsible for the experimental observations. This example of a misinterpretation based on a Bosonic analysis stresses how important it is to include the Coulomb interaction and Fermion character of carriers when analyzing the properties of semiconductors.

Superposition Principle: Observation of Quantum Optical Correlations

The above normal-mode-coupling investigations have shown interesting nonlinear effects, but they also revealed that the ultimate QED limit – demonstrating

discrete states of light directly – has not yet been reached. Alternatively, a QED investigation may concentrate on other fundamental features of quantum mechanics. One possibility is to study the implications of the superposition principle which states that the joint properties of a light–matter system can always be expressed as a superposition that combines light and matter wavefunctions. The most dramatic consequence can be observed in so-called entangled wavefunctions which cannot be factorized into light and matter parts. In a factorized wavefunction, the light and matter parts are independent whereas entangled wavefunctions conditionally connect light and matter wavefunctions. To elaborate the subtle details of entanglement, we first analyze a simple example. Assume that light can be in two different polarization states, $|\sigma^+\rangle$ or $|\sigma^-\rangle$, and the matter part is either excited $|\text{up}\rangle$ or de-excited $|\text{down}\rangle$. A wavefunction, $[|\text{up}\rangle + |\text{down}\rangle]$ $[|\sigma^+\rangle + |\sigma^-\rangle]$, is clearly a superposition of the fundamental states, and at the same time the light and matter parts are completely factorized. However, the wavefunction $[|\text{up}\rangle\ |\sigma^+\rangle + |\text{down}\rangle\,|\sigma^-\rangle]$ is entangled, since the light and matter parts cannot be separated. In the entangled state, measurement on the light state will conditionally determine a definite state of the matter, whereas the factorized state has no such conditionality. The entanglement has far-reaching consequences which cannot be understood with a classical analysis. For example, the principles of teleportation and quantum computing follow directly from the controlled manipulation of different parts of the entangled wavefunction. For atomic systems, wavefunction entanglement has been demonstrated and utilized in several experiments. For semiconductors, the direct manipulation and detection of the wavefunction seems difficult due to the overwhelming complexity of the many-body wavefunctions. Once again, the entanglement and the wavefunction are simplest for low-dimensional structures; direct entanglement effects have been demonstrated recently in a single quantum dot and between a pair of dots. Also for more complicated semiconductor systems, such as a quantum well in a microcavity, the entanglement can be observed as correlations between light and matter. In this case, the existence of QED correlations basically means that light and matter properties depend conditionally on each other. In general, the direct entanglement and QED correlation investigations have a large development potential for semiconductors.

When a semiconductor is excited with an external light pulse, entanglement-related correlations couple the classical and luminescence emission dynamics. The resulting dynamic interplay between the semiconductor Bloch and luminescence equations is mainly mediated by the correlation between photons and electron–hole densities. In the following, we analyze a microcavity configuration where a strong pump pulse generates large QED correlations. The effect of the correlations is then measured by the response of a weak probe beam. Figure 6 shows a comparison of theory and experiment of probe reflection in a configuration where the pump and probe do not have any spectral overlap. The measured probe reflection displays long-living oscillations as a function of time delay, i.e., phase difference, between the pump and the probe. Only by including the QED correlation in the theory can the oscillatory probe reflection be explained. When the QED contributions are omitted from the theory, the phase difference does not have any effect on the probe reflection. Thus, this experiment–theory example represents a direct observation of the cavity QED effects in semiconductors. Figure 6 also shows more pronounced oscillations when two phase-locked pump pulses provide the excitation; again the full QED theory explains the enhanced oscillation features.

The QED features can also alter the normal-mode coupling characteristic of a weak probe beam. Figure 7 shows a comparison of theory and experiment for a situation where the pump spectrum is

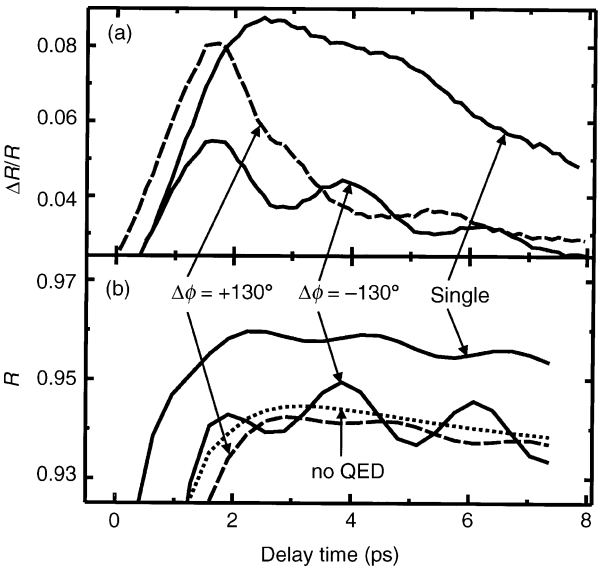

Figure 6 (a) Measured differential reflectivity and (b) computed reflection probability of the probe pulse as function of probe delay with respect to the excitation pulse. For two-pulse excitations, ±130° relative phase shifts are used. The dotted line is computed without the QED correlations. located between the two normal-mode coupling resonances. Both the theory and experiment show a new third resonance which follows the energetic position of the pump. The third peak is a direct consequence of the QED correlations. Since the third peak is generated from the QED field–carrier correlations generated by the pump pulse, its magnitude follows the intensity of the pump. As the probe intensity is decreased the relative effect of the QED correlations is increased so that the third peak grows in the probe transmission.

In these QED investigations, the cavity plays an important role since the mirror feedback leads to a significant amplification of the QED effects through the enhanced light–matter coupling. From a practical point of view, normal-mode coupling also provides well-separated spectral features which can be used as classical-emission reference points.

Heisenberg Uncertainty Principle: Squeezing of Light Emission

Quantized light effects can also be investigated by measuring the light fluctuations of the field directly. To maximize the quantum effects, we analyze the field fluctuations in the emission directions where the classical field vanishes. This situation can be realized in planar quantum-well structures which are nearly free of disorder. In such systems, a light pulse propagating perpendicular to the structure leads to transmission and reflection of classical light only along the excitation axis. If the detection is performed at an angle, the so-called secondary emission is purely quantum mechanical. However, the classical and quantum emissions are coupled in the same way as for the QED correlation study. The resulting fluctuations of secondary emission obey the Heisenberg uncertainty principle; in the following, the special quantum features of these fluctuations are investigated.

In the full analysis, we determine the variance ΔX and ΔY of the emission as shown in Figure 8 (see also Figure 1). The Heisenberg uncertainty principle requires that the quadrature fluctuations obey $\Delta X \Delta Y \geq 1$. For a specific quadrature, the minimum uncertainty limit is usually defined to be $\Delta X = 1$ or $\Delta Y = 1$. If ΔX and ΔY are different, the observed light field is squeezed; and if the variance in one quadrature is less than one, the field is squeezed below the minimum uncertainty limit. In both cases, the field has a strong quantum nature; in particular, squeezing below unity suggests that measurements can be more accurate than the standard quantum limit for that quadrature.

To illustrate the behavior of the quantum fluctuations, we excite the quantum well resonantly with a relatively strong pulse. The emission is detected at an angle of 45° away from the excitation axis. Since the excitation pulse is relatively strong, the carrier density starts to oscillate during the pulse because Fermionic carriers can be excited only once; thus, further excitation actually leads to de-excitation. In other words, when these states become almost fully excited, the pulse can no longer excite the system, and we observe periodic de-excitation and excitation analogous to the Rabi-flopping of a strongly excited two-level system. Figure 8 shows the exciting pulse and corresponding quadrature fluctuations during the excitation process. As long as the pulse is present, the squeezing is at the 4% level and oscillates with the Rabi-flopping frequency. The quadrature fluctuations clearly show squeezing below the minimum uncertainty limit. Hence, the field has obvious quantum properties.

Similar squeezing and quantum characteristics statistics have been predicted and observed in the photon statistics of resonance fluorescence from two-level atoms subjected to an intense coherent light beam. The quantum properties of the scattered light

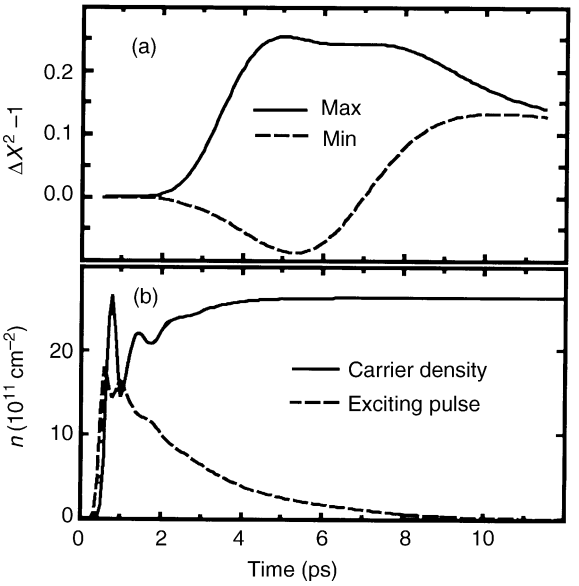

Figure 9 Squeezed light from a quantum well inside a microcavity: (a) the time evolution of maximum and minimum of the quadrature fluctuations; (b) the corresponding density and light field intensity at the quantum well.

in both quantum-well and atomic emission are enhanced when the driving field forces the system to oscillate between the excited and de-excited state. Just as described above, when the system becomes de-excited, it can no longer emit an additional photon; this inhibition manifests itself as sub-Poissonian photon statistics and squeezing in the mode quadratures. When the excitation pulse re-excites the system, such restrictions are no longer imposed. Thus, the field properties show quantum features oscillating with the Rabi-flopping frequency. Squeezing effects can also be observed with excitation by an electric current; for example, amplitude squeezing of diode laser emission has been demonstrated by controlling the electron statistics of the current flow.

The squeezing investigations demonstrate that some QED effects are expected to be seen without a cavity. Figure 9 shows the quadrature fluctuations when the cavity is added to the squeezing analysis. We observe qualitatively similar squeezing, but now the level of squeezing is enhanced up to 30% compared to the minimum uncertainty. This is once again a demonstration how QED effects can be amplified by using an increased light–matter coupling provided by the cavity.

Summary

This article overviews some of the most intriguing features of cavity quantum electrodynamics in semiconductors. Even though the related research has started only recently, several important quantum phenomena have already been predicted and measured: (a) the discrete quantum mechanical states of light and/or matter can be measured with strong coupling; (b) the consequences of the superposition principle have been detected as light–matter entanglement; and (c) the Heisenberg uncertainty principle has been tested via the squeezing of light. In all cases, the cavity enhances light–matter coupling leading to more pronounced quantum effects. Compared to atomic systems, the semiconductor has strong Coulomb correlation effects due to the relatively high density, which makes the analysis challenging. However, the semiconductor can also provide new mechanisms like the photon/carrier-density correlations which trigger new unexpected quantum phenomena.

The field of semiconductor quantum optics is very active and is developing rapidly. It benefits both from advances in computer capabilities and in semiconductor crystal growth. The increasing computer capacity allows more profound, accurate, and realistic modeling of semiconductor structures. At the same time, advances in crystal growth technology provide us with improved samples which are almost disorderless. In particular, the growth of quantum

wells with narrower exciton linewidths and quantum dots with larger dipole moments and reduced dephasing rates may be achieved, which is certain to make quantum features increasingly apparent and unavoidable.

All these research efforts eventually focus on producing devices utilizing quantum mechanical principles. One of the main objectives endeavors to develop quantum logic components for building blocks of quantum computers. Similar expanding possibilities can be expected, e.g., for accuracy of detection, device efficiency, and component design in general. Considering all of this, we are almost guaranteed to see new astonishing advancements; in this bright future, semiconductor cavity QED research will most likely be a pre-eminent element.

Atom Optics

A D Cronin and D E Pritchard, Massachussetts Institute of Technology, Cambridge, MA, USA

In 1923 Louis de Broglie suggested that particles of matter propagate as waves with a wavelength

$$\lambda_{dB} = h/p \qquad [1]$$

where h is Planck's constant and p is the particle's momentum. This breakthrough idea motivated Schrödinger's equation, which is the equation of motion of quantum mechanics.

Schrödinger's equation is a wave propagation equation, and therefore implies the existence of a whole new type of optics – matter wave optics – in which electron waves, neutron waves, atom waves, and entire molecule waves can be manipulated coherently. Such optics enable new measurement technologies and devices that depend on matter wave interference.

Guided by a knowledge of light waves, one can understand that the de Broglie wavelength of a particle sets the scale for focusing, diffraction, and interference. However, there are differences between

matter and light. For example, the vacuum is tremendously dispersive for matter waves. In other words, the group velocity for a particle depends on its de Broglie wavelength, while for light waves the group velocity is independent of wavelength.

To illuminate the mathematical connection with light optics, we note the wave equation for light is

$$\nabla^2 \vec{E} = \mu\varepsilon \frac{\partial^2 \vec{E}}{\partial t^2} \qquad [2]$$

where $\vec{E} = \vec{E}(\vec{x}, t)$ is the optical electric field, and the parameters μ and ε may vary throughout space, describing an index of refraction. The wave equation for matter waves is Schrödinger's equation:

$$\left(-\frac{\hbar^2 \nabla^2}{2m} + V \right) \psi = i\hbar \frac{\partial}{\partial t} \psi \qquad [3]$$

where $\psi = \psi(\vec{x}, t)$ is the probability amplitude, or wavefunction, for a particle of mass m. Here, the potential energy V can vary throughout space, and thus control the phase and amplitude of propagating atoms. Just as density for photons is proportional to $\vec{E}(\vec{x})^2$, the probability density for particles is given by $|\psi(\vec{x})|^2$.

In a vacuum $V = 0$ and $(\mu_0 \varepsilon_0)^{-1/2} = c$, and if we assume that both ψ and E have a time dependence described by $e^{-ik\omega}$, the wave equations become

$$\left[\nabla^2 + \frac{\omega^2}{c^2} \right] \vec{E} = 0 \qquad [4]$$

and

$$\left[\nabla^2 + \frac{2m\omega}{\hbar} \right] \psi = 0 \qquad [5]$$

which look similar, but have a critical difference stemming from the single time derivative in Schrödinger's equation. To see how this makes the vacuum dispersive for matter waves, but not for light, consider a propagating plane wave of either ψ or $\vec{E}$ described by $e^{i(kx - \omega t)}$ (for either kind of wave, $k \equiv 2\pi(\lambda)^{-1}$). Using the wave equation for light waves, the dispersion relation is

$$\omega = ck \qquad [6]$$

where c is the phase (and group) velocity of light, which is independent of k. The same plane wave substituted into Schrödinger's equation for matter waves yields the dispersion relation

$$\omega = \frac{\hbar k^2}{2m} \qquad [7]$$

This is quadratic for matter waves, which means the group velocity $v_g = d\omega/dk$ is twice the phase velocity $v_p = \omega/k$, and both still depend on k.

From an engineering perspective, matter wave optics consists of lenses, mirrors, beam-splitters, and other components of an optics toolkit. The fact that electrons and neutrons can be transmitted through solid material, and that electrons can be reflected or refracted by static electromagnetic fields, has enabled optical elements to be created for these kinds of matter waves. For atoms, however, finding suitable materials for lenses or mirrors is a daunting task, since with rare exceptions (e.g., cold H on liquid He) atoms thermalize on surfaces rather than elastically bouncing off or passing through them. This was the major obstacle which delayed the blossoming of atom optics until the mid-1980s.

This obstacle has now been circumvented, but only with difficulty. Electromagnetic fields (whose spatial configurations are severely constrained by Maxwell's equations) can change the potential energy of neutral atoms, but since an atom's net charge is zero, provide only a weak and highly dispersive index of refraction based on the atom's polarizability or magnetic moment. However, these effects are tremendously enhanced if the electromagnetic fields oscillate near a transition frequency of the atom. Hence, propagating waves and standing waves of single-frequency laser light have become standard tools in atom optics. Standing light waves are often referred to as a light crystal, because the periodic potential can diffract atom beams.

An alternative source of atom optical components is based on nanofabrication. Thin sheets of material with patterned holes serve as absorptive atom optics by transmitting atom waves only through the nanometer scale openings. A variety of techniques have been used to make physical diffraction gratings, zone plates, and holograms for atom waves. Methods such as electron beam lithography and ultraviolet photolithography both rely on sophistocated etching procedures to make the final free-standing structures. Thus, in either approach – near-resonant light, or miniature physical structures – current technologies such as the tunable laser or nanofabrication techniques have been required for the development of useful atom optics.

While coherent manipulation of atom waves is often the goal, incoherent manipulations are possible also, e.g., if photons are spontaneously scattered. Dissipative processes offer an additional class of possibilities such as increasing the brightness of an atom source, and are therefore an important part of atom optics. This article excludes atom slowing and trapping, and focuses instead on atom diffraction – a coherent

process which can be used to make beam splitters for atom interferometers.

Nanofabricated Atom Optics

Because atoms stick to surfaces, mechanical structures are absorptive atom optics. Yet the de Broglie waves transmitted through slots of a mask are nearly unaffected, provided the mask is thin enough. This is because the van der Waals potential energy of interaction with nearby surfaces falls off rapidly for neutral atoms.

Consider, for example, an atom wave packet being diffracted by a mechanical grating made with physical bars and slots as shown in Figure 1. Initially, let the atom wave packet have a slowly varying spatial envelope, $f = f(x, y, z)$, and momentum only in the $\hat{x}$-direction, $\vec{p} = \hbar\vec{k}_0 = h(\lambda_{dB})^{-1}\hat{x}$, so the wavefunction can be written as

$$\psi = fe^{i(k_0 x - wt)} \qquad [8]$$

Immediately after the grating, only the portions of the wavefunction passing through slots remain nonzero, as depicted in Figure 2. Here, the wavefunction is now periodic both due to the grating lattice vector $k_g\hat{y}$ and the initial wavevector $k_0\hat{x}$. According to the Schrödinger equation, a periodicity in any direction implies a momentum in that direction. Thus, variation of ψ in the $\hat{y}$ variation gives rise to a new momentum distribution.

The square wave modulating the envelope of the wave packet can be described by a Fourier sum times the incident wavefunction

$$\psi = fe^{i(k_0 x - \omega t)} \sum_{n=-\infty}^{\infty} a_n \cos(nk_g y) \qquad [9]$$

where $k_g = 2\pi(d_g)^{-1}$ is the grating lattice vector. The only other physical parameter of the grating is the open fraction, γ, and this determines the Fourier amplitudes a_n

$$a_n = \frac{\sin(n\pi\gamma)}{n\pi} \qquad [10]$$

From the principle of superposition (which is applicable here because the Schrödinger equation is linear) the wavefunction can be written as a sum of traveling waves with wavevectors $\vec{k}_n$:

$$\psi = f\sum_{n=-\infty}^{\infty} a_n e^{(i\vec{k}_n\cdot\vec{r} - wt)} \qquad [11]$$

$$\vec{k}_n = \frac{k_0\hat{x} + nk_g\hat{y}}{N} \qquad [12]$$

where, just as in standard optics, the factor N serves to keep $|\vec{k}_n|$ on a spherical shell, i.e., the grating does not add energy to the atom.

Inserting this expression for the wavefunction into Schrödinger's equation we get the dispersion relation

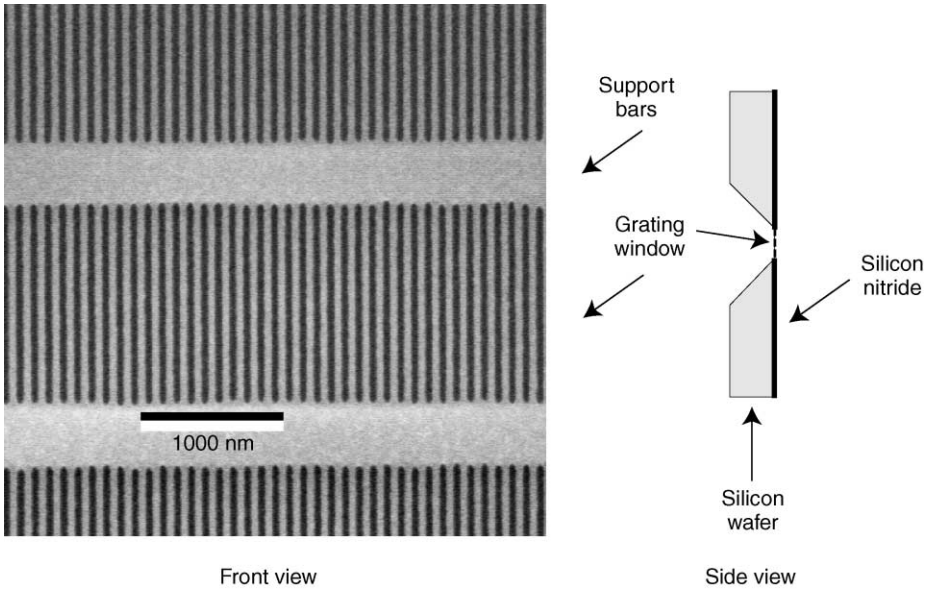

Figure 1 Scanning electron microscope image of a silicon nitride diffraction grating for atom waves. The bars (light) absorb, and the slots (dark) transmit atom waves. The grating period is 100 nm, the open fraction is 0.67, and the free-standing bars are supported every 5 μm with a thicker strip of silicon nitride material. The grating was fabricated by Tim Savas and Henry I Smith at MIT NanoStructures laboratory.

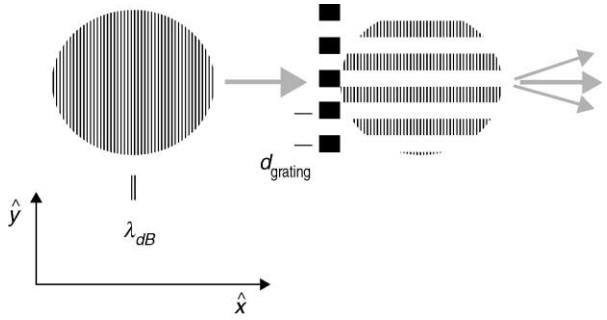

Figure 2 Schematic diagram of an atom wavepacket passing through an absorbing grating, as seen from above. The atom wavepacket is depicted before and after passing through the grating from left to right.

for matter waves and a different group velocity, v_n, for each k_n

$$\hbar\omega = \frac{\hbar^2 k_n^2}{2m} \qquad [13]$$

$$v_n = \frac{d\omega}{dk_n} = \frac{\hbar k_n}{m} = p_n/m \qquad [14]$$

Thus, diffraction through a grating puts an atom into a coherent superposition of different momenta, each separated by $\sim\hbar k_g\hat{y}$. Some time later, the atom will be in a coherent superposition of multiple locations, and the far-field probability density will be peaked at integer multiples of the diffraction angle

$$\Theta_D = \frac{k_g}{k_0} = \frac{\lambda_{dB}}{d_{\text{grating}}} \qquad [15]$$

where d_{grating} is the lattice spacing of the grating and the small-angle approximation for $\sin(\theta)$ has been used. Exactly as in light optics, these diffraction gratings are good momentum spectrometers, i.e., the diffraction angle is a measure of longitudinal momentum. (Contrary to light optics, group velocity can also be used to measure matter wave momentum.) Coherence between the diffraction orders remains until a perturbation occurs which would (even in principle) be sufficient to determine which path the atom took. This assertion has been tested with atoms in an interferometer (discussed below).

Atom flux in the nth diffraction order is given by

$$I_n = \left(\frac{\sin(n\pi\gamma)}{n\pi}\right)^2 \qquad [16]$$

To resolve the diffracted orders the initial transverse momentum distribution of the atoms must be smaller

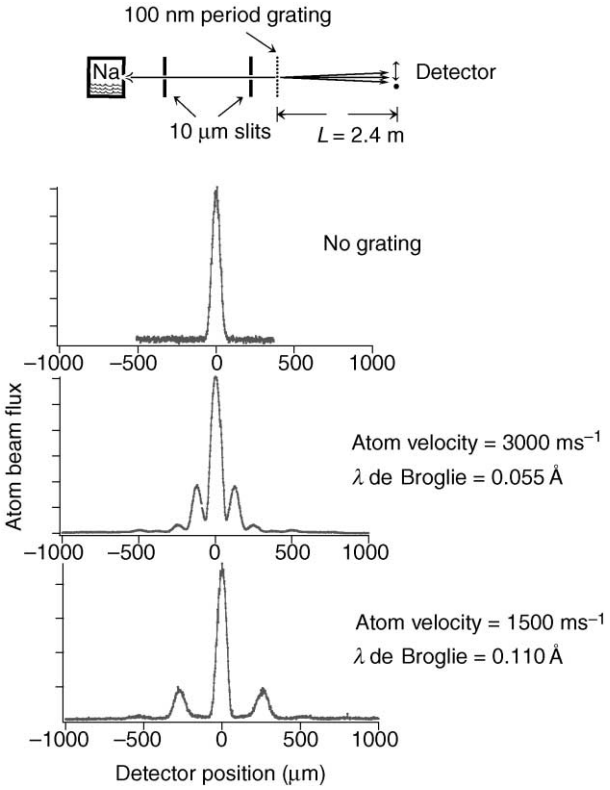

Figure 3 Diffraction data from a beam of sodium formed by passing atoms through two collimating slits followed by a nanofabricated diffraction grating. The momentum of the atoms determines their de Broglie wavelength, and thus their diffraction angle $\sin(\Theta_D) = \lambda_{dB}/d_{\text{grating}}$. These data were obtained at MIT by the authors.

than k_g, and the time until the far-field observation must be sufficiently large given the beam width. At intermediate times, the atom waves are in the Fresnel diffraction region where the Talbot effect can be observed. This effect causes the atom waves to form a replica of the grating in free space at integer multiples of the Talbot length, $Z_T = 2d^2_{\text{grating}}\lambda_{dB}^{-1}$.

Figure 3 shows the far-field diffraction pattern from a beam of sodium (^{23}Na) atoms using a material grating with a period of 100 nm. The atom beam velocity peaked at 1500 ms^{-1} corresponds to a de Broglie wavelength of 0.11 Å; thus, $\Theta_D \approx 10^{-4}$ rad. (The beam of 3000 ms^{-1} atoms diffracts at half this angle.) The spread in longitudinal velocity of $\sigma_v/v \approx 6\%$ can be deduced from the data because it slightly increases the width for higher order diffraction peaks. The open fraction of the grating, $\gamma \approx 60\%$, can also be determined from the diffraction data, because it determines the relative intensity of the orders. Effects of the atoms' finite size and interaction with the grating bars make small corrections to this simple theory.

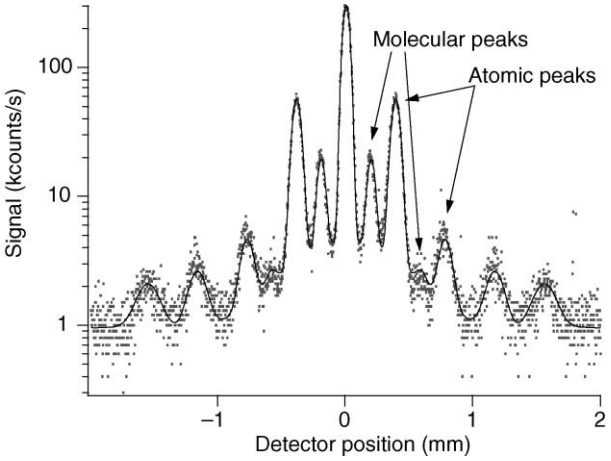

Figure 4 Diffraction data using a mixed beam of sodium atoms (Na) and sodium dimer molecules (Na_2). From this source molecules have the same speed as atoms, thus twice the momentum. Thus, molecule waves are diffracted at half the diffraction angle compared to atom waves. These data were obtained at MIT by the authors.

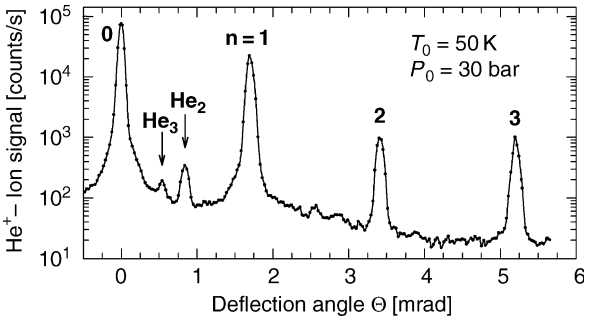

Figure 5 Diffraction of helium atoms and helium molecules through a nanofabricated grating. These data, reproduced with permission from Wieland Schoellkopf, were obtained at the Max-Planck-Institute in Göttingen.

Nanofabricated atom optics differ from those based on light forces in a number of ways: they are amplitude structures (with corresponding loss of transmission intensity), they are species-independent, their scale size can be several times smaller than attainable with light, and they can be arbitrarily patterned since they are fabricated by electron beam lithography. Insensitivity to species is demonstrated in Figure 4, where a beam of Na_2 molecules and Na atoms is diffracted and separated by a nanofabricated diffraction grating. The flexibility of electron beam lithography has allowed fabrication not only of diffraction gratings, but also of spherical and cylindrical zone plates, as well as a combination of lens and a hologram that generates a focused atom image. One stunning application laid to rest a long-standing argument concerning whether a stable bound state of the $^4He_2$ dimer exists. For this a diffraction grating was used to separate and resolve $^4He_2$ and more massive clusters (Figure 5). Subsequently a nano-sieve was used to estimate the size of the $^4He_2$ dimers to be 62 ± 10 Å.

Standing Waves of Light

In contrast to nanofabricated structures, standing waves of near-resonant light are phase gratings for atoms. The optical electric field dynamically polarizes the atoms and causes a shift to the ground state energy (the ac-Stark shift). For optical electric fields oscillating above (below) the atomic resonance frequency, the ac-Stark shift increases (decreases) potential energy for atoms and in either case perturbs the de Broglie wave phase.

In many respects, the interaction of an atom with a standing light wave is richer than the more familiar topic of light–atom interactions in a traveling light wave. Part of this richness reflects two ways in which a standing wave can be considered, either as two counter-propagating traveling waves or as a single, stationary standing wave. The standing wave–atom interaction is capable of transferring momentum in well-determined quantities, coherently splitting atomic wave packets, and generating forces much larger than possible with spontaneously scattered light. Not surprisingly, this interaction has many distinct facets that only appear in different regimes of the interaction parameters (intensity, detuning, and pulse duration) and atomic parameters (mass, initial momentum with respect to the standing wave, and excited state natural lifetime).

We begin with the Bragg scattering of atoms from a standing wave light grating. Although it can be difficult to realize the physical conditions that assure its occurrence, pure Bragg scattering is simpler than intermediate cases involving spontaneous decay (from light too close to resonance) or Kapitza–Dirac diffraction (from shorter interaction times).

Consider a standing wave light grating formed by two counter-propagating plane waves (traveling parallel to the z-axis) of equal amplitude, E_0, wavevector, k, frequency, ω, polarization vector, $\hat{e}$, and temporal envelope function, $f(t)$:

$$\vec{E}(z,t) = E_0 f(t)\sin(kz - \omega t)\hat{e} + E_0 f(t)\sin(kz + \omega t)\hat{e} \quad [17]$$

$$= 2E_0 f(t)\sin(kz)\cos(\omega t)\hat{e} \quad [18]$$

We would like to work with momentum states as our atomic basis, thus it is easiest to consider the

description of the electric field driving the transitions in terms of two counter-propagating traveling waves of definite momentum (eqn [17]), as opposed to the single standing wave they jointly form (eqn [18]).

Momentum is transferred by paired stimulated absorption and emission processes, resulting in a transfer of photons between the traveling waves. An N_B^{th} order diffraction process transfers N_B photons from one traveling wave to the counter-propagating traveling wave and changes the atomic momentum by $2N_B\hbar k\hat{z}$. Furthermore, atomic population is transferred only between $|g, -N_B\hbar k\rangle$ and $|g, +N_B\hbar k\rangle$, where $|g(e), \pm N\hbar k\rangle$ denotes a two-level atom in its ground (excited) state with momentum $\pm N\hbar k$ parallel to the standing wave axis. The excited state remains nominally unpopulated so long as the temporal envelope function, $f(t)$, does not have strong frequency components near the laser detuning

$$\delta = \omega - \omega_0 \qquad [19]$$

where ω_0 is the unperturbed frequency of the atomic transition. Furthermore, for a given initial state ($|g, -N_B\hbar k\rangle$) the uniqueness of the final state ($|g, +N_B\hbar k\rangle$) occurs because of the fundamental assumption that makes Bragg scattering so simple to describe; the uncertainty in the photon energy driving the transitions is small compared to the energy separation between neighboring momentum states. A quantitative discussion of the validity of this assumption will be given later.

We now calculate the probability, $P_1^B(\tau)$, of the first order ($N_B = 1$) Bragg process. Scattering transfers an atom from $|g, -\hbar k\rangle$ to $|g, +\hbar k\rangle$ when the atoms interact with a constant light intensity for a time τ (i.e., in eqns [17] and [18] $f(t)$ is a square wave of unit amplitude and duration τ). The geometry for Bragg diffraction from a standing wave of light is shown in Figure 6, and the energy/momentum states involved in the transition are depicted in Figure 7.

Considering the electronic degree of freedom, we rewrite the Schrödinger equation as

$$(\mathcal{H}_0 + \mathcal{H}_{\text{int}})|\psi\rangle = i\hbar\frac{\partial}{\partial t}|\psi\rangle \qquad [20]$$

where the total Hamiltonian $\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_{\text{int}}$ is a matrix. The wavefunction is a vector of coefficients c_i in the basis $\{|g, -\hbar k\rangle, |e, 0\rangle, |g, +\hbar k\rangle\}$, with normalized population amplitudes for each

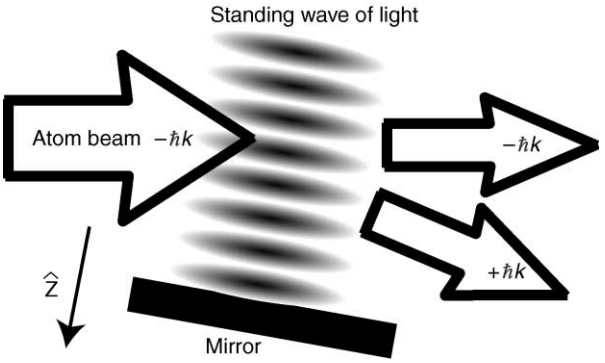

Figure 6 Two counter-propagating running waves of light superimpose to form a standing wave of light. This 'light crystal' acts as a diffraction grating for atoms, shown here in the configuration for Bragg diffraction.

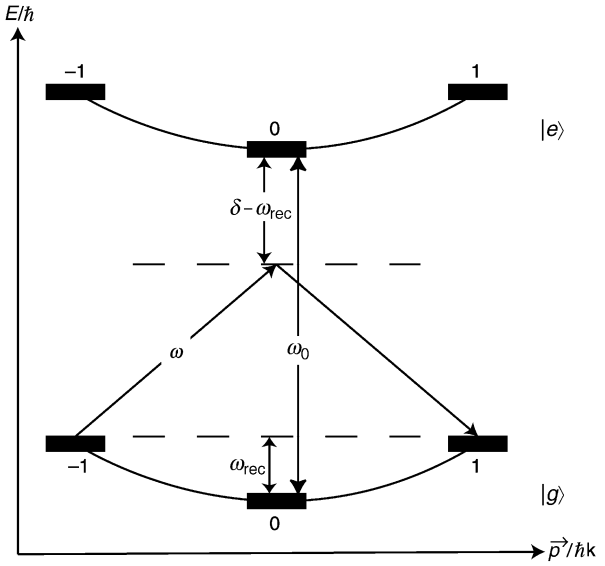

Figure 7 Energy vs. momentum diagram describing atomic states involved in Bragg diffraction. The total energy is due to the electronic state ($|g\rangle$, $|e\rangle$) plus the kinetic energy associated with the recoil from photon emission (or absorption). In Bragg diffraction, atoms make a coherent transition from $|g, -\hbar k\rangle \leftrightarrow |g, +\hbar k\rangle$. component:

$$|\psi\rangle = \begin{pmatrix} c_{-1}(t) \\ c_0(t) \\ c_{+1}(t) \end{pmatrix} \qquad [21]$$

In the electric dipole approximation, the interaction Hamiltonian is $\mathcal{H}_{\text{int}}(t) = -\vec{\mu}\cdot\vec{E}(t)$, where $\mu = \langle e|q\vec{r}|g\rangle\cdot\hat{e}$ is the electric dipole matrix element connecting the ground ($|g\rangle$) and excited ($|e\rangle$) states

of the atom. $\hat{e}$ is the polarization vector of the light and q is the charge of the electron. By momentum conservation, only the plane wave traveling in the $\pm\hat{z}$ direction couples the $|e,0\rangle \leftrightarrow |g,\mp\hbar k\rangle$ transitions. By using this argument, we are effectively viewing the electric field as a quantum mechanical operator. Expanding the sinusoidal variation of the electric field in terms of complex exponentials and treating the spatially dependent complex exponential terms as quantum mechanical momentum translation operators yields the interaction Hamiltonian:

$$\mathcal{H}_{\text{int}} = \frac{\hbar\omega_R}{2}\begin{pmatrix} 0 & ie^{i\omega t} & 0 \\ -ie^{-i\omega t} & 0 & ie^{-i\omega t} \\ 0 & -ie^{i\omega t} & 0 \end{pmatrix} \qquad [22]$$

For example, $e^{\pm ik\hat{z}}|g,n\hbar k\rangle = |e,(n\pm 1)\hbar k\rangle$ describes absorption, and for stimulated emission, $e^{\mp ik\hat{z}}|e,n\hbar k\rangle = |g,(n\pm 1)\hbar k\rangle$. This procedure includes the rotating wave approximation. In addition, we have neglected any frequency components associated with the sudden switch on of the fields and the finite duration of the light–atom interaction. In formulating $\mathcal{H}_{\text{int}}$, the strength of the light–atom interaction is parameterized by the single-photon Rabi frequency:

$$\omega_R = \frac{\mu E_0}{\hbar} \qquad [23]$$

Without loss of generality, we will take μ and hence ω_R to be positive, real-valued quantities.

The total Hamiltonian follows simply by including the electronic and kinetic energy terms:

$$\mathcal{H}_0 = \hbar\begin{pmatrix} \omega_{\text{rec}} & 0 & 0 \\ 0 & \omega_0 & 0 \\ 0 & 0 & \omega_{\text{rec}} \end{pmatrix} \qquad [24]$$

where the single-photon recoil energy, E_{rec}, of an atom of mass m is given by

$$E_{\text{rec}} = \hbar\omega_{\text{rec}} = \frac{\hbar^2k^2}{2m} \qquad [25]$$

Making the *ansatz* for the solution wavefunction as

$$|\psi\rangle = \begin{pmatrix} c_{-1}(t)e^{-i\omega_{\text{rec}}t} \\ c_0(t)e^{-i\omega_0 t} \\ c_{+1}(t)e^{-i\omega_{\text{rec}}t} \end{pmatrix} \qquad [26]$$

and substituting into the Schrödinger equation yields three coupled first-order differential equations:

$$\dot{c}_{\pm1}(t) = \mp\frac{\omega_R}{2}e^{i\Delta t}c_0(t), \qquad [27]$$

$$\dot{c}_0(t) = \frac{\omega_R}{2}e^{-i\Delta t}\big(c_{+1}(t) - c_{-1}(t)\big), \qquad [28]$$

where $\Delta = \delta + \omega_{\text{rec}} = (\omega - \omega_0) + \omega_{\text{rec}}$. Differentiating eqn [27] and substituting eqn [28] into the result yields two coupled second-order differential equations:

$$\ddot{c}_{\pm1}(t) - i\Delta\dot{c}_{\pm1}(t) + \frac{\omega_R^2}{4}\big(c_{\pm1}(t) - c_{\mp1}(t)\big) = 0 \qquad [29]$$

With the initial conditions:

$$c_{-1}(0) = 1 \qquad [30]$$

$$c_0(0) = 0 \Rightarrow \dot{c}_{\pm1}(0) = 0 \qquad [31]$$

$$c_{+1}(0) = 0 \qquad [32]$$

and the assumption $\Delta^2 \gg \omega_R^2$, the solutions to eqn [29] are

$$c_{-1}(t) = e^{-i\frac{\omega_R^{(2)}}{2}t}\cos\left(\frac{\omega_R^{(2)}}{2}t\right) \qquad [33]$$

$$c_{+1}(t) = ie^{-i\frac{\omega_R^{(2)}}{2}t}\sin\left(\frac{\omega_R^{(2)}}{2}t\right) \qquad [34]$$

where the two-photon Rabi frequency is

$$\omega_R^{(2)} = \frac{\omega_R^2}{2\Delta} \rightarrow \frac{\omega_R^2}{2\delta}, \quad |\delta| \gg \omega_{\text{rec}} \qquad [35]$$

with both transitions driven at equal single-photon Rabi frequencies, ω_R.

Substituting the solution of eqn [33] or [34] into eqn [27] yields an expression for the excited state amplitude:

$$c_0(t) = -i\frac{\omega_R}{2\Delta}e^{-i\Delta t}e^{-i\omega_R^{(2)}t} \qquad [36]$$

This will be important in calculating the rate of spontaneous emission events later.

The solutions for $c_{-1}(t)$ and $c_{+1}(t)$ oscillate with the interaction duration, τ, yielding the result for the $|g,-\hbar k\rangle \rightarrow |g,+\hbar k\rangle$ transition probability:

$$P_1^B(\tau) = |c_{+1}(\tau)|^2 = \sin^2\left(\frac{\omega_R^{(2)}}{2}\tau\right) \qquad [37]$$

Thus, the system oscillates between the two momentum states $|g,-\hbar k\rangle$ and $|g,+\hbar k\rangle$ in a manner analogous to the Rabi oscillation of atomic population between two resonantly coupled states. This solution with

oscillatory probabilities for the two Bragg coupled states is known as the Pendellösung and has been observed for atoms, neutrons, and X-rays (Figure 8). The nice feature here is that the strength of the grating can be actually controlled by the intensity of the light.

Viewing Bragg scattering as a two-photon transition from the initial ground state to the final ground state with opposite momentum, illuminates the close connection with a Raman transition between two internal sub-states of the ground state manifold, each with its own external momentum state. The formalism describing the Raman transition is basically the same as that presented here, except the two transitions can be driven at different single-photon Rabi frequencies, ω_{R1} and ω_{R2}, so that the generic two-photon Rabi frequency is given by $\omega_R^{(2)} = \omega_{R1}\omega_{R2}/2\Delta$, where Δ is the detuning from the intermediate state.

An N_B^{th} order Bragg process (similar to a $2N_B$-photon Raman process) is a coherent succession of N_B two-photon transitions from $|g, -N_B\hbar k\rangle$ to $|g, +N_B\hbar k\rangle$ with $2N_B - 1$ intermediate states of the form:

$$|e, (-N_B + 1)\hbar k\rangle, |g, (-N_B + 2)\hbar k\rangle \ldots$$

$$\ldots |g, (N_B - 2)\hbar k\rangle, |e, (N_B - 1)\hbar k\rangle$$

Such a process is characterized by a $2N_B$-photon Rabi frequency given by

$$\omega_R^{(2N_B)} = \frac{[\omega_R]^{2N_B}}{2^{2N_B-1}\Delta_1\Delta_2\cdots\Delta_{2N_B-1}} \qquad [38]$$

where Δ_n is the detuning from the n^{th} intermediate state. Figure 9 shows what this process would look like for an N_B^{th} order Bragg transition where the intermediate state detunings are given by

$$\Delta_n = \left\{ \begin{array}{ll} \delta + (2N_B n - n^2)\omega_{\text{rec}} : & n \text{ odd} \\ (2N_B n - n^2)\omega_{\text{rec}} : & n \text{ even} \end{array} \right\} \qquad [39]$$

Substituting these detunings into eqn [38] yields the N_B^{th} order Bragg transition $2N_B$-photon Rabi frequency, $\omega_R^{(2N_B)}$:

$$\omega_R^{(2N_B)} = \frac{[\omega_R]^{2N_B}}{2^{4N_B-3}[(N_B - 1)!]^2\delta^{N_B}\omega_{\text{rec}}^{N_B-1}} \qquad [40]$$

where we have assumed $|\delta| \gg N_B^2\omega_{\text{rec}}$.

To ensure that the system truly undergoes Bragg scattering, and validate the assumption that only states of equal kinetic energy and opposite

momentum are coupled, the overall exposure time, τ, of the atoms to the fields must be limited both from below and above.

The lower bound on τ is necessary to resolve the final momentum state ($|g, N_B\hbar k\rangle$) from neighboring momentum states ($|g, (N_B \pm 2)\hbar k\rangle$) two photon recoil momenta away. Avoiding population transfer into these states requires that the energy separation be resolvable, or

$$\tau(\delta E) \gg h \qquad [41]$$

For first-order Bragg scattering processes ($N_B = 1$) the nearest lying momentum states that may be mistakenly populated are $|g, \pm 3\hbar k\rangle$, for which

$$\delta E = \frac{p^2_{n=3}}{2m} - \frac{p^2_{n=1}}{2m} = 8\hbar\omega_{\text{rec}} \qquad [42]$$

Therefore

$$\tau \gg \frac{h}{8\hbar\omega_{\text{rec}}} = \frac{\pi}{4\omega_{\text{rec}}} \qquad [43]$$

For sodium atoms (^{23}Na) in 590 nm light, $\tau \gg 6\ \mu$s is the lower bound required for first-order Bragg scattering.

For all higher-order ($N_B > 1$) Bragg scattering processes, the nearest momentum states are $|g, \pm(N_B - 2)\hbar k\rangle$, which limits the interaction time to

$$\tau \gg \frac{\pi}{2(N_B - 1)\omega_{\text{rec}}} \qquad [44]$$

which for $N_B \gg 1$ reduces to

$$\tau \gg \frac{\pi}{2N_B\omega_{\text{rec}}} \qquad [45]$$

The upper bound on the interaction duration is necessary to avoid spontaneous emission. The interaction duration must be short enough so that the expected number, N_s, of spontaneous emission events per atom during the time τ is negligible. N_s is simply given by the product of the excited state fraction (eqn [36]) and the probability of spontaneous decay given that the atom is in the excited state:

$$N_s = |c_0(t)|^2\Gamma\tau = \frac{\omega_R^2}{4\Delta^2}\Gamma\tau \qquad [46]$$

where Γ is the natural decay rate of the excited state. Avoiding spontaneous emission ($N_s \ll 1$) while still having a significant probability for transitions ($\omega_R^{(2N_B)}\tau \simeq \pi$) forces one to work in the regime where $\Delta \gg \Gamma$, which is a practical requirement to avoid spontaneous emission and maintain coherence. For sodium atoms on the 590 nm transition, $\Gamma = 6.3 \times 10^7\ \text{s}^{-1}$, and a typical choice in Bragg diffraction experiments is $\Delta = 50\Gamma$, or $\Delta/2\pi = 500$ MHz.

Briefly, to relate Rabi frequency to optical intensity, the transition rate W on resonance with a Lorentzian spectral line is given by Fermi's golden rule:

$$W = \frac{\omega_R^2}{\Gamma} = \frac{\lambda^2_{\text{photon}}}{2\pi}\frac{I}{\hbar\omega} \qquad [47]$$

where the last term can be regarded as the cross section for absorption multiplied by intensity in units of photon flux. Hence

$$\omega_R^2 = \Gamma\frac{\lambda^2_{\text{photon}}}{2\pi}\frac{I}{\hbar\omega} \qquad [48]$$

For Na atoms in 12 mW(cm)$^{-2}$ resonant light, $\omega_R = \Gamma = 6.3 \times 10^7\ \text{s}^{-1}$. Both the probability of Bragg scattering and the spontaneous emission increase linearly with $\omega_R^2\tau\Gamma^{-1}$. However, spontaneous emission decreases as Δ^2 while the Bragg scattering probability decreases as Δ. Thus, as shown in **Figure 10**, at sufficient detuning and laser power, Bragg scattering occurs with no spontaneous emission. For reference, 12 mW(cm)$^{-2} \times 10\ \mu$s corresponds to $\omega_R^2\tau\Gamma^{-1} = 630$ for sodium atoms.

Bragg scattering of atoms from a standing light wave was first observed at MIT in 1988. A supersonic atomic beam was diffracted from a standing wave of near-resonant laser light as depicted in **Figure 6**. The angle between the atomic beam (of thermal wavelength λ_{dB}) and the light grating (of periodicity $\lambda_L/2$) was tuned to the appropriate Bragg angle, θ_B, where:

$$\lambda_{dB} = \lambda_L \sin(\theta_B) \qquad [49]$$

Population transfer corresponding to both first- and second-order Bragg scattering was observed (**Figure 7**). The experiment required a sub-recoil transverse momentum spread of the atomic beam in order to resolve the different momentum states in the far field and limit the final state to only one

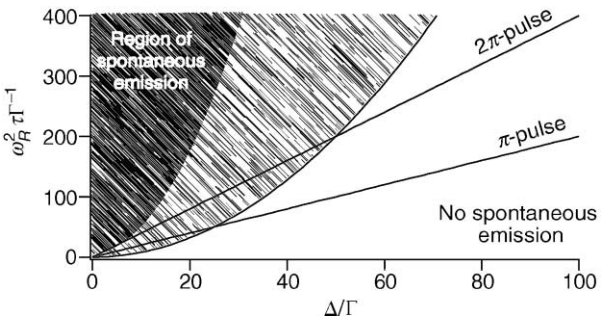

Figure 10 The conditions for which $N_s > 0.02(0.10)$ are hashed in light(dark) gray. ω_R^2/Γ is proportional to optical intensity. The line labeled π-pulse indicates the parameters which cause complete first-order Bragg diffraction. The line labeled 2π-pulse indicates conditions where population is completely transferred back to the initial state (Pendellösung oscillation).

diffracted order. The Pendellösung was observed as an oscillation in population transfer as a function of standing wave intensity, $I \propto \omega_R^{(2)}$, for a fixed interaction time, τ.

Atomic beam diffraction from an optical standing wave is a continuous-wave (CW) experiment in which the selectivity needed for the Bragg process is imposed by good angular resolution of the particle beam and a high degree of parallelism between the light crystal planes. This ensures that of the various final Bragg orders allowed by momentum conservation, only one conserves energy (energy conservation is exact in a CW experiment). For atoms scattering from a light crystal, parallelism of the crystal planes requires highly parallel photon momentum that implies a minimum width of the standing wave (the diffraction limit for the collimated photons). The transit time, τ, of the atoms across this width then exceeds the lower bound given in eqn [44].

The excellent collimation required of the atomic beam to ensure resolution of the Bragg scattered atoms reduces the intensity of the source by many orders of magnitude. A Bose–Einstein Condensate (BEC) is an attractive alternative source of atoms because its momentum spread is typically an order of magnitude below a single-photon recoil momentum. To Bragg diffract atoms initially in a stationary BEC, it is easier to move the light crystal than to accelerate the condensate. This is done by simply frequency shifting one of the traveling waves so that the resultant standing wave formed by its interference with the unshifted traveling wave moves with the proper velocity ($N_B\hbar k/m$) relative to the stationary atoms to impart the necessary momentum. The Bragg scattered atoms will then have momentum $2N_B\hbar k$ in the laboratory frame. The resonance condition thus becomes a condition on relative detuning, δ_{N_B}, between the two laser beams forming the diffraction grating. For N_B^{th}-order Bragg diffraction, the relative detuning is given by

$$\delta_{N_B} = \frac{2N_B\hbar k^2}{m} = 4N_B\omega_{\text{rec}} \qquad [50]$$

The first demonstration of Bragg scattering in a BEC was at NIST in 1999. They used Bragg scattering mainly as a tool to manipulate the momentum of the BEC, observing up to sixth-order processes. At MIT the interaction time was lengthened (to ≈100 times the lower bound of eqn [44] for first-order Bragg scattering), creating a new type of spectroscopy called Bragg Spectroscopy. It is a spectroscopic measurement of the shift of the Bragg scattering frequency due to the Doppler shift ($k \cdot v$) from the atoms' motion together with any mean field interaction. (These effects can be separated by going to higher-order Bragg scattering to enhance the Doppler shift.)

Bragg Spectroscopy was used to observe the momentum distribution of a BEC in a magnetic trap. The width of the Bragg resonance curve was primarily due to a 2 kHz Doppler-broadening that yielded the momentum distribution of the condensate. The spread in the corresponding velocity distribution was very small ($\approx 0.5\ \text{mm s}^{-1}$), even smaller than allowed by the Heisenberg uncertainty limit for a particle confined in the ground state of a harmonic trap. This reflects the increase in size of the condensate due to the mean field repulsion (^{23}Na, used in the MIT experiment, has a positive scattering length). The distribution was Heisenberg uncertainty limited at the observed size of the BEC, establishing for the first time that the coherence length of the condensate was equal to its size. In addition, the narrow Bragg resonance was shifted by the repulsive interactions within the condensate, resulting in a spectroscopic measurement of the mean-field energy.

Kapitza–Dirac Scattering

Diffraction of neutral atoms from a standing wave of near-resonant light with a short interaction time ($\tau_{KD} \ll 1/\omega_{\text{rec}}$) has come to be called Kapitza–Dirac scattering, in honor of their pioneering suggestion. In 1933, Kapitza and Dirac predicted that an electron beam propagating in a standing light wave would undergo stimulated Compton scattering and be reflected. This process has a tiny cross-section, equal to the classical electron radius squared: $\sigma_{\text{Compton}} = 8\pi/3(e^2/mc^2)^2 \approx 6 \times 10^{-25}\ \text{cm}^2$, and has only recently been observed using extremely high laser intensities. If the electrons are replaced by atoms, however, the scattering cross-section for resonant light $\sigma_{\text{atom}} = (1/2\pi)\lambda_{\text{photon}}^2 \approx 4 \times 10^{-10}\ \text{cm}^2$ is 15 orders of magnitude larger. This large cross-section, together with the ready availability of tunable lasers, has allowed stimulated scattering, both in the Kapitza–Dirac and Bragg regimes, to become the primary tool for the coherent manipulation of atoms.

In Kapitza–Dirac scattering, atomic motion during the interaction time is small compared to the characteristic dimensions of the interaction potential. This is equivalent to the eikonal approximation for scattering or the thin-lens approximation in optics. The idea is that the phase of the incident particle changes along each classical trajectory, but not the amplitude. Thus, there may be momentum transfer perpendicular to the trajectory, but the trajectory is not significantly displaced (until after the interaction is over). Mathematically, this regime

can be treated by neglecting the atomic kinetic energy term in the Hamiltonian (the Raman–Nath approximation).

The standing wave interaction may be treated by considering the standing wave (ac-Stark shift) potential resulting from the applied fields given in eqn [18]:

$$V(z,t) = \frac{\hbar\omega_R^2}{\delta} f^2(t)\sin^2(kz) \qquad [51]$$

where we have assumed $\delta \gg \Gamma$, because the constraint $N_s \ll 1$ (eqn [46]) holds in this regime as well, where N_s is the expected number of spontaneous emission events per atom during the time τ. Although we neglect the kinetic energy term in the Hamiltonian, we continue to will treat z in eqn [51] as an operator.

Given the initial atomic wavefunction in momentum space, $\psi(p_0)$, the atomic wavefunction immediately after the interaction is given by

$$\psi(p) = e^{-\frac{i}{\hbar}\int^t dt' U(z,t')}\psi(p_0) \qquad [52]$$

$$= e^{-i\frac{\omega_R^2}{2\delta}\tau} e^{i\frac{\omega_R^2}{2\delta}\tau\cos(2kz)}\psi(p_0) \qquad [53]$$

where $\tau = \int dt' f^2(t')$ and the integral is over the interaction duration. With the use of the identity for Bessel functions of the first kind, $e^{i\alpha\cos(\beta)} = \sum_{n=-\infty}^{\infty} i^n J_n(\alpha) e^{in\beta}$, the atomic wavefunction can be written as

$$\psi(p) = e^{-i\frac{\omega_R^2}{2\delta}\tau} \sum_{n=-\infty}^{\infty} i^n J_n\left(\frac{\omega_R^2}{2\delta}\tau\right) e^{i2nkz}\psi(p_0) \qquad [54]$$

$$= e^{-i\frac{\omega_R^2}{2\delta}\tau} \sum_{n=-\infty}^{\infty} i^n J_n\left(\frac{\omega_R^2}{2\delta}\tau\right) \psi(p_0 + 2n\hbar k) \qquad [55]$$

States with $2N\hbar k$ of momentum are populated with the probability:

$$P_N = J_N^2(\theta), \quad N = 0, \pm 1, \pm 2, \ldots \qquad [56]$$

where

$$\theta = \frac{\omega_R^2}{2\delta}\tau = \omega_R^{(2)}\tau \qquad [57]$$

is the pulse area. This leads to a transverse rms momentum of the diffracted atoms that is linearly proportional to the pulse area:

$$p_{\text{rms}} = \sum_{n=-\infty}^{\infty} (n\hbar k)^2 P_n = 2^{1/2}\theta\hbar k \qquad [58]$$

The maximum and minimum bounds on the interaction time, τ, and the amount of momentum transfer to the atoms are discussed in the next section.

Kapitza–Dirac diffraction of atoms was first observed at MIT in 1986. Diffraction of a well-collimated (subrecoil) supersonic atomic beam was observed after passage through the tightly focused waist of a near-resonant standing wave (Figure 11). Significant diffraction into momentum states $|g, \pm 10\hbar k\rangle$ was observed (Figure 12).

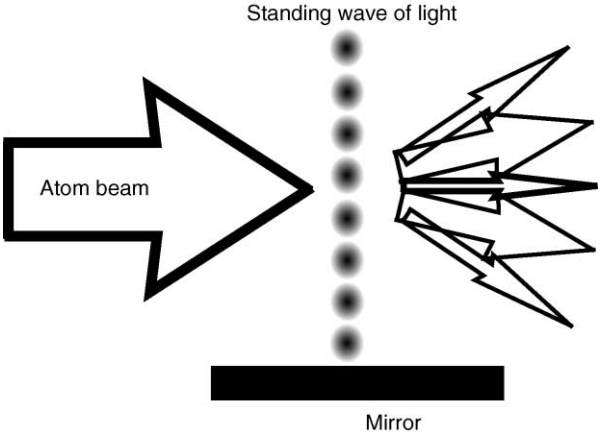

Figure 11 Two counter-propagating running waves of light superimpose to form a standing wave of light. The more narrow beam shown here represents the configuration for Kapitza–Dirac diffraction.

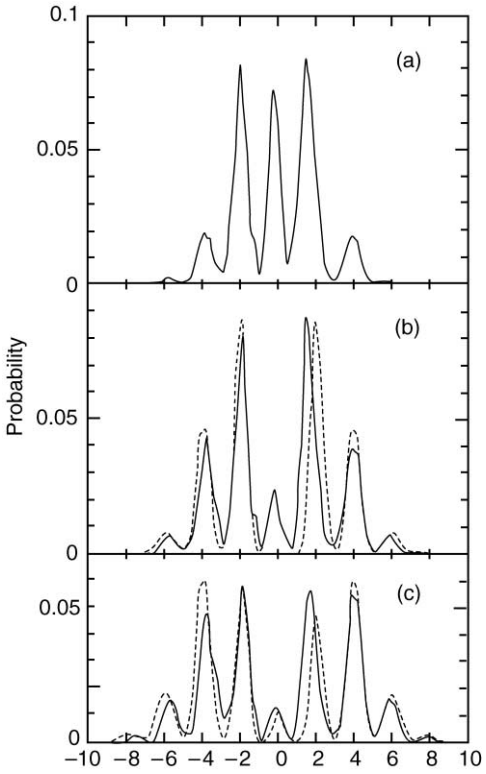

Figure 12 Kapitza–Dirac diffraction of an atomic beam from a standing wavelight grating. The solid lines are experimental data, the dashed lines are theoretical curves. Even higher diffracted orders should be observable in the future using laser beams directed at small BECs for somewhat longer times.

Comparison of Atom-Standing Wave Interactions

The atomic motion induced by interaction with a standing light wave varies qualitatively with the interaction parameters. Figure 13 summarizes the various interaction regimes of an atom with a standing wave in terms of the two most basic parameters: the two-photon Rabi frequency, $\omega_R^{(2)} = \omega_R^2/2\delta$, and the duration of the interaction, τ. To render the plot independent of atomic species, $\omega_R^{(2)}$ is given in units of the single-photon recoil frequency, ω_{rec}, and τ is given in units of the inverse single-photon recoil frequency, ω_{rec}^{-1}. Thus, for ^{23}Na the point (1,1) on Figure 13 corresponds to (6.4 μs, $2\pi \times 25$ kHz). The product of the two-photon Rabi frequency and the duration of the interaction is the pulse area, $\theta = \omega_R^{(2)}\tau$ (eqn [57]), which is likewise the product of the pair of coordinates forming a point on the plot.

The lines KD1(KD10) on Figure 13 show where the first maxima of $P_{1,10} = J_{1,10}^2(\theta)$ (eqn [56]) occur, corresponding to the maximum possible population transfer into the first and tenth Kapitza–Dirac diffracted order respectively. Since the momentum distribution of diffracted atoms depends only on the pulse area (θ), all Kapitza–Dirac orders are parallel to each other and further offset from the origin in increasing order number.

The Kapitza–Dirac regime ends at large interaction times where the Raman–Nath approximation fails due to motion of the atoms down the slope of the standing wave potential. We show these lines dashed as the interaction time approaches the beginning of the classical oscillation regime, and terminate these lines where the oscillation produces its first focus, at the first focus line. This line corresponds to the atoms completing a quarter period of oscillation in the standing wave potential, $\tau = \tau_{\text{osc}}/4$, where the oscillation time is derived from the approximation that the potential $\langle V(z,t)\rangle_t$ (eqn [51]) is harmonic

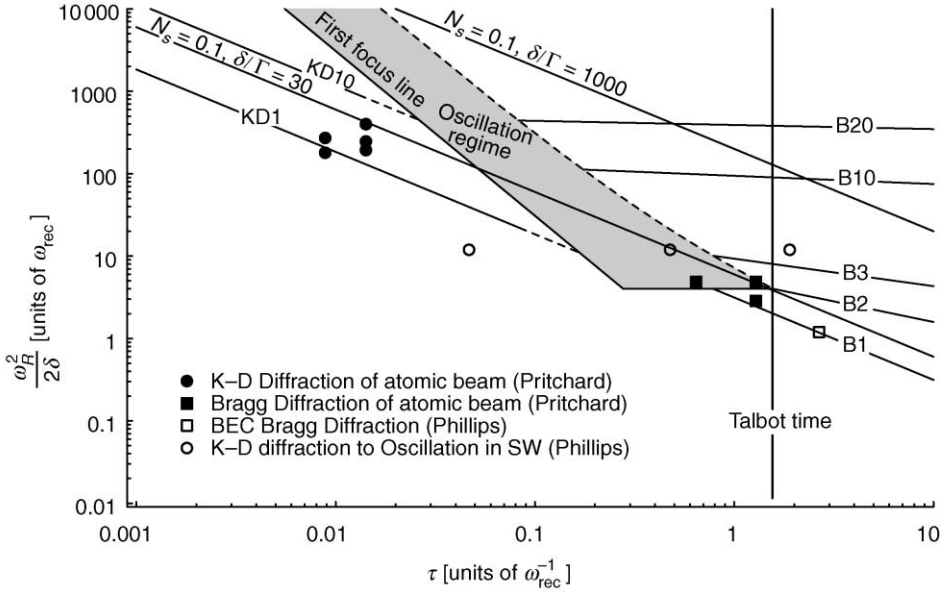

Figure 13 Atomic diffraction from a standing light wave. The vertical axis is the two-photon Rabi frequency, $\omega_R^2/2\delta$, in units of the single-photon recoil frequency, ω_{rec}, and the horizontal axis is the pulse duration, τ, in units of the inverse single-photon recoil frequency, ω_{rec}^{-1}. The scaling is chosen to eliminate the atomic species dependence of the plot. All coherent momentum transfer processes are destroyed by spontaneous decay, which occurs with probability $N_s = 0.1$ along the lines labeled accordingly and parameterized by the given ratio δ/Γ. Lines KD1 and KD10 show conditions for the maximum transfer into the first and tenth Kapitza–Dirac diffracted order respectively. As the interaction time is increased the Raman–Nath approximation is violated (termination of Kapitza–Dirac curves) and the atoms enter the oscillatory regime, executing at least a quarter period of oscillation above the first focus line (shaded area). Cures B1, B2, B3, B10, and B20 correspond to conditions that generate complete Bragg reflection in the first-, second-, third-, tenth-, and twentieth-order respectively. Experimental conditions are shown as points. Filled circles: Kapitza–Dirac diffraction of an atomic beam (Pritchard 1986). Filled squares: Bragg diffraction of an atomic beam (Pritchard 1988). Open squares: Bragg diffraction of a BEC (Phillips 1999). Open circles: transition from Kapitza-Dirac diffraction to oscillation of a BEC in a standing wave light pulse (Phillips 1999). about the minimum:

$$\tau_{\text{osc}} = \frac{\pi}{\omega_R}\left(\frac{|\delta|}{\omega_{\text{rec}}}\right)^{1/2} \qquad [59]$$

In the shaded region of Figure 13, the atoms will oscillate classically about the potential minimum, causing a periodic focusing of the atoms alternately in position and momentum space. However, anharmonicities of the potential away from its minimum will degrade the quality of the focusing effects.

The maximum diffracted order that can be significantly populated by the light–atom interaction is limited by energy conservation. Classically, the maximum momentum transfer to the atoms due to the sudden switch on of the standing wave is delivered to atoms that convert the full height of the standing wave potential ($\hbar\omega_R^2/\delta$), into kinetic energy. This gives

$$\frac{p_{\text{max}}^2}{2m} \simeq \frac{\hbar\omega_R^2}{\delta} \Rightarrow p_{\text{max}} \simeq \omega_R\left(\frac{2\hbar m}{\delta}\right)^{1/2} \qquad [60]$$

Equating the maximum absorbed momentum, p_{max}, to an integer number of two-photon recoil momenta yields the maximum expected diffracted order, N_{max}:

$$p_{\text{max}} = 2N_{\text{max}}\hbar k \Rightarrow N_{\text{max}} \simeq \frac{\omega_R}{2}(\omega_{\text{rec}}\delta)^{-1/2} \qquad [61]$$

This is just half of the square-root of the standing wave potential height measured in units of the single-photon recoil energy:

$$N_{\text{max}} = \frac{1}{2}\left(\frac{\omega_R^2}{\frac{\delta}{\omega_{\text{rec}}}}\right)^{1/2} = \frac{1}{2}\left(\frac{\omega_R^{(2)}}{\omega_{\text{rec}}}\right)^{1/2} \qquad [62]$$

As the two-photon Rabi frequency is reduced, N_{max} falls below unity. As a result, there is no longer time for the higher-order multi-photon processes to generate significant amplitudes in diffracted orders with $N > 1$ before dephasing due to the kinetic energy term (eqn [24]) becomes significant and the higher-order processes become negligible. Only a small population is ever transferred to the $N = \pm 1$ orders and it does not oscillate at ω_{rec}. Therefore the classical oscillation regime does not extend below $N_{\text{max}} \simeq 1$ where it is terminated on Figure 13.

Classical oscillation would result in atoms with momentum from zero up to the maximum allowed by energy conservation. Therefore, the classical focusing of atoms must be manifest as an atomic population distribution over many of the quantized momentum states (separated by $2\hbar k$) allowed by energy conservation (eqn [61]). However, as the interaction time lengthens and extends into the Bragg regime, the populated momentum states become restricted by energy conservation until only the oscillatory Pendellösung into and back from only one final state remains. Therefore, we have ended the classical oscillation regime where the Bragg condition (eqn [44]) is satisfied. The Bragg regime presupposes a smooth light pulse shape. For a pulse with sharp edges, classically oscillatory behavior can still be observed at longer times than included in the shaded region of Figure 13, which is why we show the large τ boundary of the classical oscillation regime as dashed.

In the Bragg regime, transfer of population is restricted to (and back from) only one final momentum state. The allowable final states are restricted by limiting the frequency bandwidth (i.e., energy uncertainty) of the light fields in the atomic rest frame. This is accomplished by lengthening the interaction time and smoothing the rise and fall of the electromagnetic fields. The parameters for a first-order Bragg transition (Table 1) are typically $\delta/\Gamma \simeq 50$, $\Gamma\tau \simeq 1$, and $\omega_R/\Gamma \simeq 10$ giving $N_s \simeq 10^{-2}$ and $\omega_R^{(2)}\tau \simeq 1$. Obtaining significant population transfer with higher-order Bragg processes requires larger intensities. Various orders (1, 2, 3, 10, and 20) of Bragg diffraction are shown as lines on Figure 13 corresponding to $\omega_R^{(2N_B)}\tau = \pi$, where $\omega_R^{(2N_B)}$ is given in eqn [40]. The lines are terminated at the appropriate interaction time determined from the final momentum state resolution condition (eqn [44]). The Bragg regime extends indefinitely to larger interaction times, which might be termed the region of Bragg spectroscopy. In experiments in this regime with ^{23}Na, atomic velocity resolution below 1 mm s^{-1} was obtained at $\tau = 80\omega_{\text{rec}}^{-1}$. The study of adiabatically expanded BECs would require larger interaction times to resolve their smaller velocity spread and weaker mean field shifts.

The Kaptiza–Dirac and Bragg regimes assume a different initial atomic momentum (in the rest frame of the standing wave) parallel to the standing

Table 1 Natural parameters and typical experimental parameters involved in standing wave diffraction. The relevant frequencies together with the corresponding times ($1/\omega$) are tabulated. The parameters for ^{23}Na have been used for system dependent quantities

ω	$\omega/2\pi$	$1/\omega$
ω_0	500 THz	0.3 fs
δ (Bragg)	500 MHz	0.3 ns
ω_R (Bragg)	100 MHz	1.6 ns
ω_R (K–D)	100 MHz	1.6 ns
Γ	10 MHz	16 ns
ω_{rec}	25 kHz	6.4 μs
ω_{osc}	1 MHz	160 ns

wave axis. Kapitza–Dirac scattering assumes no component of the initial atomic momentum along this axis. The efficiency of Kapitza–Dirac diffraction falls rapidly as the initial momentum in units of the photon momentum approaches $1/\omega_{\text{rec}}\tau$. To observe N_B^{th}-order Bragg scattering, the initial atomic momentum along the standing wave axis must have (nonzero) magnitude $N_B\hbar k$. Without adhering to this constraint, no final momentum state will be energetically degenerate with the initial state and the atomic sample will not respond to the presence of the standing wave, even if the interaction parameters are appropriate ($\omega_R^{(2N_B)}\tau \simeq 1$) for N_B^{th}-order Bragg scattering.

The condition $N_s = 0.1$ (eqn [46]), where N_s is the expected number of spontaneous emission events per atom during the light–atom interaction, is drawn on Figure 13 for two ratios (30 and 1000) of standing wave detuning, δ, to the atomic excited state natural lifetime, Γ. For fixed δ/Γ, we see that $N_s \propto \theta$, thus conditions with an increased pulse area (above and to the right of the $N_s = 0.1$ lines) result in a proportionally increased N_s. These $N_s = 0.1$ lines are extended across all regimes of Figure 13 because restricting spontaneous emission is required for both Kapitza–Dirac and Bragg scattering. As N_s approaches unity, the correct optical potential describing the light–atom interaction no longer is eqn [51], and scattering of atoms becomes an incoherent process which can lead to new possibilities such as a complex valued optical potential. Thus, while the standing wave fields in pure Bragg or Kapitza–Dirac scattering behaved as phase gratings for atoms, light gratings on resonance can effectively become amplitude diffraction gratings.

Atom Interferometry

In the 19th century, Fizeau (1853), Michelson (1881), Rayleigh (1881), and Fabry and Perot (Fabry 1899) exploited the interference properties of light waves to create the light interferometer which has since resulted in many beautiful experiments and precise measurements. Using technologies invented since the Second World War, the initial ideas of de Broglie and Schrödinger have evolved into construction of interferometers for neutrons, electrons, and atoms. These new interferometers are proving to be valuable tools for probing fundamental physics, for studying quantum mechanical phenomena, and for making inertial measurements.

The scientific value of interferometry with atoms and molecules has long been recognized. In fact, the concept of an atom interferometer was patented in 1973 and it has been extensively discussed since. Atom interferometry offers great richness stemming from the varied internal structure of atoms, the wide range of properties possessed by different atoms (e.g., mass, magnetic moment, absorption frequencies, and polarizability), and the great variety of interactions between atoms and their environment (e.g., static E–M fields, radiation, and other atoms).

Light interferometers are generally based either on achromatic beamsplitters such as half-silvered mirrors or on other semi-transparent membranes whose structure is small compared to the wavelength of the wave they are splitting. Lacking material structures that are either transparent to atoms or smaller than their de Broglie wavelength, diffraction gratings have been pressed into service both as beamsplitters and mirrors for atom waves. This means that atom interferometers are constrained to designs which somehow compensate for the dependence of diffraction angle on the wavelength of the individual atoms. In spite of this challenge, a surprising variety of atom and molecule interferometers have been built since 1991. A majority have used the three-grating configuration in which the first grating splits the incident beam, the second reverses the differential momenta given by the first, and the third recombines the two beams at the location where they overlap. Both material gratings and standing waves of light have been used in the Raman–Nath, Bragg, and adiabatic regimes to obtain interference fringes. Some designs render the interference fringes in position space, others in internal state space.

Figure 14 shows the MIT setup for a three-grating atom interferometer which features sufficient separation between interfering paths to accommodate an interposed metal foil. This allows different fields or media to act on atom waves only in one of the two

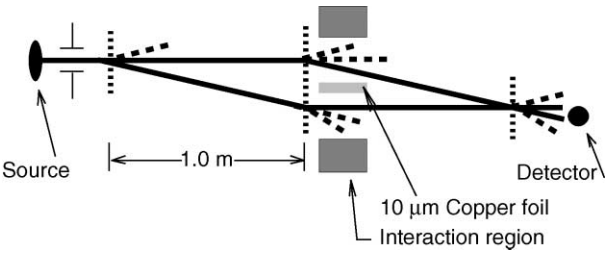

Figure 14 An interferometer for atoms built with three nanofabricated gratings. Each atom propagates in a superposition of two paths, shown in bold. The beam of atoms is well enough collimated, and the diffraction angle is large enough, that a metal barrier can be inserted between the two paths inside the interferometer. The interference fringes are observed by translating one grating transverse to the atom beam. See for example: Berman PR (ed.) (1997) *Atom Interferometry*. San Diego, CA: Academic Press.

arms of the interferometer. Such an interaction region has been used to measure phase shifts due to an electric field applied to only one of the interfering paths. The phase difference between the two paths is then given by the Feynman path integral:

$$\phi = \frac{-i}{\hbar}\int V(x)dt \qquad [63]$$

where

$$V = -\frac{1}{2}\alpha E^2 \qquad [64]$$

is the potential energy due to the electric filed E, and α is the electric polarizability of the atoms. The resulting phase shift of the interference fringes (**Figure 15**) has been used to measure the polarizability of sodium atoms to unprecedented accuracy.

Phase shifts have also been measured due a dilute target gas in one arm of the interferometer. In this case there is a complex index of refraction for the forward scattered atoms (some attenuation, and some phase shift) which depends on matter wave wavelength. Recent measurements reveal glory oscillations in the matter wave index of refraction due to passing through a dilute gas, and are a sensitive probe of interatomic potentials.

In the domain of inertial sensing, atom interferometers have been used to the local gravitational acceleration, $\vec{g}$, Newton's constant, G, gravity gradients, $\nabla\vec{g}$, and rotations Ω, each with sensitivity rivaling if not exceeding any other method. The Sagnac phase shift, due to rotations, for a two-path interferometer is

$$\phi_S = \frac{4\pi}{\lambda_{dB}v}\vec{\Omega}\cdot\vec{A} \qquad [65]$$

where v is the velocity of atoms, $\vec{A}$ is the enclosed area of the interferometer, and $\vec{\Omega}$ is the rotation rate. The two factors in the denominator, λ_{dB} and v, are both $\sim 10^5$ times larger for light than for atoms, which is why atom interferometers have the potential to be 10^{11} times more accurate than optical interferometers. In practice, atom interferometers only outperform laser gyros by a small amount because they have dramatically smaller enclosed areas and particle flux than optical interferometers.

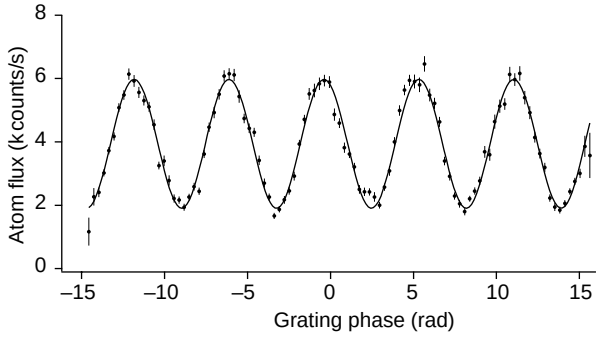

Figure 15 Interference fringes from atoms. 2π of grating phase corresponds to translating the grating one grating period, or 100 nm. These data were obtained at MIT.

Since the first atom interferometers for Na and He^* began working in 1991, others have been made for Li, Ar^*, Ca, Cs, K, Mg, Ne^*, Rb, and Li_2, Na_2, I_2, C_{60} and C_{70} molecules, interferometers starting with trapped atoms have been made for Cs, Ca, He^*, Mg, and Rb. Interferometers using Bose–Einstein condensates have been demonstrated with Na and Rb. These lists are still growing. Diffraction from a single grating has been observed for molecules as large as C_{70} buckyballs, which may someday be used in a three-grating interferometer.

Conclusion

The manipulation of atoms using light forces from standing light waves is a rich subject. The seminal suggestion of Kapitza and Dirac laid dormant for 50 years due to lack of experimental technology. However, in the 1980s this suggestion was realized with atomic sources and considerably extended both experimentally and theoretically. In the early 1990s, coherent standing wave manipulation and nonofabricated atom optics became the two major routes to making atom interferometers. As the new century begins, these techniques are being refined further with improved sources, new detection schemes, and better atom optics. Replacing thermal atomic beams by Bose–Einstein condensates (BECs), as sources of atoms, will revolutionize the field of atom optics just as lasers did in light optics.

Conversely, stimulated light scattering and nanostructures provide new ways to study atomic and molecular properties, such as Bragg spectroscopy for BEC characterization. As progress continues, exciting developments should be forthcoming, such as definitive measurements of the fine structure constant, α, atom gyroscopes that are far superior to the best laser gyroscope technology, and improved studies of BECs. Another area that is on the brink of spectacular development is the confinement of coherent matter waves in atom waveguides and the development of the scientific and technological opportunities that these represent, in analogy to fiber optic waveguides for light.

While we have described the application of nanofabrication techniques to atom optics, it is possible to imagine technology transfer in the other direction. The fundamental problem of fabricating

ever smaller structures might be tremendously advanced by atom optics because the de Broglie wavelength of atoms is so much smaller than that of light, permitting them to be focused to directly deposit much smaller features than possible with photolithography.

History and Perspective

Quantum optics and laser physics have entered a new era. This started with the invention of the laser and the associated theoretical developments such as the theory of photon correlations and statistics, and the quantum theory of the laser. Later, new and novel lasers such as the free electron laser and tunable dye laser fueled many new research directions. With the development of the micromaser, quantum optics became a beautiful new test bed for the study of nonequilibrium statistical physics of photons interacting with matter in a controlled environment. The realization that a deeper understanding was needed to understand the measurement process led to the utilization of the laser as a probe of gravity, and to insight into nonclassical processes such as quantum nondemolition measurements and the production of squeezed states of light.

Effects of atomic coherence in quantum electronics have a long history. One of the first examples was the Hanle effect: excitation by polarized light creates atomic coherence that can evolve in a magnetic field, causing the change of polarization of the resulting fluorescence. Another important example is the interference of decay processes, first suggested by Fano. Modern schemes utilizing quantum coherence in atomic vapors or solid media usually involve strong coupling laser fields (laser drives). In each case, the effect of quantum coherence can be understood as interference of multiple (usually two) transition paths between quantum states of a system.

In the past decade, the concepts of atomic coherence and interference have led to many new and surprising innovations in laser physics such as electromagnetically induced transparency (EIT), refractive index enhancement, lasers without population inversion, ultra-slow light group velocity, storage of the quantum states of light, teleportation of quantum states, and nonlinear optics at an ultra-low intensity level.

Electromagnetically Induced Transparency

One of the most vivid manifestations of quantum coherence effects is the reduction of absorption in a three-level system that is driven by a coherent laser field. This effect is known as electromagnetically induced transparency, or EIT. We consider in more detail the case when the probe and drive fields are in a so-called Λ-configuration (Figure 1a) named after the appearance of the level scheme. In the conventional usage, the two lower levels are coupled to the upper level with two lasers. One of the lasers may be strong and is called the driving or coupling laser, and the other is weak and is called the probe laser.

Consider a quasi-monochromatic laser field E_d (called the 'driving' field, or 'coupling' field) and probe field E_p interacting with a three-level medium of Figure 1a. This interaction is described by a density matrix ρ_{ij}, where i, j take the values a, b, c. Within the

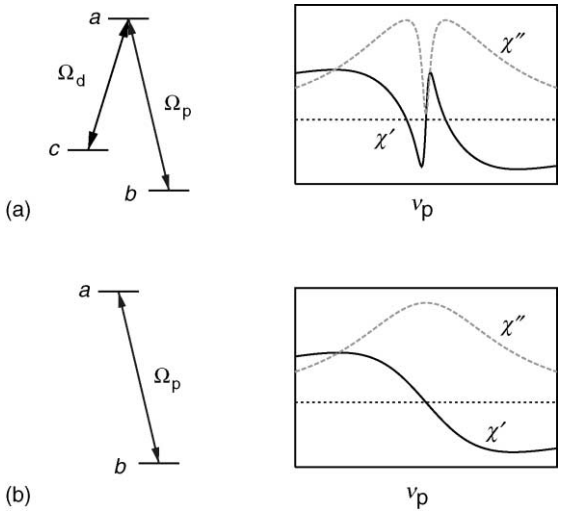

Figure 1 Real and imaginary parts of the susceptibility as functions of the frequency of the probe laser for (a) three-level Λ–type atoms, and (b) two-level atoms.

density matrix approach, quantum coherence in the system has the precise meaning of an off-diagonal element of the density matrix at the two-photon transition c–b. To have strong quantum coherence in a Λ-system, one must excite a large value of ρ_{cb}.

It is convenient to simplify the equations from the very beginning by using the rotating-wave approximation. We introduce slowly varying complex amplitudes of fields and polarizations and neglect their second derivatives. For example, for the probe field applied at the $a \rightarrow b$ transition we write

$$E_{\mathrm{p}}(z,t) = \frac{1}{2}\varepsilon_{\mathrm{p}}(z,t)\exp(-\mathrm{i}\omega_{\mathrm{p}}t + \mathrm{i}k_{\mathrm{p}}z) + \mathrm{c.c.} \qquad [1]$$

After introducing the complex Rabi frequency $\Omega_{\mathrm{p}}(z,t) = d_{\mathrm{p}}\varepsilon_{\mathrm{p}}(z,t)/2\hbar$, the wave equation for waves propagating in the z-direction can be written as

$$\frac{\partial\Omega_{\mathrm{p}}}{\partial z} + \frac{n_{\mathrm{p}}}{c}\frac{\partial\Omega_{\mathrm{p}}}{\partial t} + \kappa_{\mathrm{p}}\Omega_{\mathrm{p}} = \frac{2\pi\mathrm{i}\nu_{\mathrm{p}}d_{\mathrm{p}}^2N}{\hbar c n_{\mathrm{p}}^2}\sigma_{ab} \qquad [2]$$

Here d_{p} is the dipole moment of the probe transition a–b, N the total volume density of atoms in the active region, κ_{p} represents cavity losses, and $n_{\mathrm{p}} = k_{\mathrm{p}}c/\omega_{\mathrm{p}}$ is the refraction index. The variable σ_{ab} is the slowly varying amplitude of the corresponding off-diagonal element $\rho_{ab} = \sigma_{ab}\exp(-\mathrm{i}\nu_{\mathrm{p}}t)$ of the density matrix. The same representation is assumed for the drive field E_{d}, with parameters n, d, ν, κ having index 'd'.

The functions σ_{ab}, σ_{ac}, and σ_{cb}, which determine the polarization response of the medium at the frequency of the external field, should be found from the density matrix equations

$$\frac{\mathrm{d}\sigma_{cb}}{\mathrm{d}t} + \Gamma_{cb}\sigma_{cb} = -\mathrm{i}\Omega_{\mathrm{p}}\sigma_{ac}^* + \mathrm{i}\Omega_{\mathrm{d}}^*\sigma_{ab} \qquad [3]$$

$$\frac{\mathrm{d}\sigma_{ab}}{\mathrm{d}t} + \Gamma_{ab}\sigma_{ab} = \mathrm{i}\Omega_{\mathrm{p}}n_{ba} + \mathrm{i}\Omega_{\mathrm{d}}\sigma_{cb} \qquad [4]$$

$$\frac{\mathrm{d}\sigma_{ac}}{\mathrm{d}t} + \Gamma_{ac}\sigma_{ac} = \mathrm{i}\Omega_{\mathrm{d}}n_{ca} + \mathrm{i}\Omega_{\mathrm{p}}\sigma_{cb}^* \qquad [5]$$

where

$$\begin{aligned}\Gamma_{cb} &= \gamma_{cb} + \mathrm{i}(\nu_{cb} - \nu_{\mathrm{p}} + \nu_{\mathrm{d}}),\\ \Gamma_{ab} &= \gamma_{ab} + \mathrm{i}(\nu_{ab} - \nu_{\mathrm{p}}),\\ \Gamma_{ac} &= \gamma_{ac} + \mathrm{i}(\nu_{ac} - \nu_{\mathrm{d}})\end{aligned} \qquad [6]$$

Here the γ's are relaxation rates of the polarizations at the corresponding transitions (the so-called homogeneous broadening). The population differences $n_{ik} = \rho_{ii} - \rho_{kk}$ are defined from eqns [2]–[6] together with the three equations for $\rho_{ii}, i = a, b, c$, with phenomenological rates of population relaxation and pumping:

$$\begin{aligned}\frac{\mathrm{d}\rho_{bb}}{\mathrm{d}t} &= -2\mathrm{Im}[\Omega_{\mathrm{p}}^*\sigma_{ab}] + r_{cb}\rho_{cc} + r_{ab}\rho_{aa} - r_{ba}\rho_{bb}\\ \frac{\mathrm{d}\rho_{cc}}{\mathrm{d}t} &= -2\mathrm{Im}[\Omega_{\mathrm{d}}^*\sigma_{ac}] + r_{ac}\rho_{aa} - r_{cb}\rho_{cc}\\ \frac{\mathrm{d}\rho_{aa}}{\mathrm{d}t} &= 2\mathrm{Im}[\Omega_{\mathrm{p}}^*\sigma_{ab}] + 2\mathrm{Im}[\Omega_{\mathrm{d}}^*\sigma_{ac}] + r_{ba}\rho_{bb}\\ &\quad - (r_{ab} + r_{ac})\rho_{aa}\end{aligned} \qquad [7]$$

Here we have included only the pumping term r_{ba} between levels b and a for simplicity. Later, we will consider the effect of incoherent pumping on gain, but in this section we put $r_{ba} = 0$. The sum of populations is evidently conserved in this model. Analysis of open systems with, e.g., flow of atoms through a cavity, leads to qualitatively similar conclusions.

Suppose that the probe field is weak, $|\Omega_{\mathrm{p}}|^2 \ll \gamma_{cb}\gamma_{ac}$, and the drive-field intensity is constant in a sample. The complex susceptibility at the probe-field frequency, which is proportional to $\sigma_{ab}/\varepsilon_{\mathrm{p}}$, is given by

$$\chi = \frac{\mathrm{i}d_{\mathrm{p}}^2N}{\hbar c}\left\{\frac{1}{\Gamma_{ab} + |\Omega_{\mathrm{d}}|^2/\Gamma_{cb}}\left(n_{ba} - \frac{|\Omega_{\mathrm{d}}|^2 n_{ca}}{\Gamma_{cb}\Gamma_{ac}^*}\right)\right\} \qquad [8]$$

This expression can be further simplified if there is no pumping to the states $|c\rangle$ and $|a\rangle$, so that we can

assume that $n_{ca} = 0$ and drop the second term in the brackets. The behavior of χ as a function of detuning from resonance $\nu_p = \nu_{ab}$ is shown in Figure 1a. In the absence of the drive field Ω_d, we retrieve the usual two-level susceptibility, shown in Figure 1b.

There are two remarkable features in the susceptibility of Figure 1a. The first one is the transparency window at the point of two-photon resonance. The absorption coefficient at resonance is

$$K'' = \frac{2\pi\nu_p d_p^2 N}{\hbar c(\gamma_{ab} + |\Omega_d|^2/\gamma_{cb})} \qquad [9]$$

Clearly, absorption can be arbitrarily small when $\gamma_{cb} \ll \gamma_{ab}$ and $|\Omega_d|^2 \gg \gamma_{cb}\gamma_{ab}$, since it is proportional to $\gamma_{cb}/|\Omega_d|^2$. For any value of $|\Omega_d|^2$, the absorption is much smaller than that resulting from simple Stark splitting of two Lorentzians. Moreover, in the most interesting case

$$\gamma_{cb}\gamma_{ab} \ll |\Omega_d|^2 \ll \gamma_{ab}^2$$

the Stark splitting is negligible while the deep and narrow EIT feature remains, with width $\gamma_{cb} + |\Omega_d|^2/\gamma_{ab}$.

Note that the intensity of the drive field required for the coherent bleaching of the medium is a factor $r_{ab}/\gamma_{cb} \gg 1$ smaller than the intensity needed for usual saturation bleaching.

EIT is closely related to the phenomenon of coherent population trapping (CPT). This can be illustrated by transforming from states $|a\rangle$, $|b\rangle$, $|c\rangle$ to a new set of states $|a\rangle$, $|B\rangle$, $|D\rangle$, where

$$|D\rangle = (\Omega_d|b\rangle - \Omega_p|c\rangle)/\sqrt{|\Omega_d|^2 + |\Omega_p|^2}$$

$$|B\rangle = (\Omega_d|b\rangle + \Omega_p|c\rangle)/\sqrt{|\Omega_d|^2 + |\Omega_p|^2}$$

It can be easily found that under the condition of two-photon resonance $\nu_p - \nu_d = \nu_{cb}$ the dipole matrix element from $|D\rangle$ to $|a\rangle$ goes to zero. This means that the population in state $|D\rangle$ does not interact with the coherent radiation field and does not contribute to absorption. That is why this state is called a non-absorbing or dark state. Under the condition $|\Omega_d|^2/\gamma_{cb}\gamma_{ab} \gg 1$ practically all the population of states $|b\rangle$ and $|c\rangle$ is optically pumped into the dark state, and only a small fraction $\propto \gamma_{cb}$ remains in the absorbing state $|A\rangle$ and contributes to absorption.

The second remarkable feature of a driven Λ-system is sharp variation of the real part of χ near the resonance, which can be used for manipulation of the group velocity of light, as discussed in the next section.

Slow, Ultra-Slow, Stored, and Frozen Light

Introduction

There are five useful definitions for the velocity of a traveling wave:

- the phase velocity, which is the speed at which the zero crossings of the carrier wave move;
- the group velocity, at which the peak of a wave packet moves;
- the energy velocity, at which energy is transported by the wave;
- the signal velocity, at which the half-maximum wave amplitude moves;
- the front velocity, at which the first appearance of a discontinuity moves.

Although these can all be different, in most cases (linear, passive, dispersive media) the last four coincide, and are usually less than the phase velocity. By using the very steep frequency dispersion in the vicinity of the narrow resonance associated with electromagnetically induced transparency (EIT), it has been shown that the group velocity of light can be reduced by approximately 100 million compared with its velocity in vacuum.

In order to understand the concept of group velocity, it is useful to consider the superposition of two waves of the same amplitude E_1 and E_2 where $E_i = E_0\cos(k_i z - \nu_i t)$ with $i = 1, 2$. Addition of these waves gives rise to the modulation shown in Figure 2:

$$E = E_0(\cos(k_1 z - \nu_1 t) + \cos(k_2 z - \nu_2 t))$$

$$= 2E_0\cos(\Delta k z - \Delta\nu t)\cos(kz - \nu t)$$

where $\Delta k = (k_1 - k_2)/2$, $\Delta\nu = (\nu_1 - \nu_2)/2$, $k = (k_1 + k_2)/2$, and $\nu = (\nu_1 + \nu_2)/2$. This superposition

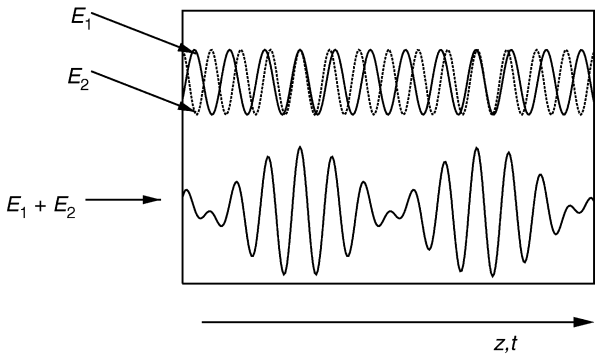

Figure 2 Interference of two monochromatic waves with different frequencies results in a wave modulated in time and space.

displays an interference pattern consisting of a rapid oscillation propagating with the so-called phase velocity,

$$v_{\text{phase}} = \frac{\nu}{k} \qquad [10]$$

and a slowly varying envelope propagating at the group velocity,

$$v_{\text{g}} = \frac{\Delta\nu}{\Delta k} \qquad [11]$$

Usually, the group velocity of wave packets consisting of more than two harmonics is given by transforming the ratio $\Delta\nu/\Delta k$ into $\mathrm{d}\nu/\mathrm{d}k$.

Slow and Ultra-Slow Light

In ordinary absorption and refraction of light, it is sufficient to consider only two atomic energy levels interacting with the light. However, in multilevel systems, coherent excitation of more than one transition can dramatically alter the dispersion and hence the group velocity. The first experiments of this effect demonstrated a group velocity of $c/13$. However, this was progressively lowered in later experiments as the steepness of the dispersion was increased, culminating in a group velocity as low as $c/300\,000\,000$ (1 m/s) in a Bose–Einstein condensate of ultra-cold sodium atoms. Slow light has been observed in a wide range of systems, from the Bose–Einstein condensates just mentioned, to hot optically dense gases of atoms and molecules, and in solids ranging from rare-earth doped crystals to solid hydrogen.

Most of these experiments occurred in a Λ system. The susceptibility of this medium has very steep dispersion without absorption, as shown in Figure 1.

The minimum possible group velocity slowed by the steep dispersion in EIT is given by

$$v_{\text{g}} = \frac{8\pi\Omega^2}{3\lambda^2 N\gamma} > 0 \qquad [12]$$

where $\gamma = \gamma_{ab} = \gamma_{ac}$. The driving field Ω should be strong enough to meet the condition $\Omega^2 \gg \gamma\gamma_{bc}$ for coherent effects. It can be shown that the group velocity approaches its minimum $v_{\text{g min}} = 8\pi\gamma_{bc}/(3\lambda^2 N)$ when $\Omega^2 \approx \gamma\gamma_{bc}$.

Bringing Light to a Halt: Frozen Light

Consider a laser pulse propagating through a medium with ultra-slow group velocity while the medium itself is moving with some velocity v in the opposite direction to the direction of laser pulse propagation. Let us denote the group velocity of the light in the frame co-moving with the atoms as $\tilde{v}_{\text{g}}$. In this frame, atoms are at rest, and hence, there is no spatial dispersion. The Galilean transformation to the laboratory frame, $k = \tilde{k}$, $\nu = \tilde{\nu} - \tilde{k}v$, where v is the atomic velocity, yields the group velocity $v_{\text{g}} = Re(\mathrm{d}\nu/\mathrm{d}k) = \tilde{v}_{\text{g}} - v$. This simple transformation shows that the light pulse is 'dragged' by the moving atoms. If the velocity of the atoms with respect to the laboratory frame is exactly equal and opposite to the group velocity of light in the frame where atoms are at rest, then we find that the group velocity in the laboratory frame is zero. We refer to this as 'freezing' of light. We may even make the group velocity negative so that the propagation direction is opposite to the wavevector (that is, that $v_{\text{g}} < 0$). The simplest example of spatial dispersion is the so-called drift dispersion corresponding to a mono-velocity atomic beam or moving sample with velocity v.

Slow light experiments in Doppler broadened systems such as warm gases allow group velocities that are much lower than the mean thermal speed (v_{T}) of the atoms in the thermal sample (Figure 3). This means that freezing of light can occur without actually moving the atomic sample. When the experimentally obtained group velocity is less than or about equal to the mean thermal speed of the atoms, a pulse of light can be stopped in a stationary cell. In this case the delay time for a pulse passing through the medium would tend to infinity (contrary to the case of a finite atomic beam) in the sense that this pulse would never leave the cell.

This is accomplished by using a single velocity group from the Maxwellian thermal distribution of atomic velocities, and adjusting the frequency of the driving field to be resonant with that velocity group (see Figure 4). In this case it is mainly the atoms in this single velocity group that support the ultra-slow group velocity as a slow EIT polariton, and the atoms

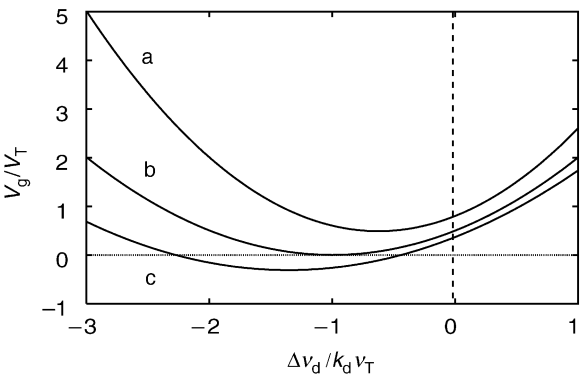

Figure 3 Ultra-slow and negative group velocity of EIT polariton versus detuning of drive laser; $\Omega = 0.25\gamma$, $k_{\text{d}}\nu_{\text{T}} = 100\gamma$, $\gamma_{cb} = 0.001\gamma$, (a) $N = 0.6\,N_{\text{cr}}$; (b) $N = N_{\text{cr}}$; (c) $N = 1.5\,N_{\text{cr}}$.

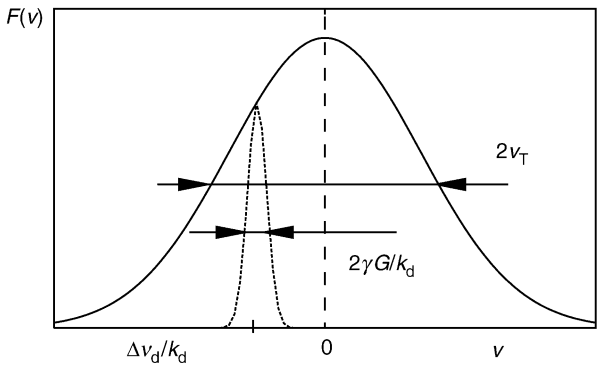

Figure 4 The velocity distribution of atoms in a cell (solid line). Effective drifting beam (dotted) selected by drive laser.

then act as an effective atomic beam. If the driving field is on resonance with the velocity group of atoms moving into the light with speed equal to $\tilde{v}$, we will have $v_g = \tilde{v}'_g - v_d$, where $\tilde{v}'_g$ is the group velocity of the light defined by the effective atom beam if those atoms were at rest. This requires that the intensity of the drive is strong enough to provide EIT for the resonant velocity group of atoms, i.e., $\Omega^2 > \gamma_{bc}\gamma$ (see Figure 4) but at the same time weak enough to avoid interaction with off-resonant atoms moving with the 'wrong' velocities (i.e. $\Omega < kv_T\sqrt{\gamma_{bc}/\gamma}$).

Storing and Retrieving Quantum Information

Photons are potentially the best particles for use in quantum computing and quantum information processing. They are the fastest, and perhaps the simplest and most robust carriers of quantum information, but their storage and manipulation is difficult without destroying their quantum state. However, for application to quantum cryptography, quantum teleportation, and quantum computation it is necessary to achieve a strong coupling between electromagnetic waves and a large nonlinear susceptibility with small losses. For this task, it may be resonant coherent media that offer the promise of success.

Recently, new coherent and reversible methods based on EIT have been found for the transfer and manipulation of photons and their quantum information. Quantum states of photons are trapped in coherently driven atomic media in which the group velocity is reduced adiabatically toward zero. The methods allow for an ideal transfer of quantum correlations between light fields and metastable states of matter. Currently, interesting applications such as quantum state memories and quantum information processing including transporting and time reversing the state of light are being investigated.

Although experiments have not yet been conducted with single quanta, proof-of-principle experiments using classical laser fields have demonstrated the technique. In these experiments control and signal light pulses propagate in a gas of three-level Λ-type atoms and excite a spatial profile of a long-lived coherence of ground spin states. This spin coherence profile contains quantum information about the 'writing' pulses. When the control field is switched back on, the signal pulse is restored via Raman scattering on the atomic coherence. Ideally, the scattered pulse is in the same quantum state as the input signal pulse, preserving entanglement, quantum statistics, etc.

Similar experiments have also shown that different reading pulses (rather than switching back on the same control pulse) can be used to obtain new tools for quantum information storage and processing. Time reversing, teleportation, color switch and multiplexing of the signal pulse of light have all been demonstrated. These new operational possibilities arise as a result of the reading of the stored information with a light pulse that is spatially separated from, has different frequency from, and propagates in the opposite direction to the signal beam.

To demonstrate these effects, one pair of control and signal pulses (the 'writing' fields) prepares a spin coherence of the lower level (Figure 5). A second control pulse (which can be thought of as a 'reading' field) scatters from this coherence resulting in the generation of a new, or 'recovered', field. This recovered field acquires some properties of the reading field because it is a Raman scattered component of the reading pulse. If the reading field pulse is centered about a frequency other than that of the writing fields, and propagates in the opposite direction to the writing fields, then the recovered field propagates in the same direction as the reading field and has a different frequency from the incident writing fields. Even if the writing and reading pulses are separated in space as well as time the scattering effect will persist. This allows the transportation of the coherence grating to another point in the atomic cell via the atomic center-of-mass motion.

In the ideal case the signal pulse profile and quantum statistics are exactly stored by the atomic coherence grating. Thus, reading by a backward propagating pulse results in a generated pulse that is also backward propagating. That is it represents an exactly time-reversed copy of the signal pulse. Similarly, atomic motion in the direction transverse to the light propagation moves the coherence grating to another spatial position. Reading the light by a spatially shifted laser results in the equivalent of

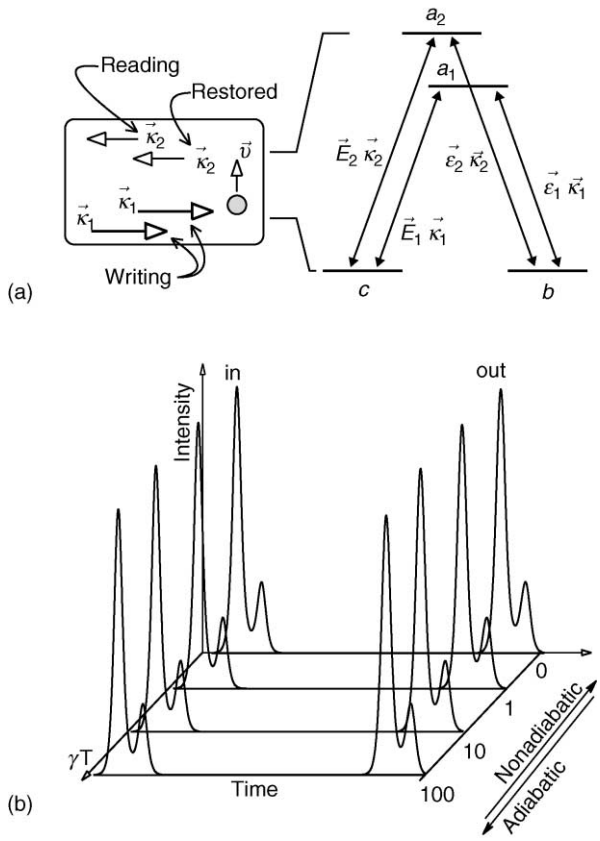

Figure 5 (a) Energy level scheme used in experiments for multiplexing, transporting, and time-reversing stored light. (b) 'Storage of light': intensity of the signal field versus time for different switching times (T) of the reading and writing fields.

'teleportation' of light by atoms in the same spirit as the teleportation of the quantum state of light by atoms that has been discussed recently. It is also possible for the frequency of the 'restored' pulse to be easily shifted by switching the frequency of the reading pulse. This means that the use of a frequency comb of reading pulses propagating in different spatial modes should result in multiplexing of the signal light.

Novel Laser Sources Based on Quantum Coherence

Introduction

In the previous sections we have seen how quantum coherence can be used to overcome resonant absorption on a transition of interest, leading to EIT. A natural question arises whether it is possible to achieve gain without population inversion at this transition, i.e. lasing without inversion (LWI). This subject has been intensively investigated since

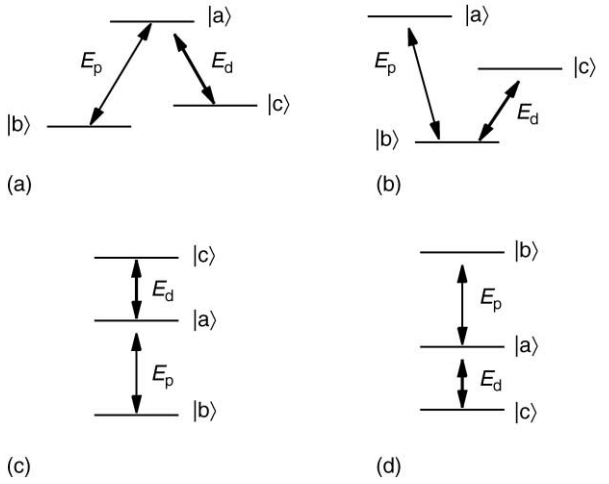

Figure 6 LWI schemes in a three-level system coherently driven by a laser field.

the early 1990s, and the first proof-of-principle experiments have been successful.

Besides the fundamental physical beauty of this phenomenon, the research effort has been motivated by potentially important applications. It is clear that LWI could be particularly useful in situations where a population inversion is difficult to maintain due to, e.g., very fast relaxation or inefficient pumping. The obvious examples are high-frequency UV, X-ray and gamma-ray lasers, or semiconductor mid/far-infrared lasers based on intersub-band transitions. Another promising application of LWI is efficient frequency up- or down-conversion. Furthermore, if resonant absorption can be eliminated, resonant nonlinear optical interactions become a reality. Since all nonlinear coefficients are maximized at resonance, highly efficient nonlinear optical generators of light can be created.

In this section we discuss the simplest possible schemes of inversionless lasing which allow one to clarify the physical origin of LWI and to see the shortcomings which have so far prevented LWI-based schemes from reaching the level of practical laser devices.

Consider a three-level system, coherently driven by a strong quasi-monochromatic field nearly resonant with one transition, and probed by a field that is nearly resonant with an adjacent transition. Some possible configurations are shown in Figure 6. We consider in detail the case when the two fields are in a Λ-configuration (Figure 6a). This is probably the most popular and well-studied scheme since it can provide probe-field gain for a very low pumping rate, when most of the population is at the lowest energy level. However, we will see that the gain

condition for the Λ-scheme is actually rather restrictive and does not allow one to realize large frequency up-conversion. For the latter purpose, ladder-type schemes (Figure 6c,d) turn out to be more favorable.

Weak-field gain in the Λ-scheme

From the general formalism presented earlier, it is straightforward to get the amplification condition

$$K'' = \mathrm{Re}\left\{\eta_\mathrm{p}\frac{1}{\Gamma_{ab}+|\Omega_\mathrm{d}|^2/\Gamma_{cb}}\left(n_{ba}-\frac{|\Omega_\mathrm{d}|^2 n_{ca}}{\Gamma_{cb}\Gamma_{ac}^*}\right)\right\}+\kappa_\mathrm{p} < 0 \qquad [13]$$

where

$$\eta_\mathrm{p} = \frac{2\pi\omega_\mathrm{p} d_\mathrm{p}^2 N}{\hbar c n_\mathrm{p}^2}$$

The physical meaning of the two terms in brackets in eqn [13], which originate from the two terms on the right-hand side of eqn [4] for σ_{ab}, can be easily understood. The first term is just the resonant one-photon absorption proportional to the population difference n_{ba}. It can be strongly reduced in the presence of a drive field Ω_d, as explained earlier. However, it can change sign and give rise to the field amplification only if $n_{ba} < 0$, meaning there is a population inversion!

The second term, originating from the product $\Omega_\mathrm{d}\sigma_{cb}$ in eqn [4], is due to the mixing of the drive field Ω_d and polarization σ_{cb} where the latter is parametrically excited by a two-photon process: $\sigma_{cb} \propto e_\mathrm{p}\sigma_{ac}^* \propto e_\mathrm{p}\Omega_\mathrm{d}^* n_{ca}$. It is this term that can overcome one-photon absorption to provide amplification without inversion in the Λ-scheme. As we see, the possibility of LWI depends crucially on our ability to excite a sufficiently large polarization σ_{cb} at the transition resonant with the beat frequency of the probe and drive fields. This conclusion is universal for all LWI schemes with a coherent drive. We see that the sometimes loosely defined term 'quantum coherence' has a precise meaning here as the polarization σ_{cb} at a two-photon transition $c-b$. It is clear that the effects of quantum coherence are maximized when γ_{cb} is small, i.e., the transition $c-b$ is long-lived.

We are of course interested in the case of weak incoherent pumping. The typical dependence of gain on detuning from two-photon resonance is shown in Figure 7. At resonance, where the gain is maximized, the amplification condition $K'' < 0$ yields (in the absence of nonresonant losses):

$$r_{ac} > 2\gamma_{cb}(r_{ab}/r_{ba} - 1) \geq r_{ab} - r_{ba} \simeq r_{ab} \qquad [14]$$

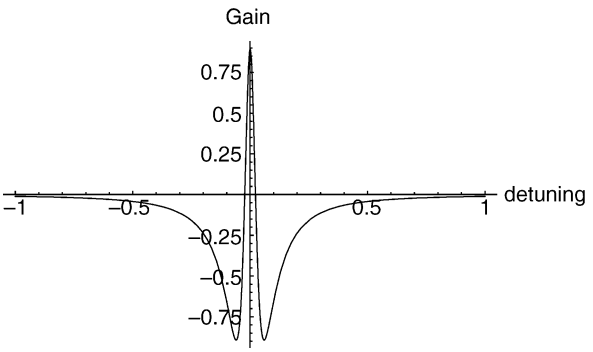

Figure 7 Gain without inversion in Λ-scheme.

because $\gamma_{cb} \geq r_{ba}/2$. Here we assumed that the incoherent pumping is weak, $r_{ba} \ll r_{ab}$, so that it does not produce population inversion at the probe transition.

Equation [14] is a simple and very important result, which is valid for all three-level laser schemes in the absence of inversion at both probe and drive transitions: the relaxation rate at the drive transition should exceed that at the probe transition. This result is an immediate consequence of the fact that the long-lived coherence σ_{cb} is inevitably destroyed by incoherent pumping, and γ_{cb} is now bounded from below. One can follow how the EIT regime is transformed into lasing as follows. With increasing incoherent pumping rate r_{ba}, EIT is actually destroyed due to the growth of $\gamma_{cb} \simeq r_{ba}/2$. In terms of CPT states, this means increase of population of the absorbing state $|B\rangle$. At the same time, the resonant Raman term in [13] also grows since n_{ac} is proportional to r_{ba}. With increase in the incoherent pumping rate, the contribution to gain overcomes the contribution to absorption if $r_{ac} > r_{ab}$.

Propagation effects

Inequality [14] has important implications for the problem of co-propagation of probe and drive fields. Indeed, to provide a significant amplification of the probe field, the absorption length $L_\mathrm{d} = \gamma_{ac}/(\eta_\mathrm{d} n_{ca})$ of the drive field should be larger than the amplification length $L_\mathrm{p} \simeq \gamma_{ac}/(\eta_\mathrm{p} n_{ca})$ of the probe. This requirement gives simply

$$\eta_\mathrm{p}/\eta_\mathrm{d} > 1 \qquad [15]$$

which in the absence of nonradiative relaxation can be rewritten as

$$\frac{r_{ab}}{r_{ac}}\frac{\nu_d^2}{\nu_p^2} > 1$$

In view of the gain condition given in eqn [14], the above requirement can be satisfied only if $\nu_d > \nu_p$, i.e., up-conversion is impossible.

An interesting solution to this problem is to realize population inversion at the driving transition. Then up-conversion can be realized with a lower relaxation rate at the drive transition as compared with probe transition. In this case in the Λ and V-schemes the two-photon term contributes to absorption at resonance, and gain is only possible far off-resonance. At the same time, in the ladder schemes shown in Figure 6c and d the gain is achieved at resonance, as discussed below in more detail.

It should also be noted that to excite laser oscillations in a high-Q cavity, large one-pass gain is not required at all, so that a Λ-scheme could still be employed for up-conversion.

Now, consider a probe field of arbitrary intensity. An important question is where the energy for amplification of the probe field comes from. It is known that for parametric processes in a transparent medium the Manley–Rowe relations are satisfied. Therefore, it might seem that the drive field is also the ultimate energy source for LWI. However, this is the case only for very large detunings of the drive and probe fields from the corresponding transition frequencies. In that case, we can neglect one-photon absorption, and the wave equations take the form typical for stimulated Raman scattering. They possess the first integral

$$\frac{|\varepsilon_d|^2}{\nu_d} + \frac{|\varepsilon_p|^2}{\nu_p} = \text{const} \qquad [16]$$

which expresses the conservation of the total number of quanta in both waves (Manley–Rowe conditions).

However, in the case of exact resonance, one can show that one-photon absorption of the drive field is always important, and the Manley–Rowe-type conservation law does not exist at all. The optimal condition for the probe field amplification is $\eta_p/\eta_d \gg 1$. In this case the stage of exponential amplification of the probe is maintained over a long distance, and the probe field intensity can grow to much larger values than the sum of initial intensities of the drive and probe fields. Apparently, the energy for the probe field amplification comes mainly from the medium, namely from the upper-level population ρ_{aa} supported by incoherent pumping.

V-Scheme

The V-scheme, shown in Figure 6b, is qualitatively similar to the Λ-scheme. An important difference is that there is now no long-lived coherence at the mixing transition c–a. Indeed, even if the transition $a \to c$ is strongly forbidden, the coherence γ_{ac} is destroyed by fast relaxations at the c–b and a–b transitions. We can immediately suggest that for the V-scheme inversionless lasing takes place at large driving field intensities exceeding the saturation value. However, one must be careful: although it appears that the reduction of absorption in the absence of pumping cannot be greater than a factor of 2, this turns out to be incorrect. Rather, almost complete transparency can be achieved, as confirmed by calculations and recent experiments. Analysis of the laser gain condition shows that the V-scheme shares with Λ-scheme the same negative feature: relaxation at the driving transition should be much faster than at the probe transition.

Schemes with Population Inversion at the Driving Transition

The above analysis illustrates the common problem of LWI schemes: the requirement of rapid relaxation at the driving transition and the resulting strong absorption of the drive field. This difficulty can be overcome in schemes with population inversion at the driving transition. Then, of course, all this makes practical sense only if the relaxation at the drive transition is much slower than that on the probe transition, so that it is easy to provide population inversion for the drive transition as compared with the probe transition. Luckily, such schemes do exist in principle, and seem to have many potential applications. The simplest possibility is the so-called ladder (or cascade) schemes shown in Figure 6c,d. LWI in ladder schemes is usually studied in the regime when there is no inversion at both probe and drive transitions. In this case gain is achieved at large detunings from two-photon resonance and under the same unfortunate condition of fast relaxation at the drive transition as compared with the probe transition. In the opposite case, population inversion at the driving transition is required for LWI at the probe transition. In ladder schemes the maximum gain of the probe field is achieved when both fields are at resonance with atomic transitions, while in V and Λ-schemes the resonance point corresponds to maximum absorption, and the gain is achieved in sidebands.

Note that population inversion at the driving transition means that the drive field can be amplified. This immediately puts forward the possibility to use a drive field which is self-generated in the same active medium. In other words, the system supports lasing with inversion at the drive frequency and LWI at the probe frequency. This situation is especially beneficial for dense gases or solids where the problems of

external drive absorption, reflection, and inhomogeneity may become otherwise insurmountable. One specific example considered in the literature is LWI on rapidly decaying UV and soft X-ray transitions in gas lasers in the presence of lasing with inversion on long-lived adjacent transitions in the visible range (as in Figure 6c). Another example is LWI on rapidly decaying mid/far-infrared intersub-band transitions in semiconductor quantum wells in the presence of lasing with inversion on the interband transition, as in Figure 6d. These interband transitions have 10^4 times longer lifetime than the intersub-band transitions.

Experiments

Experimentally, amplification without inversion has been observed in rarefied atomic vapors in the early and mid-1990s. In particular, amplification of a probe beam in the Λ-configuration was realized in atomic samarium, sodium, and cadmium, while the V-scheme was successfully implemented in atomic rubidium. Inversionless laser oscillation was observed in a V-scheme in rubidium vapor and a Λ-scheme in a sodium atomic beam. In all of these proof-of-principle experiments, the frequencies of the probe and drive fields were very close to each other, and the coherence was excited between two hyperfine states or Zeeman sublevels. One-pass gain of a few per cent was observed.

Nonlinear Optical Sources Based on Quantum Coherence

Excitation of a strong coherence has a profound impact on nonlinear optical interactions. Strong scattering on the polarization wave excited at the beat frequency of two or more laser fields allows one to achieve huge nonlinear coefficients and conversion efficiencies. A particularly impressive example is ultra-broadband collinear Raman generation in a resonant Λ-scheme, that has been observed experimentally. A pair of strong laser pulses propagating in molecular deuterium excites a strong polarization wave at a beat frequency close to a vibronic transition in deuterium. As a result, a comb of Raman sidebands from the infrared to the deep-UV region of the spectrum has been observed.

Another example is an extremely efficient simultaneous blue light and mid-infrared generation in a four-wave mixing experiment in rubidium vapor. Here, all four fields are resonant with corresponding transitions.

A final example illustrates the use of self-generated drive fields for nonlinear generation. It has been suggested that one can use two intracavity generated laser modes in a semiconductor quantum-well laser for the difference frequency, sum frequency, and second-harmonic generation in fully resonant three-wave mixing processes. This idea has already been successfully realized in two-wavelength quantum-cascade lasers, and experiments with other types of semiconductor lasers are under way.

The whole field of resonant nonlinear optics, stemming from original ideas of LWI in systems with quantum coherence, is now in explosive development.

Summary

Atomic coherence effects have already found many important applications in metrology and low-intensity nonlinear optics. Novel applications in quantum nonlinear optics, laser physics, and quantum information processing seem to be feasible. The coherence allows the storage of information about the probe light, its transportion in space, time reversing, and multiplexing the light. Moreover, the coherence allows an increase of the coupling between light fields such that it becomes possible to study the interaction between single photons. New coherent radiation sources based on the ideas of LWI and coherent nonlinear optics are at the stage of active research. There are surely many other applications ahead.

Quantum information is an emerging field of technology that encompasses the application of fundamental quantum mechanical phenomena, such as entanglement, to tasks in information processing and communications. The importance of optical technology in quantum information is not surprising, given the success of quantum optics in the investigation of these fundamental phenomena and the pre-eminent role of optics in modern communications. This article describes some of the important advances in photonic quantum information and discusses the prospects for the future.

Basic Notions: Qubits and Entanglement

Qubits

Quantum information is usually confined to two-level quantum systems, which are referred to as quantum bits, or qubits. The qubits form the register of a quantum computer or carry the information in a quantum communications channel. Physical examples of qubits under active study include the spin degrees of freedom of an electron or spin-1/2 nucleus, two well-isolated energy levels of an atom or trapped ion, and the polarization degrees of freedom of a photon; here we concentrate on the latter.[1] The two states of each qubit are generically denoted by $|0\rangle$ and $|1\rangle$ (although, because of our concentration on optical polarization, we shall use the horizontal and vertical states $|H\rangle$ and $|V\rangle$ interchangeably with $|0\rangle$ and $|1\rangle$ when describing experiments). An arbitrary state of a single qubit, $|\psi\rangle = \alpha|0\rangle + \beta|1\rangle$, is specified by the complex probability amplitudes α and β associated with the two possible states, constrained by $|\alpha|^2 + |\beta|^2 = 1$. States for which α and β are deterministic quantities are referred to as pure states; when they are stochastic, the state is mixed, and must be described by a density matrix, e.g., $\rho = \sum_i p_i|\psi_i\rangle\langle\psi_i|$, where p_i is the probability of the pure state $|\psi_i\rangle$. Pure states are a useful but unattainable ideal, just like a perfectly coherent laser beam; in reality even the best-prepared quantum states have some level of mixedness, which can be quantified by the entropy: $S \equiv -Tr(\rho \ln \rho) = -\sum_i \lambda_i \ln \lambda_i$, where λ_i are the eigenvalues of the matrix ρ.

Multiqubit States and Entanglement

For two qubits, the possible pure states of the system are specified by four probability amplitudes:[2] $|\psi_2\rangle = \alpha|00\rangle + \beta|01\rangle + \gamma|10\rangle + \delta|11\rangle$, with $|\alpha|^2 + |\beta|^2 + |\gamma|^2 + |\delta|^2 = 1$, and, e.g., $|00\rangle \equiv |0\rangle \otimes |0\rangle$ denoting the state in which the first and the second qubits are both in state $|0\rangle$. In general, 2^n amplitudes are needed to characterize a pure state of n qubits. Immediately we can see one advantage of quantum systems for information storage: if each distinct probability amplitude is regarded as a data register, the size of the memory grows exponentially with the number of qubits. Further, if one were to flip just one qubit, for example the second, the state would be transformed into $|\psi'_2\rangle = \beta|00\rangle + \alpha|01\rangle + \delta|10\rangle + \gamma|11\rangle$, where all of the amplitudes have been affected. This simple example demonstrates the notion of quantum parallelism, one of the most powerful properties of quantum information processors.

If the two-particle state can be written as a product of two single-particle states, i.e., if $\alpha|00\rangle + \beta|01\rangle + \gamma|10\rangle + \delta|11\rangle = (A|0\rangle + B|1\rangle) \otimes (C|0\rangle + D|1\rangle)$, then these two particles can be considered as separate, unconnected entities: the state is said to be separable.[3] When the state cannot be written in this form, it is called an entangled state. Entanglement is one of the most fascinating fundamental properties of quantum systems: Erwin Schrödinger described it as '*the* characteristic trait of quantum mechanics … that enforces its entire departure from classical lines of thought.' Consider performing a measurement on the second of the two qubits, to establish which of its two states the particle was in, leaving the first qubit

[1] Recently some attention has been devoted to quantum information based on continuous variables, such as those arising in connection with 'squeezed light'. However, here we will focus on discrete systems, i.e., qubits.

[2] Qubits are assumed to be distinguishable particles, and so the wavefunctions describing their states need not be symmetrized under exchange of particles.

[3] When mixture is also present, the state is separable if it can be written as $\rho = \sum_i p_i \rho_i^A \otimes \rho_i^B$, i.e., as a sum of product states for systems A and B.

untouched. The result would collapse the state of the first qubit into one of two possibilities: either $|\phi_0\rangle = (\alpha|0\rangle + \gamma|1\rangle)/\sqrt{P_0}$ if the outcome of the measurement were 0 (which occurs with probability $P_0 = |\alpha|^2 + |\gamma|^2$) or $|\phi_1\rangle = (\beta|0\rangle + \delta|1\rangle)/\sqrt{P_1}$ if it were 1 (with probability $P_1 = |\beta|^2 + |\delta|^2$). Thus the state of the first qubit is instantaneously projected into a specific state by performing a measurement on the second qubit, which can be in a completely different location. This example demonstrates the nonlocality of quantum mechanics, which has been confirmed experimentally in some depth by a number of elegant quantum optics experiments over the last 30 years.

The fidelity $F = |\langle\Phi|\Psi\rangle|^2$ characterizes the overlap of two states.[4] The fidelity of $|\phi_0\rangle$ and $|\phi_1\rangle$ is a way to quantify the amount of entanglement in the initial two-qubit state. If the final two states are identical, the fidelity will be unity, and the initial state is separable; conversely if the two final states are orthogonal and occur with equal probability, then in a sense the initial state is maximally entangled, since the largest possible nonlocal influence would occur due to the measurement. Mathematically, the fidelity of the two final states is $|\langle\phi_0|\phi_1\rangle|^2 = 1 - C^2/4P_0P_1$, where $C = 2|\alpha\delta - \beta\gamma|$ is called the concurrence of the state. If $C = 0$, the state is separable; if $C = 1$, the state is maximally entangled.[5]

As discussed below, entanglement forms the heart of a number of quantum information protocols, such as dense coding, teleportation, and one type of quantum key distribution (also known as quantum cryptography), and large-scale entangled states of many qubits seem to be a requirement for the more ambitious goal of practical quantum computing.

Creating Entangled States Experimentally

Entangled states can currently be created in a controlled manner using technologies such as ion traps, cavity quantum electrodynamics, and optical spontaneous parametric down-conversion (SPDC). Down-conversion is a nonlinear optical process by which an incident 'pump' photon can be split (or down-converted) into a pair of longer-wavelength daughter photons (historically called 'signal' and 'idler') in a crystal possessing a $\chi^{(2)}$ nonlinearity, such as beta-barium borate (BBO). Mathematically, the process is described using the creation and annihilation operators of the field modes $(\hat{a}_\lambda^\dagger, \hat{a}_\lambda)$, thus:

$$|\Phi_{\text{out}}\rangle = \exp\left[-i \sum_{p,s,i} c_{p,s,i} (\hat{a}_p^\dagger \hat{a}_s \hat{a}_i + \hat{a}_i^\dagger \hat{a}_s^\dagger \hat{a}_p) \right] |\Phi_{in}\rangle$$

where the triple sum is over all field modes (subscripts p, s, and i refer to pump, signal, and idler modes, respectively) and $c_{p,s,i}$ is a coefficient linearly dependent on the second-order nonlinear susceptibility $\chi^{(2)}_{ijk}$ and also on the birefringent properties of the crystal. Further, $c_{p,s,i}$ will be negligibly small unless both total photon energy and momentum are conserved (i.e., $\omega_p = \omega_s + \omega_i$ and $\vec{\kappa}_p = \vec{\kappa}_s + \vec{\kappa}_i$, where $\vec{\kappa}$ is the intracrystal momentum).

One particularly efficient method for using this phenomenon to create entangled states is as follows. For a specific geometry (type-I phase matching), the daughter photons emerge from the crystal with identical polarizations (perpendicular to the parent polarization and the crystal optic axis) on opposite sides of a cone that is centered about the pump beam (Figure 1a). Because each photon is in a definite state of polarization, the two photons are not in an entangled state. Two crystals, aligned with their axes of symmetry oriented at 90° to each other, as shown in Figure 1b, can then be used to create an entangled state.[6] With crossed crystals, two processes are possible: the parent photon can down-convert in the first crystal to yield two vertically polarized photons, or it can down-convert in the second crystal to yield two horizontally polarized photons. Because it is impossible to distinguish which of these processes has occurred, the state of the daughter photons is a coherent quantum-mechanical superposition of the states that would arise from each crystal alone; the output of the crossed crystals is photons in the maximally entangled state $|\Phi_+\rangle \equiv \frac{1}{\sqrt{2}}(|HH\rangle + |VV\rangle)$.[7]

Figure 2 shows how this basic source can be adapted to produce any pure quantum state of two photons by placing rotatable half- and quarter-wave plates (which can be used to transform the

[4] The generalized fidelity between mixed states ρ_A and ρ_B is $F = |Tr\sqrt{\sqrt{\rho_A}\rho_B\sqrt{\rho_A}}|^2$.

[5] The concurrence can also be generalized to mixed states, although it has a much more complicated expression. The quantification of entanglement for mixed states with more than two subsystems is presently an active area of research.

[6] Another widely used method employs type-II phase matching in a single crystal. The down-conversion photons are emitted with perpendicular polarizations along a pair of cones. Pairs emitted along particular directions are in the maximally polarization-entangled state $|\psi_-\rangle = \frac{1}{\sqrt{2}}(|HV\rangle - |HV\rangle)$. Such a source was used in the first demonstrations of superdense coding and quantum teleportation.

[7] Note that in an arbitrary basis $|\theta\rangle \equiv \cos\theta|H\rangle + \sin\theta|V\rangle$ and $|\theta^\perp\rangle \equiv -\sin\theta|H\rangle + \cos\theta|V\rangle$, this maximally entangled state has the form $|\Phi_+\rangle = \frac{1}{\sqrt{2}}(|\theta\theta\rangle + |\theta^\perp\theta^\perp\rangle)$, demonstrating that the nonlocal correlations are present regardless of the bases used to represent the state.

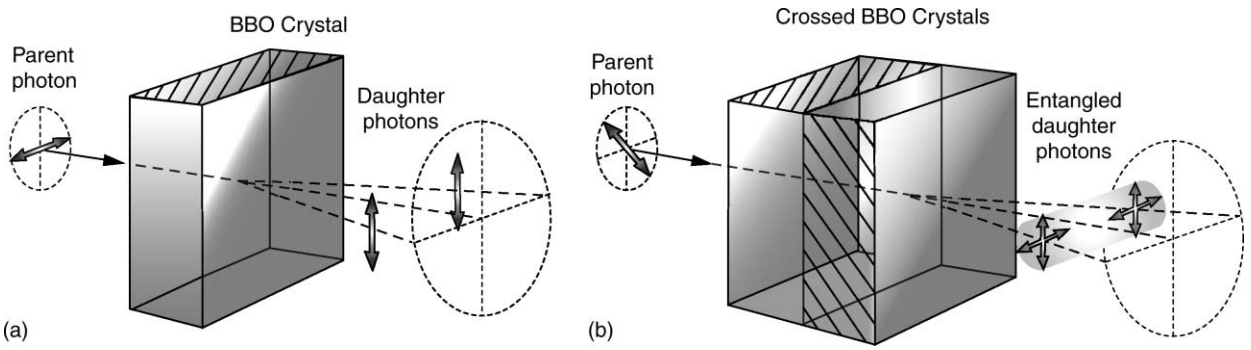

Figure 1 An entangled-photon source. (a) For a given orientation of the nonlinear crystal, a horizontally polarized parent photon produces a pair of vertically polarized daughters. The daughters emerge on opposite sides of an imaginary cone. The cone's axis is parallel to the original direction taken by the parent photon. The two daughter photons are not in an entangled state. Reorienting the BBO crystal by 90° will produce a pair of horizontally polarized daughters if a vertically polarized pump beam is used. (b) Passing a photon polarized at 45° through two crossed BBO crystals can produce two photons in an entangled state. Because of the Heisenberg uncertainty principle, there is no way to tell in which crystal the parent photon 'gave birth,' and so a coherent superposition of two possible outcomes results: a pair of vertically polarized photons or a pair of horizontally polarized photons. (Adapted with permission from James DFV and Kwiat PG (2002) Quantum state entanglement: creation, characterization, and application. *Los Alamos Science* 27: 52–67.)

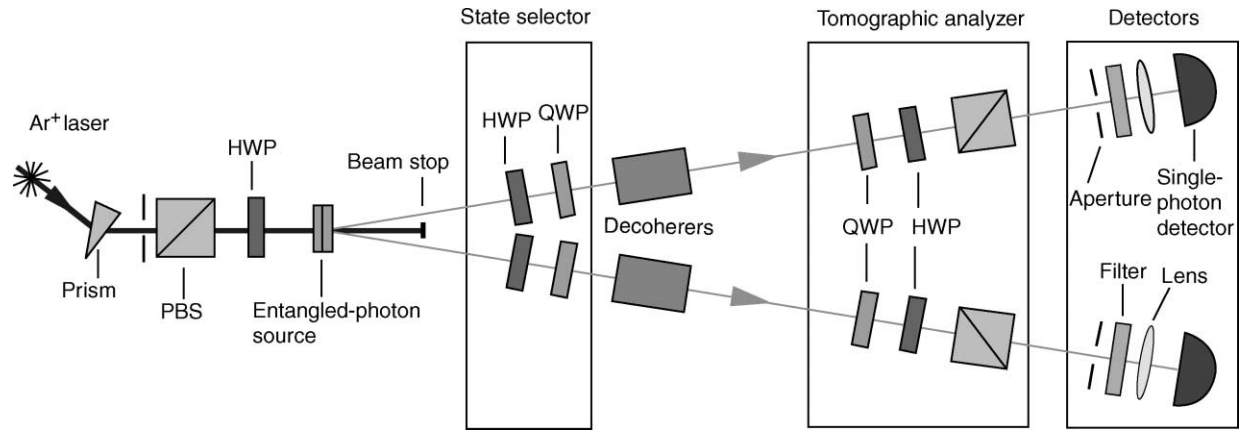

Figure 2 Creating and measuring two-photon entangled states. The 'pump' photons are created, for example, in an argon ion laser and are linearly polarized with a polarizing beamsplitter (PBS). The half-wave plate (HWP) rotates the polarization state before the photon enters the pair of nonlinear crystals that constitute the entangled-photon source; the initial angle of pump polarization controls the entanglement of the pair produced. Each photon's polarization state can be altered at will by the subsequent HWP and quarter-wave plate (QWP). The decoherers following the state selection allow the production of mixed photon states. The optical elements (QWP, HWP, and PBS) in the tomographic analyzer allow the measurement of each photon in an arbitrary basis. Coincidence measurements of photons allow the quantum state to be determined. (Adapted with permission from James DFV and Kwiat PG (2002) Quantum state entanglement: creation, characterization, and application. *Los Alamos Science* 27: 52–67.)

polarization state of a single photon) before the crystal pair and in the paths of the two daughter photons. To create mixed states, a long birefringent crystal can be used to delay one polarization component with respect to the other. If the delay is longer than the coherence time of the photons, the horizontal and vertical components are effectively decohered; that is, the phase relationship between the different states is destroyed.

The figure also shows schematically the apparatus required for measuring the quantum state. In classical optics, four Stokes parameters are required to specify the polarization of a single beam (i.e., an ensemble of uncorrelated photons); for a pair of photons, 16 projective measurements, each with different wave plate settings, is required. From these 16 measurements, all of the elements of the 4×4 density matrix describing the (in general, mixed) state of the photon pairs can be deduced. This is an example of quantum state tomography, a technique that has found application to a number of quantum optical systems.

Quantum Key Distribution

Two parties, historically known as Alice and Bob, want to have a secret conversation. A generic, classical encryption protocol would begin when Alice and Bob convert their messages to separate binary streams of 0's and 1's, which are then encrypted and decrypted with a set of secret 'keys' known only to the two. Each key is a random string of 0's and 1's that is as long as the binary string comprising each message. To encrypt, Alice (the sender) sequentially adds each bit of the key to each bit of her message, using addition modulo 2. She then sends the encrypted message over a public channel to Bob, who decrypts it by simply repeating the addition modulo 2 of the key to the message. This type of encryption, known as a one-time pad, is currently the only provably secure encryption protocol. But the one-time pad is effective only if Alice and Bob never reuse the key, and more obviously, if the key remains secret. A potential eavesdropper, Eve, cannot be allowed to glean any part of the bit stream that makes up the key. Therein lies a central problem of cryptography – how can secret keys be created and then securely distributed?

Quantum key distribution (QKD) exploits the fundamentally indivisible nature of photons to perform this task. There are a variety of QKD protocols; here we describe one that employs entangled photon pairs (see Figure 3). Alice and Bob use a source such as the one described above to produce maximally entangled photons in the state $|\Phi_+\rangle \equiv \frac{1}{\sqrt{2}}(|HH\rangle + |VV\rangle) = \frac{1}{\sqrt{2}}(|45°,45°\rangle + |-45°,-45°\rangle)$. One photon goes to Alice and the other to Bob. For each pair, Alice and Bob randomly and independently analyze their respective photons (using a polarizing beamsplitter) in the H/V or the 45°/−45° basis. They record a bit value of 0 for all H or 45° results, and a 1 for all V or −45° results. After a sufficient number of measurements (dictated by the length of the key), Alice and Bob have a public discussion, e.g., over the internet. For each detected photon, they announce which basis they used for the measurement, but not the actual measurement result. Whenever they made the same basis choice (50% of the time), the correlations of the entangled state ensure their measured bit values agree. By contrast, they discard the results when they used different bases, because their measurements are completely uncorrelated (see Table 1).

An eavesdropper (Eve) cannot tap the line, as she might with conventional communications, because of the indivisibility of individual photons and the fact

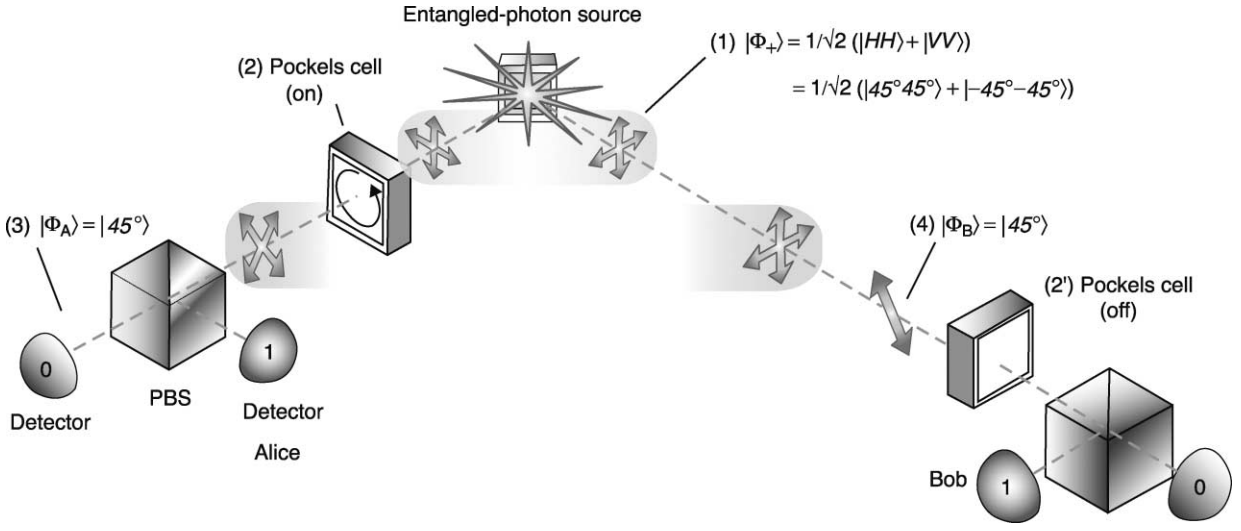

Figure 3 Quantum cryptography using entangled photons. Entangled photons can be used to create a pair of identical cryptographic keys. One member of an entangled pair (1) is sent to Alice, and the other to Bob. Alice and Bob each randomly and independently analyze their respective photon in one of two linear polarization bases with a polarizing beamsplitter (PBS); the basis can be actively chosen using a Pockels cell before the PBS, as shown, to rotate the polarization (alternatively, the 'choice' could be made by directing the photon onto a nonpolarizing 50/50 beamsplitter; in the transmitted path, one analysis basis is used, in the reflected path, the other is used). In the example shown, Alice used the 45°/−45° basis (2), and measured 45° polarization (3), thus projecting Bob's photon into the identical state (4). Since he chose the H/V analysis basis (2′), he is equally likely to detect a 0 or a 1. By subsequent public discussions Alice and Bob determine the events for which they used the same analysis basis (and discard the other events). For these events Alice and Bob will have obtained identical measurement results, which they may interpret as raw key material. After classical error correction and privacy amplification techniques are applied, the remaining string is the sought-after shared secret key. Table 1 Polarization entanglement-based quantum cryptography protocol

Alice's analysis basis	H/V	H/V	45°/−45°	H/V	45°/−45°	45°/−45°	H/V	45°/−45°
Alice's measurement result[a]	*H*	–	*−45°*	*V*	*45°*	*45°*	*V*	*−45°*
Alice's bit value	0	–	1	1	0	0	1	1
Bob's analysis basis	H/V	45°/−45°	45°/−45°	45°/−45°	H/V	45°/−45°	H/V	HV
Bob's measurement result	*H*	*−45°*	*−45°*	*45°*	*H*	–	*V*	*H*
Bob's bit value	0	1	1	0	0	–	1	0
Public discussion: Both photons detected and same basis used?	yes	no	yes	no	no	no	yes	no
Remaining secret key	0		1				1	

[a]In some cases Alice or Bob may not detect a photon due to loss or detector inefficiency. These events simply do not contribute to the key data.

that arbitrary quantum systems cannot be accurately cloned.[8] If Eve steals Bob's photon (a 'denial-of-service' attack), the photon's information never becomes part of the key. Thus, although a wiretap would reduce the rate of the transmission, it would not jeopardize the security of the key. Eve can try to intercept the photon, measure it, and send another one to Bob. But any measurement Eve would make to determine the photon's polarization state would perturb the photon and collapse the entangled state. The photon she sends to Bob would therefore only be 'classically' correlated with Alice's photon. Consequently, Eve's intervention necessarily induces additional errors into Bob's key, which Alice and Bob can detect by publicly revealing a small subset of their actual key. Unfortunately, even with no eavesdropper, the encryption keys created by any real-world quantum cryptography system typically possess a few-percent errors. To make sure their key is secure, Alice and Bob ascribe all errors to Eve and then estimate the maximum amount of information available to the eavesdropper. They then use a classical privacy amplification protocol to reduce Eve's knowledge of the secret key to less than one bit by reducing the length of the key. It has been proven that if the initial error probability per bit is greater than ~15%, no secret bits will remain after error detection and privacy amplification.

Researchers are working to make entanglement-based quantum cryptography more practical. Also, a number of longer distance quantum cryptography demonstrations using weak pulses have been carried out, over tens of kilometers in fibers and in free space. In fact, the first commercially available systems have recently been announced (in Europe and the United States).

[8] The no-cloning proof is very simple. If we have a copying operation such that $|0\rangle|c\rangle \rightarrow |0\rangle|0\rangle$ and $|1\rangle|c\rangle \rightarrow |1\rangle|1\rangle$ ($|c\rangle$ is the initial state of the copier), then by linearity, a superposition becomes an entangled state, instead of two copies: $\frac{(|0\rangle+|1\rangle)}{\sqrt{2}}|c\rangle \rightarrow \frac{(|0\rangle|0\rangle+|1\rangle|1\rangle)}{\sqrt{2}} \neq \frac{(|0\rangle+|1\rangle)}{\sqrt{2}}\frac{(|0\rangle+|1\rangle)}{\sqrt{2}}$.

Table 2 Method to convert the initial state $|\Phi_+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$ into any of the four Bell states

Alice's operation	*Polarization transformation*	*Resultant two-qubit state*
$\hat{I}$, the identity	H → H; V → V	$\|\Phi_+\rangle = \frac{1}{\sqrt{2}}(\|00\rangle + \|11\rangle)$
$\hat{\sigma}_x$	H → V; V → H	$\|\Psi_+\rangle = \frac{1}{\sqrt{2}}(\|01\rangle + \|10\rangle)$
$i\hat{\sigma}_y$	H → V; V → −H	$\|\Psi_-\rangle = \frac{1}{\sqrt{2}}(\|01\rangle - \|10\rangle)$
$\hat{\sigma}_z$	H → H; V → −V	$\|\Phi_-\rangle = \frac{1}{\sqrt{2}}(\|00\rangle - \|11\rangle)$

Quantum Superdense Coding

It is possible for Alice to send Bob two bits of classical information using a single qubit in the quantum superdense coding protocol. Suppose that Alice and Bob share one qubit each of an entangled pair in the maximally entangled state $|\Phi_+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$, where we have returned to the generic labeling scheme for the qubit states. Alice has two classical bits of information, which is equivalent to one of four choices. She can encode this information by applying one of four possible transformations on her qubit; a suitable set of transformations are the three Pauli matrices and the identity (i.e., do nothing). This set of operations can be performed experimentally on photon qubits quite easily, e.g., using waveplates, as indicated in Table 2. The four resultant two-qubit states are all maximally entangled and are orthonormal. They form a special basis for the two-qubit states, the Bell basis, which is of particular use in analyzing entanglement.

Alice now sends her qubit to Bob, e.g., through an optical fiber. Bob can then perform a Bell state analysis[9] on his qubit pair, i.e., a projective measurement of the two-qubit state in the Bell basis. The result

[9] Complete discrimination of all four Bell states is presently an unsolved technical problem: for photons one needs either a nonlinear interaction (which is typically very weak) or to exploit so-called 'hyper-entanglement' involving other entangled degrees of freedom of the photons.

immediately reveals the choice of operation Alice made, and in effect, two bits of classical information have been encoded on a single qubit.

Quantum Teleportation

Another application of entanglement is quantum state teleportation (Figure 4), in which the infinite amount of information contained in an arbitrary qubit state $|\psi\rangle = \alpha|0\rangle + \beta|1\rangle$ is transferred by communication of two bits of classical information between Alice and Bob, if they also share two qubits in the maximally entangled state $|\Psi_-\rangle$. The three-photon initial state (i.e., the input photon plus the two entangled photons) is

$$|\psi_0\rangle = (\alpha|H\rangle + \beta|V\rangle) \otimes \tfrac{1}{\sqrt{2}}(|HV\rangle - |VH\rangle),$$

which can be rewritten with the first two photons (the input plus the first half of the entangled pair) represented by the Bell state basis:

$$\begin{aligned}|\psi_0\rangle = \tfrac{1}{2}\{&|\Phi_+\rangle \otimes (-\beta|H\rangle + \alpha|V\rangle)\\ &+ |\Phi_-\rangle \otimes (\beta|H\rangle + \alpha|V\rangle)\\ &+ |\Psi_+\rangle \otimes (-\alpha|H\rangle + \beta|V\rangle)\\ &+ |\Psi_-\rangle \otimes (-\alpha|H\rangle - \beta|V\rangle)\}.\end{aligned}$$

Now suppose that a Bell state measurement is performed on the first two photons. The third photon

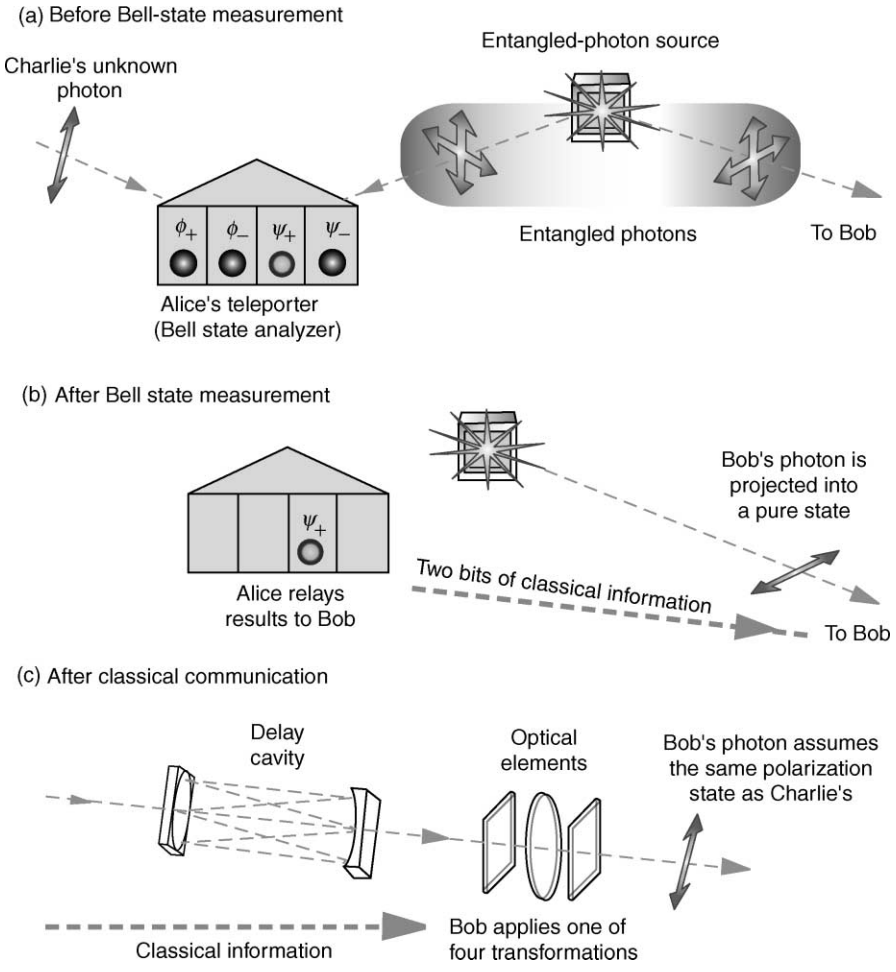

Figure 4 Quantum state teleportation. (a) Teleportation requires an entangled photon source, a Bell state analyzer and a classical communications channel. One entangled photon goes to Bob and the other to Alice, who also receives a photon of unknown polarization state. (b) Alice performs a joint polarization measurement of the two photons and relays the result to Bob using two classical bits of information. The photon going to Bob is projected into a pure state as a result of Alice's measurement. (c) Upon receiving Alice's classical information, Bob performs a simple transformation on his photon (which he has been storing), such as a rotation of the polarization vector. The resulting state of his photon is then identical to the unknown state Alice wished to teleport. (Adapted with permission from James DFV and Kwiat PG (2002) Quantum state entanglement: creation, characterization, and application. *Los Alamos Science* 27: 52–67.)

is immediately projected into one of four possible states, which can be transformed back into the state of the original input photon by a simple operation, e.g., with a waveplate. For example, if the Bell state measurement produced the result $|\Psi_+\rangle$, the third photon is immediately 'collapsed' into the pure state $|\psi_3\rangle = -\alpha|H\rangle + \beta|V\rangle$. By applying a π-phase shift to the horizontal polarization (relative to the vertical), $|\psi_3\rangle$ can be transformed into the original input state: $|\psi'_3\rangle = \alpha|H\rangle + \beta|V\rangle$. Alice (who does the Bell state measurement) need only communicate to Bob (who wants to receive the teleported photon) which of the four Bell states she measured. Note that during the entire teleportation procedure, neither Alice nor Bob can obtain any idea of the values of the parameters α and β, which specify the state. Also, because Alice's measurement collapses the unknown state, there is only a single copy at the end of the protocol.

Quantum state teleportation was first demonstrated experimentally by Zeilinger and coworkers (University of Innsbruck, Austria). The group was able to determine two of the four Bell states unambiguously (the other two states gave the same experimental signature) and proved for those cases that the state of the input photon could indeed be transferred to Bob. Other experiments have realized modified forms of quantum teleportation in different systems. For example, Kimble's group (California Institute of Technology) teleported the coherent state of an optical mode using squeezed (rather than polarization-entangled) light. Researchers have recently suggested how teleportation might form the basis of a distributed network of quantum communication channels, and how it might enable quantum computing in all-optical systems.

Other Application of Optical Entanglement

Quantum Computing

The most challenging and powerful application of quantum information is large-scale quantum computing. Two features that make quantum information processing potentially powerful are the exponentially large Hilbert space, which gives quantum registers very large capacities, and quantum parallelism, which means that data processing tasks can be performed very efficiently. One fundamental drawback, which severely constrains useful applications of quantum computers, is that the final measurement can only produce a number of classical bits equal to the number of qubits. Thus, quantum computers are limited to performing tasks in which a small amount of information is meant to be gleaned from processing a large amount of data; examples include searching an unstructured database for a specific entry (Grover's algorithm) or finding the periodicity of a function (the quantum Fourier transform). This second task is central to Shor's factor-finding algorithm, the most famous quantum computing algorithm to date.

A practicable quantum computer technology must have at least the following features, first identified by DiVincenzo:

- A set of well-characterized, distinguishable qubits to form a quantum data storage register.
- The ability to initialize the qubits of the register in a simple fiducial state.
- Decoherence times that are much longer than the time needed to perform logical operations.
- The ability to perform any single qubit operation on any qubit in the register, and the ability to perform two-qubit conditional logic gates (such as the CNOT gate: $\alpha|00\rangle + \beta|01\rangle + \gamma|10\rangle + \delta|11\rangle \rightarrow \alpha|00\rangle + \beta|01\rangle + \gamma|11\rangle + \delta|10\rangle$). Together, these operations constitute a universal set of quantum gates, from which all other gates can be synthesized.
- The ability to measure each qubit.

All-optical schemes have been used to implement small quantum algorithms. However, most of the approaches are not scalable, due to the limitations of non-linear optics to perform a CNOT gate at the single-photon level. Recent proposals have suggested that very high efficiency single-photon detectors, along with sources of single photons 'on-demand,' allow scalable quantum computing with only linear optics; preliminary two-qubit gates have been experimentally demonstrated. A number of other promising candidate technologies that meet DiVincenzo's five requirements are being pursued vigorously. For example, the ability to create multi-qubit entanglement and perform reliable measurements on trapped ions cooled and manipulated by lasers has recently been demonstrated. Solid state systems offer the possibility of scalability, and a number of schemes, such as quantum dots, isolated impurities with nuclear spins, and superconducting quantum interference devices (SQUIDs), are being investigated. It is possible that the final quantum computing technology may take the form of a hybrid between various present approaches.

Lithography

Lithography, in which a pattern is optically imaged onto some photoresistive material, is the primary method of manufacturing microscale or nanoscale

electronic devices. An inherent limitation of this process is that details smaller than a wavelength of light cannot be written reliably. However, quantum state entanglement might circumvent this limitation. Under the right circumstances, the interference pattern formed by beams of entangled photons can have half the classical fringe spacing. Quantum lithography requires two beams of photons, a coherent superposition consisting of the state in which two photons are in beam A while none are in B, and the state in which no photon is in beam A while two photons are in B. Such number-entangled states can be made in the laboratory, and the predictions about fringe spacings have been verified. However, other obstacles must be overcome to surpass current classical-lithography techniques.

Two-Photon Imaging and Microscopy

At present, two-photon microscopy is widely used to produce high-resolution images, often of biological systems. However, the classical light sources (lasers) used for the imaging have random spreads in the temporal and spatial distributions of the photons, and the light intensity must be very high if two photons are to intersect within a small enough volume to cause a detectable excitation. Such high intensity can damage the system under investigation. Because the temporal and spatial correlations may be much stronger between members of an entangled photon pair, much weaker light sources could be used, which would be much less damaging to the systems being observed. The development of such systems is currently an active area of research.

List of Units and Nomenclature

Entanglement: a property of quantum systems consisting of two or more distinct subsystems, often separate particles. When transformations on one system do not affect the other, the state is said to be separable; when this is not the case, and the quantum state of the overall system cannot be resolved into separate states of the individual pieces, the system is entangled.

Pure and mixed states: when the probability amplitudes specifying a quantum state are deterministic, the state is said to be pure; when the amplitudes are random quantities, the state is mixed. The distinction is similar to that of coherent and partially coherent optical fields.

Quantum computer: an information processing device that exploits quantum mechanical phenomena to greatly enhance computational power for certain problems. Some mathematical problems thought to be intractable on conventional computers can, in theory, be performed efficiently on a quantum computer.

Quantum crytography (also known as quantum key distribution): a quantum information protocol by which two parties acquire a shared series of random numbers (a cryptographic key) by exploiting the quantum nature of light. Absolute security can be proven by virtue of the indivisibility and uncopy-ability of individual quanta.

Quantum state tomography: a means by which quantum states can be determined experimentally by performing a series of appropriate measurements on multiple identically prepared systems. From such measurements, the elements of the density matrix, which fully specifies the state, may be inferred.

Quantum superdense coding: A quantum information protocol by which two bits of classical information may be communicated by a single quantum bit, initially part of an appropriate entangled quantum state.

Quantum teleportation: a quantum information protocol by which the unknown quantum state of one particle can be transferred to another distant particle, using a pair of entangled particles, a projective measurement, and exchange of two bits of classical information.

Qubit (quantum bit): a two-level quantum mechanical system, which constitutes the building blocks of quantum information processing devices. Examples include a spin-1/2 particle, an atom with two well-isolated levels, or the polarization of a photon.

Laser Cooling of Ions

H Walther, University of Munich and Max-Planck-Institute for Quantum Optics, Garching, Germany

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

The fact that light can exert a mechanical force on atoms by the transfer of linear momentum was recognized as long ago as the 1930s, when Frisch demonstrated the deflection of an atomic beam using resonant light. With the advent of tunable laser light in the early 1970s, a much larger excitation rate for atoms was achieved, leading to a much stronger deflection. A little earlier it was also observed that in addition to the force resulting from photon recoil, a dipole force is also produced in a focused light beam so that even small solid particles can be trapped and manipulated. The original proposal for laser cooling of atomic gases was put forward in 1975 and later laser cooling of trapped ions was proposed. The principle of laser cooling is very simple. The ion is excited by laser light below a resonance frequency; in order that a transition can be made, the residual energy has to be taken from the kinetic energy of the particle, leading to cooling of the particle. In this article, we will discuss this cooling process in more detail.

Laser Cooling of Ions in a Radiofrequency Trap

Of the various proposed and realized methods for laser cooling of atoms or trapped ions, sideband cooling is conceptually the simplest and most efficient. It allows a trapped particle to be cooled to the quantum-mechanical ground state of a harmonic trap potential. The process can be regarded as anti-Stokes Raman scattering of the pseudomolecule formed by the ion and the trap. If the linewidth of an optical transition in this atom is smaller than the vibrational frequency of the trapped ion, both electronic levels of the transition split into a ladder of resolved vibrational levels. The absorption spectrum consists of a carrier at the resonance of the free atom and sidebands at multiples of the vibrational frequency. With a laser tuned to the m-th lower frequency sideband, each absorption of a photon will reduce the vibrational energy of the atom by m quanta. Since the subsequent spontaneous re-emission will, on average, not change the vibrational excitation, repeated photon scattering processes lead to efficient cooling of the atom. This cooling will continue until the absorption probability for the low-frequency sidebands decreases when approaching the vibrational ground state of the ion in the trap. The final temperature is limited by the heating process caused by photon recoil. However, after the ion is cooled to the vibrational ground state this heating process disappears, when the vibrational energy of the ion is larger than the recoil energy of a photon. In this case, the recoil is taken up by the entire trap setup, as it is the case in the Mössbauer effect.

Despite these obvious advantages of sideband cooling, relatively few experiments have been made using this method. This is because the regime, where the oscillation frequency ω is larger than the natural linewidth Γ of an optical transition (the so-called 'strong binding regime'), is not easily accessible. Vibrational frequencies of ions in standard electromagnetic traps are of the order of 1 MHz, whereas linewidths of electric dipole transitions in positive ions are in the range 20–50 MHz. In this 'weak binding regime' with $\Gamma > \omega$, laser cooling of trapped

ions is essentially analogous to Doppler cooling of free atoms. The minimum temperature is given by the Doppler limit $k_B T = \hbar\Gamma/2$, and the mean vibrational quantum number is $\langle n\rangle = \Gamma/2\omega > 1$. The first experiments with cooling on resolved sidebands, therefore, used a strongly forbidden optical transition or stimulated Raman transitions. In these cases, however, sideband cooling is inevitably slow and it was used only to extract a few vibrational quanta from Doppler-precooled ions. In both experiments the vibrational ground state was reached to a very good approximation (mean quantum number $\langle n\rangle \approx 0.05$). Raman sideband cooling has also recently been applied to neutral atoms in optical traps.

Laser cooling of trapped ions was motivated by their possible use for optical frequency standards where the relativistic Doppler shift, as well as the Stark shift due to the trap potential, are eliminated at low temperatures. Cooling to the ground state also opens up the possibility of studying a well-controlled mechanical quantum oscillator experimentally. This led to the realization of nonclassical states of motion, investigation of quantum decoherence phenomena, and the demonstration of a quantum logic gate for quantum computing.

Sideband Cooling

Most theoretical treatments of sideband cooling consider a static harmonic trap, whereby the time dependence of the potential of the radio-frequency (rf) ion trap is neglected. In such a model a running laser wave $\propto\exp(ikr)$ of wave number k induces transitions between the eigenstates $|n\rangle$ and $|n'\rangle$ of a harmonic oscillator. The relevant transition matrix elements are

$$U_{n'n} = \langle n'|\exp(ikr)|n\rangle \qquad [1]$$

$$U_{n'n} = \exp(-\eta^2/2)\sqrt{\frac{n_<!}{(n_< + \Delta n)!}}(i\eta)^{\Delta n} L_{n_<}^{\Delta n}(\eta^2) \qquad [2]$$

Here $\eta = kx_0 = k\sqrt{\hbar/2m\omega}$ is the Lamb–Dicke parameter for the spatial extension x_0 of the ground state, $n_<$ the smaller of the two numbers n and n', $\Delta n = |n - n'|$, and L_n^m denotes the generalized Laguerre polynomial. In the case of high vibrational excitation $n, n' \gg 1$, $U_{n',n}$ can be approximated as

$$U_{n+\Delta n,n} \approx i^{\Delta n} J_{\Delta n}(2\eta\sqrt{n}) \qquad [3]$$

with the Bessel function of n-th order J_n. The argument of the Bessel function is the product of the wave number and the classical vibration amplitude of the highly excited state. This is the result one would expect for the frequency-modulated spectrum of a classical oscillator. For arguments β among the Bessel functions $J_n(\beta)$, those of order $n \approx \beta$ have the largest modulus. Consequently, during the initial stages of cooling it is most efficient to tune the laser so that it induces transitions with $\Delta n \approx 2\eta\sqrt{n} \gg 1$.

For the final stages of cooling one can usually assume that the ion is in the Lamb–Dicke regime, i.e., that it is localized within dimensions of the optical wavelength. A detailed study of the limits of sideband cooling in a static trap was carried out in 1984. The final distribution of population over the vibrational states is thermal and can be characterized by a mean occupation number $\langle n\rangle$ or a temperature $T = \hbar\omega/k_B \ln(1 + 1/\langle n\rangle)$. The number $\langle n\rangle$ is a rational function of the four frequencies involved, i.e., the natural linewidth Γ, the oscillation frequency in the trap ω, the laser detuning δ, and the Rabi frequency ω_R. For certain limiting cases, simple expressions for the mean vibrational excitation $\langle n\rangle$ can be derived from the general result. The lowest vibrational excitation is achieved in the case of well-resolved sidebands ($\omega \gg \Gamma$) and under weak laser excitation ($\omega_R \ll \Gamma$), tuned to the first sideband ($\delta = -\omega$):

$$\langle n\rangle = \left(\alpha + \frac{1}{4}\right)\frac{\Gamma^2}{4\omega^2} \qquad [4]$$

The constant α depends on the geometry of excitation and photon re-emission and is of the order of 1. In the case of strong saturation ($\omega_R \gg \Gamma$) of the first sideband ($\delta = -\omega$), the mean vibrational quantum number is proportional to the laser intensity:

$$\langle n\rangle = \frac{\omega_R^2}{8\omega^2} \qquad [5]$$

This case is of practical relevance if one wants to detect a fluorescence signal on the cooling transition, for example, to measure the internal state of the ion in a double-resonance experiment, while keeping the ion cooled. For the choice of parameters $\omega_R = \omega = -\delta$, the ion is still predominantly in the vibrational ground state ($\langle n\rangle \approx 1/8$), but photons are scattered from the wing of the saturation-broadened carrier at a rate $P = \Gamma\omega_R^2/(\Gamma^2 + 2\omega_R^2 + 4\delta^2) \approx \Gamma/6$, which is already one-third of the maximum scattering rate. Finally, in the case of large laser detuning ($\delta \gg \Gamma$, ω, ω_R), the energy is proportional to the detuning because the lower vibrational levels are no longer depleted by the laser:

$$\langle n\rangle \approx \frac{\alpha + 1}{4}\frac{\delta}{\omega} \qquad [6]$$

If the Lamb–Dicke parameter satisfies $\eta \ll 1$, the strength of the sidebands can be calculated from a power series expansion of the matrix elements of eqn [2] and the thermal distribution of population over the oscillator levels. The $U_{n',n}$ are evaluated to first-order in η only. In this approximation, the height of the first lower-frequency sideband in the absorption spectrum relative to the carrier is $\eta^2\langle n\rangle$ and that of the first higher-frequency sideband $\eta^2(\langle n\rangle + 1)$. This information can be used to determine experimentally the vibrational quantum number from the absorption spectrum. The strengths of the higher-order sidebands contain higher powers of η^2 and therefore decrease rapidly.

Let us now briefly review some facts about the motional spectrum of an ion in a Paul trap, which is not just a static system but possesses an explicitly time-dependent potential. The equation of motion for a classical particle of charge e and mass m in the quadrupole potential of the trap $\phi(r,z) = (V_0 - U_0 \cos \Omega t)(r^2 - 2z^2)/2r_0^2$ is given by the Mathieu differential equation:

$$\frac{\delta^2 r}{\delta \tau^2} + (a_r - 2q_r \cos 2\tau)r = 0 \qquad [7]$$

with dimensionless parameters:

$$\tau = \frac{\Omega}{2}t, \qquad a_r = \frac{4eV_0}{m\Omega^2 r_0^2}, \qquad q_r = \frac{2eU_0}{m\Omega^2 r_0^2} \qquad [8]$$

Here a static voltage V_0 and an alternating voltage with amplitude U_0 and frequency Ω are applied to a Paul trap with the radius of the ring electrode r_0. The equation of motion for the z coordinate is obtained by multiplying the parameters a and q by the factor -2. The general solution of the Mathieu equation in the first stability region of the (a,q) parameter space can be written by using the Floquet ansatz:

$$r(\tau) = A\sum_{j=-\infty}^{\infty} c_j \cos(2j+\beta_r)\tau + B\sum_{j=-\infty}^{\infty} c_j \sin(2j+\beta_r)\tau \qquad [9]$$

where A and B are constants determined by the initial conditions, and the c_j and β_r depend on a and q. In the first stability region, where most of the experiments are carried out, the value of β_r is between 0 and 1. According to eqn [9] the motional spectrum of the ion has resonances at

$$\omega_{r,j} = \left(j \pm \frac{\beta_r}{2}\right)\Omega, \qquad j = 0, 1, 2\ldots \qquad [10]$$

In the adiabatic approximation, which is valid for $a, q^2 \ll 1$, the motion of the ion can be separated into an oscillation at the driving frequency Ω, the so-called micromotion, and a slower oscillation, called the secular motion, describing the oscillation in the time-averaged pseudopotential. This pseudopotential describes the effect of the ponderomotive force of the oscillating trapping field that drives the ion to the field minimum at the center of the trap. Since, in the quadrupole trap the pseudopotential is harmonic, the solution to the equation of motion can be approximated as

$$r(\tau) = r_0 \cos\beta_r\tau\left(1 + \frac{q_r}{2}\cos 2\tau\right) \qquad [11]$$

The approximate expression for β_r is $\beta_r = \sqrt{q_r^2/2 + a_r}$ and the secular frequencies are given by

$$\omega_r = \frac{\Omega}{\sqrt{8}}\sqrt{q_r^2 + 2a_r}, \qquad \omega_z = \frac{\Omega}{\sqrt{2}}\sqrt{q_r^2 - 2a_r} \qquad [12]$$

which are the lowest-order resonances $\omega_{r,z} = \beta_{r,z}\Omega/2$ in the Floquet ansatz, eqn [9]. From eqn [11] it is seen that the amplitude of motion at the resonances $\Omega \pm \omega$ is a factor $q_r/4$ smaller than those at the resonance ω. It is noteworthy that the frequency Ω of the driving field does not appear directly in the motional spectrum, but only in combination with the secular frequency ω. This changes, however, if there is an additional static force acting on the ion, displacing it from the center of the quadrupole. The approximate solution to the equation of motion then becomes:

$$r(\tau) = r_1 + r_0 \cos\beta\tau\left(1 + \frac{q_r}{2}\cos 2\tau\right) \qquad [13]$$

and a resonance at Ω appears. The force that displaces the ion by r_1 may be due to static electric stray fields or the presence of a second ion in the trap. These effects can have a strong influence on sideband laser cooling of the trapped ions. A number of theoretical studies have been published on the quantum-mechanical treatment of the Paul trap. The explicitly time-dependent potential does not allow stationary states with time-independent energy eigenvalues. One can, however, as in the case of the pseudopotential model, distinguish between two time-scales and construct wave functions of the harmonic secular oscillator that show some additional breathing motion at the trap frequency. A quantum-mechanical theory of sideband cooling in the time-dependent potential of the Paul trap thus far exists only for special cases; in 1994 there was a case where the ion was localized in the Lamb–Dicke regime at the node of a standing laser wave and time

averaged kinetic energies were calculated. Minima of the energy that agree with the results of the theory for the static harmonic trap to within a factor of 2 were found. The strongest modifications to the predictions of the cooling theory for the static trap arise in the dependence of the energy on the laser detuning. The influence of the micromotion gives rise to heating for certain regions of negative laser detuning (on the high-frequency side of a low-frequency micromotion sideband) and to cooling for some positive detunings (on the low-frequency side of a high-frequency micromotion sideband).

Trapped LASER-cooled ions have a variety of applications in spectroscopy and other fields.

In the following, a phenomenon will be discussed where observations during the cooling process of ions in traps is interpreted as phase transitions between chaotic and ordered ion structures during the cooling process.

Generation of Chaos During the Cooling Process and Phase Transitions to Ordered Configurations

Using a Paul trap, it is possible to study the physics of a few-body phase transition of ions. The ordered state of the trapped ions can be observed directly by monitoring their resonantly scattered light. The transition to an ordered or 'crystalline' configuration is expected when the Coulomb coupling constant which corresponds to the ratio of Coulomb energy to the kinetic energy of a particle, is larger than 1. The ordered structures represent configurations of maximum density for the ions, they are determined by the trap potential pushing the ions towards the trap center, and by the Coulomb repulsion between the ions acting in the opposite direction, so that minimum energy configurations are finally adopted. The system corresponds to an ordered one-component plasma or a strongly coupled plasma.

In the following, computer simulations of the phase transition in the Paul trap will be reviewed. In the trap the ions are subjected to five different forces. These are the force $\mathbf{F}^{(\mathrm{trap})}$, arising from the dynamical rf trapping field, the Coulomb interaction between the ions $\mathbf{F}^{(\mathrm{Coul})}$, the laser cooling force $\mathbf{F}^{(\mathrm{laser})}$, a random force $\mathbf{F}^{(\mathrm{rand})}$ arising from the recoil of the spontaneously emitted photons, and a parasitary force $\mathbf{F}^{(\mathrm{cont})}$, arising from a contact potential, which may be generated unintentionally by locally coating the electrodes with the trapped atoms.

The potential generated by the rf voltage applied to the hyperbolic electrodes of the trap is given by

$$\phi(\mathbf{r},t) = \varphi(t)[x^2 + y^2 - 2z^2]$$
$$\varphi(t) = \frac{U_0 + V_0\cos(\Omega t)}{r_0^2 + 2z_0^2} \qquad [14]$$

where U_0 and V_0 are the dc and ac components of the voltages applied to the trap. From eqn [1] we obtain the trapping force and the resulting equation of motion of a single ion in the trap:

$$\mathbf{F}^{(\mathrm{trap})} = m\ddot{\mathbf{r}} = \mathbf{e}\nabla\phi(\mathbf{r},t) = -2\mathbf{e}\varphi(t)[\mathbf{r} - 3z\mathbf{e}_z] \qquad [15]$$

where m, $\mathbf{r}$, and $z\mathbf{e}_z$ denote the mass of the ion, the position, and the $z\mathbf{e}_z$-component of the position vector, respectively.

The Coulomb interaction between the particles results in the force:

$$\mathbf{F}_i^{(\mathrm{Coul})} = \frac{e^2}{4\pi\varepsilon_0}, \sum_{m\neq 1}\frac{\mathbf{r}_i - \mathbf{r}_m}{[\mathbf{r}_i - \mathbf{r}_m]^3} \qquad [16]$$

In the process of laser cooling, every scattered photon changes the momentum of an ion on the average by an amount $\hbar k$.

The ensemble average of the resulting laser cooling force acting on the i-th ion is thus:

$$\mathbf{F}_i^{(\mathrm{laser})} = \hbar k R[\mathbf{r}_i(t);\ \dot{\mathbf{r}}_i(t)] \qquad [17]$$

The number $N_i(l)$ of spontaneously emitted photons from the i-th ion during the l-th cycle of period $T = 2\pi/\Omega$ is

$$N_i(l)\int_{(l-1)T}^{lT} R[\mathbf{r}_i(t);\dot{\mathbf{r}}_i(t)]\mathrm{d}t \qquad [18]$$

In the simulations, it is assumed that these N_i spontaneous photons are emitted one by one, at the end of each rf cycle, rather than emitting them one by one, according to the appropriate photon-statistics during the cycle. The orientation of the unit vector $\hat{\mathbf{u}}_j$, which points in the direction of the j-th emitted photon, is chosen at random, but weighted with a $\cos^2$ distribution (dipole characteristic) with respect to the laser polarization axis. This way, only the linearly polarized spontaneously emitted photons have been simulated in the calculations. The circularly polarized ones, which occur with a $\sin^2$ distribution, have been neglected. The random force $\mathbf{F}_i^{(\mathrm{rand})}$, is thus:

$$\mathbf{F}_i^{(\mathrm{rand})}(t) = \hbar k\sum_{l=-\infty}^{\infty}\delta(t - lT)\sum_{j=1}^{N_i}\hat{\mathbf{u}}_j \qquad [19]$$

In some of the calculations, a contact potential has been taken into account which is generated experimentally by a coating of the quadrupole electrodes by the trapped particles. Close to the center of the trap, the contact potential gives rise to an approximately homogeneous electric field. Altogether, the motion of the i-th particle is governed by the sum of the above forces, that is:

$$m\ddot{\mathbf{r}}_i = \mathbf{F}_i^{(\mathrm{trap})} + \mathbf{F}_i^{(\mathrm{Coul})} + \mathbf{F}_i^{(\mathrm{laser})} + \mathbf{F}_i^{(\mathrm{rand})} + \mathbf{F}_i^{(\mathrm{cont})} \qquad [20]$$

Given appropriate initial conditions, the eqns of motion [20] are integrated forward in time to obtain the trajectories of the n-ion system. These trajectories provide all the information necessary to find the quantities of interest, such as the occupation probability density of the i-th ion in phase space (i.e., the probability density of finding the i-th ion at a given position, and with a given velocity), the (total) kinetic energy, and the fluorescence intensity.

Some of the results of the described simulations will be summarized below. Figure 1 shows the excitation spectrum of the ions as a function of laser detuning. The experiment confirms the results of the simulations.

Owing to the Coulomb interaction of the ions at particular phases of the cooling process, chaos in the ion cloud is observed leading to a heating process of the ions by the applied field of the trap. This heating mechanism was investigated in the simulations in detail and the summary of the results is given in Figure 2.

For zero laser power and large r, there is no net heating of the ions. This is confirmed by the experiments, in which, even in the absence of a cooling laser, large clouds of ions can be stored in a Paul trap over several hours without being heated out of the trap. The ions are far apart, the Coulomb force is small, and on short time-scales the ions behave essentially like independent singly stored ions. For this reason, this part of the heating diagram is called the 'Mathieu regime' as it is well described by the Mathieu equation [7]. Turning on a small laser power, the rms radius r reduces drastically due to laser

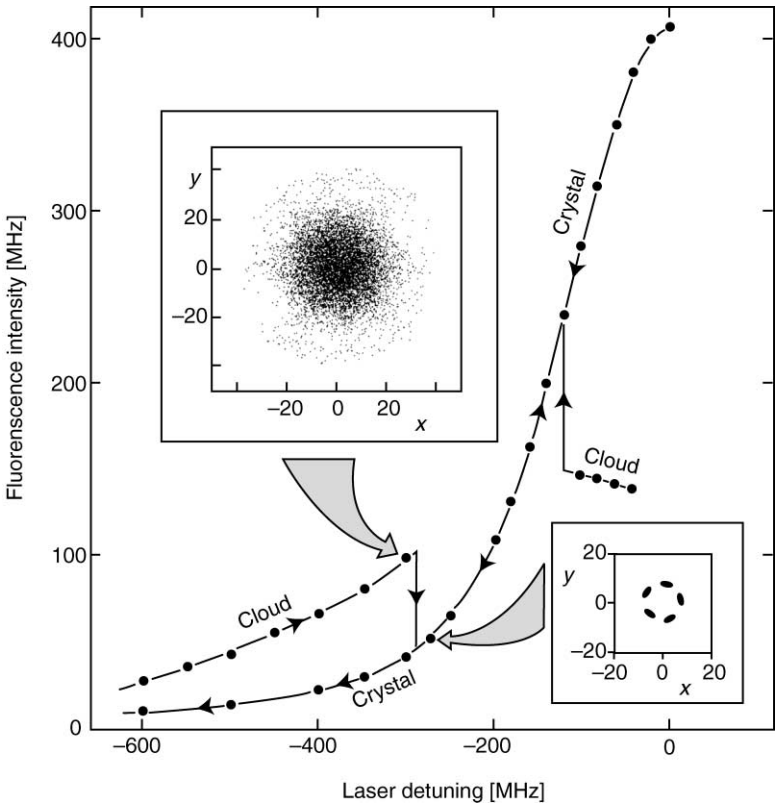

Figure 1 Excitation spectrum of five ions as a function of laser detuning. When the laser detuning is changed the cooling rate of the ion is varying. Two phase transition points (and bistability) are apparent. Insets show the results of the molecular dynamics calculations shortly before and after the jump, which demonstrates directly the existence of a transition from a cloud phase to a crystalline state. The units given at the insets are μm.

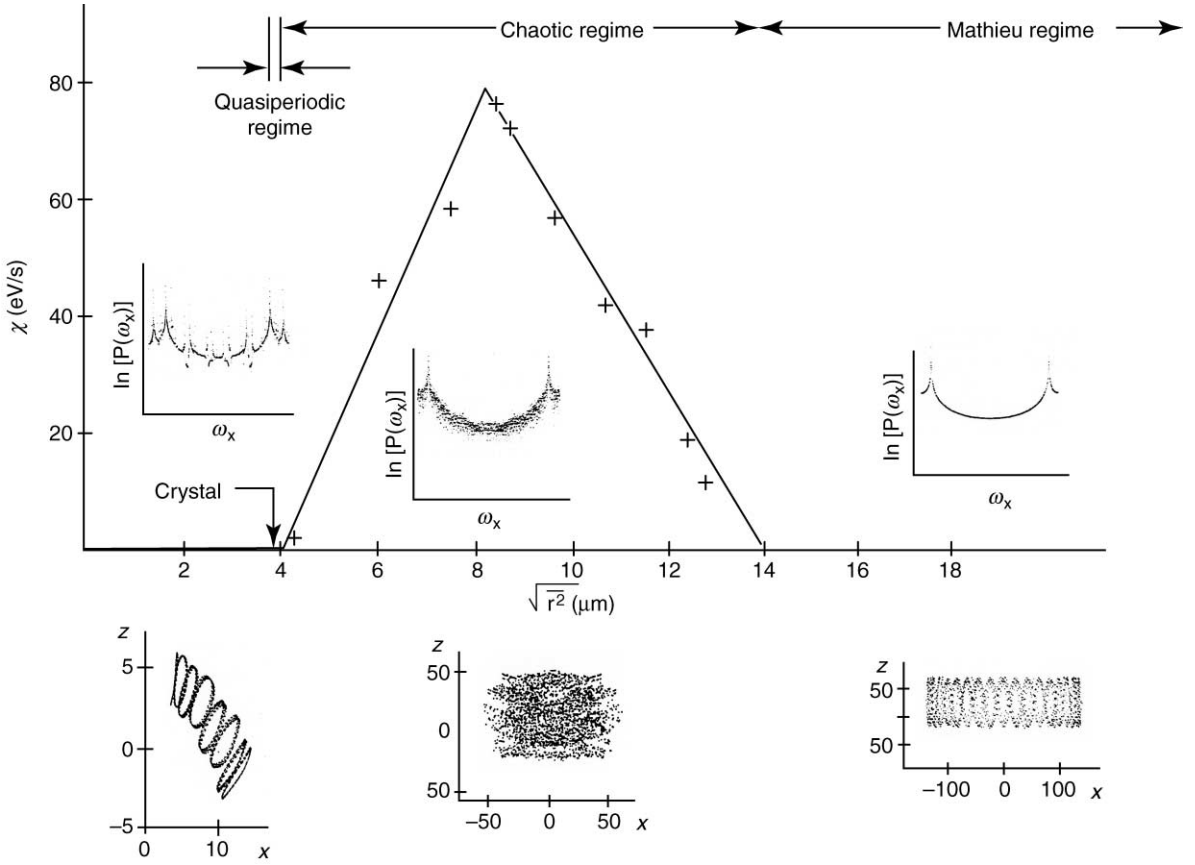

Figure 2 Average heating rate of five ions in a Paul trap versus the rms radius of the ion configuration. The insets show the power spectrum and the corresponding stroboscopic Poincaré sections in the x–z plane of relative separation for two ions in three characteristic domains: the quasiperiodic regime, the chaotic regime and the Mathieu regime. All length scales are in units of micrometers. Units gives at the x–z axis of the insets are in μm.

cooling, but comes to a halt at about 14 μm where chaotic rf heating sets in and balances the cooling power of the laser. Increasing the laser power results in an even smaller cloud. The smaller cloud produces more chaotic rf heating, as seen clearly by the negative slope of the heating curve (Figure 2) in the range $8 < r < 14$ μm.

In the range 4 μm $< r <$ 8 μm, there is still chaotic heating, but the slope of the heating curve is positive. As a consequence of the resulting triangular shape of the heating curve, at about 8 μm, the chaotic heating power can no longer balance the cooling power of the laser, and the cloud collapses into the 'crystalline' state located at $r \approx 3.8$ μm; a 'phase transition' has occurred. Due to this collapse, the behavior of the heating rate in the range 3.8 μm $< r <$ 8 μm cannot be studied by equilibrating laser cooling and rf heating. In this case, we start out from the crystal state and slightly displace the ions to explore the 'vicinity' of the crystal. We observe no heating for 3.8 μm $< r <$ 4 μm, but quasiperiodic motion, and thus name this regime the 'quasi-periodic' regime. We call the upper edge of the quasiperiodic regime ($r \approx 4$ μm) the 'chaos threshold'. An initial condition beyond the chaos threshold, i.e., satisfying $r > 4$ μm, leads to heating and expansion of the ion configuration and numerical data relevant for the shape of the heating curve can be taken during this 'explosion phase'. The laser power P is set to zero for this type of experiment. We conjecture that, apart from the trivial case of a single stored ion, the heating curve is 'universal', i.e., its qualitative shape, including the existence of the chaotic regime, does not depend on the number of simultaneously trapped ions.

For the quasiperiodic, the chaotic and the Mathieu-regime, respectively, the corresponding type of power spectrum are shown in the insets above the abscissa of Figure 2. The data were actually taken from the case of two ions, but would look similar in the five-ion case. A discrete spectrum in the quasi-periodic regime and a complicated

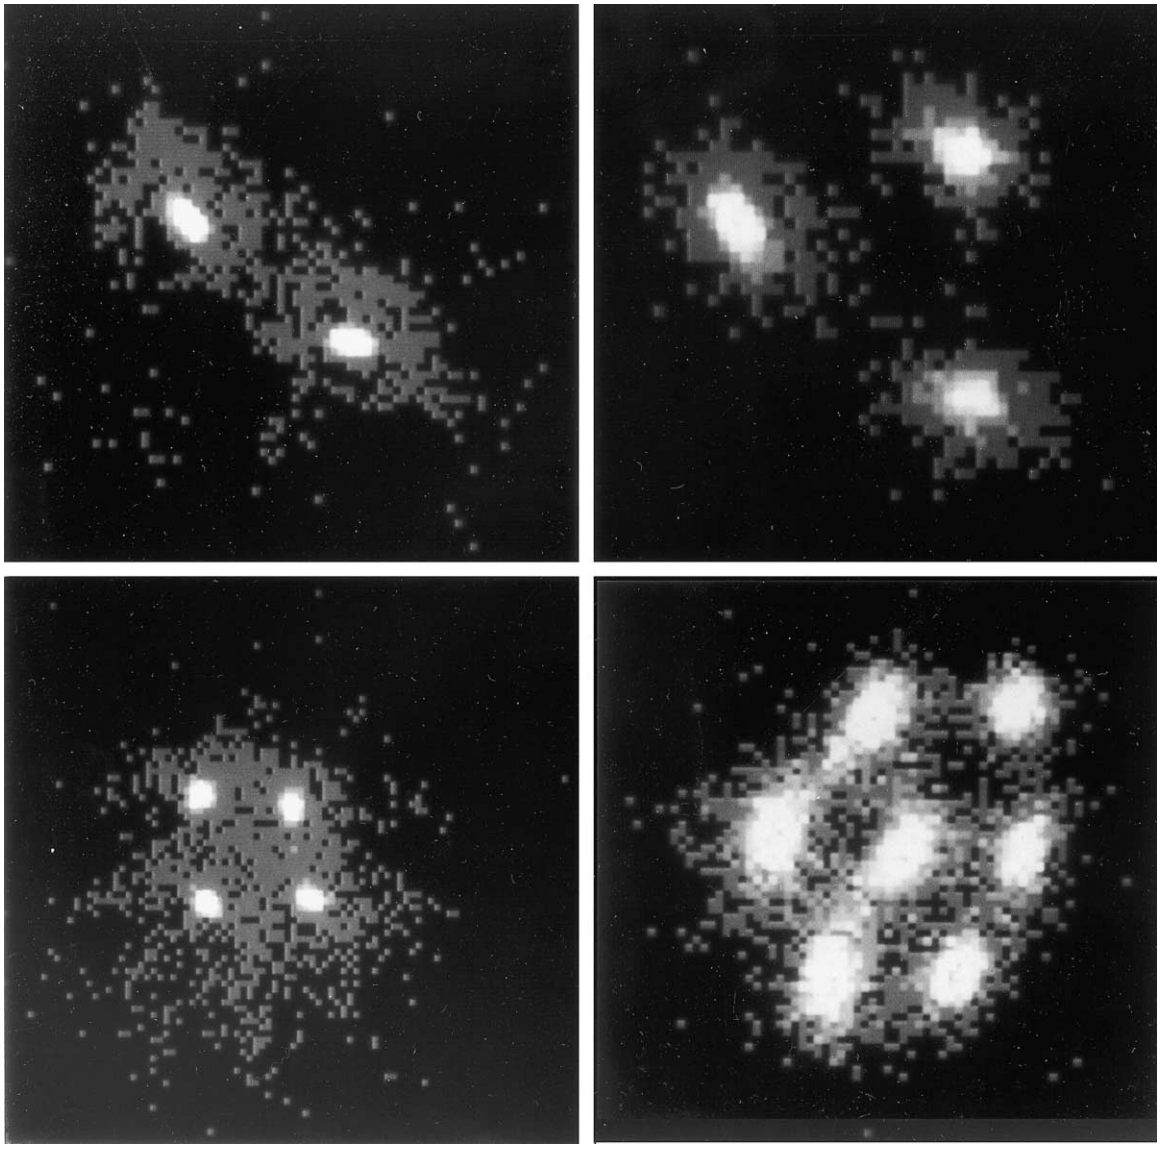

Figure 3 Ordered ion configuration of two, three, four, and seven laser-cooled Mg^+ ions confined in a Paul trap and observed using resonantly scattered light. The average ion separation is 20 μm. The structures of four and seven ions are slightly deformed owing to contact potentials in the trap.

noisy spectrum in the chaotic regime is obtained. The spectrum in the Mathieu regime is again quite simple and dominated by the secular motion frequency. Stroboscopic pictures of the locations of two ions in the x–y plane of the trap characterizing the three regions, are shown on the insets below the abscissa of Figure 2.

Some of the ordered ion structures observed experimentally are shown on Figures 3 and 4. The structures in Figure 3 were obtained in a Paul trap; the others are measured in a storage ring leading to quasi-linear structures of the ion configurations, depending on the symmetry of the trap. Ordered ion structures have also been observed in Penning traps. Due to the symmetry of this trap rotationally symmetric structures are observed.

Conclusion

Laser cooling of ions in traps provides an excellent tool for numerous experiments, varying from tests of basic physics to important and new applications in quantum information processing. The linear ion structure shown on Figure 4 is presently investigated in many laboratories in order to realize gates for

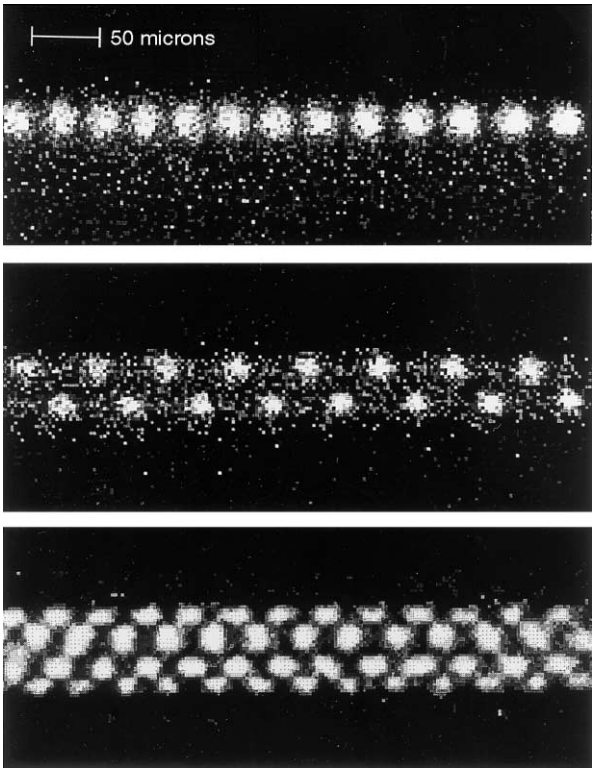

Figure 4 Crystalline structures of laser-cooled $^{24}Mg^{+}$ ions in the quadrupole storage ring. At a low ion density the ions form a string along the field axis (upper). Increasing the ion density transforms the configuration to a zigzag (middle). At still higher ion densities, the ions form ordered helical structures on the surface of a cylinder, e.g., three interwoven helices (lower). As the fluorescent light is projected onto the plane of observation in this case the inner spots are each created by two ions seated on opposite sides of the cylindrical surface, resulting in a single, bright area. quantum computing. Single trapped ions in cavities may be used as deterministic light sources for secure single photon communication links. Furthermore, in many laboratories single laser-cooled ions are investigated as the basis for new time and frequency standards, being several orders of magnitude more accurate than our present atomic clock.

Introduction

It is a well-known fact that the speed of commercial microprocessors is doubling, roughly, every 18 months (Moore's law). This speedup is achieved mainly at the expense of reducing the size of the microchip. If this tendency is to continue, it seems unavoidable that quantum mechanical effects will eventually become important.

Remarkably, far from being a technological nuisance, the fact that information carriers are truly quantum mechanical systems offers an entirely new paradigm for computation. As opposed to classical bits, with logical values 0 and 1, quantum bits (qubits) can be prepared in arbitrary, normalized superpositions of the logic values. In addition, quantum states of multiqubit systems can be entangled, i.e., cannot be written as tensor products of states of the individual components. The theoretical description of entanglement requires a huge number of parameters which, in fact, grows exponentially with the number of particles that are involved. This exponential number of new degrees of freedom is responsible for the computational potential that quantum systems offer. Recently it has been demonstrated theoretically how we can harness this potential in the form of quantum algorithms, including Shor's factorization algorithm and Grover's protocol for data base search.

From a theoretical point of view, the implementation of quantum computation is greatly simplified by the fact that any unitary transformation involving an arbitrarily large number of qubits can be decomposed into two building blocks: single qubit operations and two-qubit controlled-NOT gates (CNOT-gates). We only need to identify two-level systems whose interaction can be mediated in a way that allows for conditional dynamics, that is, the second system undergoes certain operation (a NOT operation in our case), conditional on the state of the first qubit. However, it is easy to convince ourselves that from the experimental point of view, the challenge is going to be formidable. The following (DiVincenzo)-checklist summarizes the necessary requirements for the potential physical realization of a quantum computer:

- The system needs to provide a well-defined qubit, with two robust levels to represent the logical values 0 and 1. Moreover, the system should be scalable.
- Both the initial preparation and the final readout of the system has to be done with sufficient accuracy.
- The system has to allow the implementation of a universal set of gates (single-qubit rotations and CNOTs gates) with sufficient high fidelity. Implicit in this requirement is the ability to address individual qubits.

From the above list it is clear that the practical realization of a quantum computer relies on the ability to achieve a delicate equilibrium: the system needs to interact strongly with selected external agents, typically laser light, both during the gate operations and the preparation and readout steps, but should be shielded from any unwanted interaction if the desired dynamics is to be preserved. Perfect, selective, shielding from the environment is not possible in practice and unwanted interactions with the surroundings will unavoidably result in some form of decoherence. In this article we will review the fundamentals of the implementation of a universal set of quantum gates using (i) atomic system coupled to a resonant field sustained in a microwave cavity and (ii) trapped ions confined in an electromagnetic trap. Atomic and ionic systems provide a good means for storing quantum information in long-lived electronic states. In addition, both neutral atoms and ions can be selectively detected with high efficiency. While none of the presented schemes is expected to be scalable to a very large number of qubits, they constitute the first prototypes for quantum registers and are expected to play an important role in applications where only a moderate number of qubits are required. These applications range from the development of new frequency standards to quantum communication protocols. We will discuss in the following sections how a set of universal gates can build within these systems and will present the state of the art of the experiments performed to date.

Quantum Computation: Basic Definitions

As stated before, the basic unit of quantum information is a qubit, an arbitrary quantum mechanical two-level system. We will associate logical values 0 and 1 with quantum states $|0\rangle$ and $|1\rangle$, the

eigenvectors of an observable such as the energy, and refer to such states as the computational basis. Any unitary operation on a qubit will be called a single qubit gate. Joint operations on more than one qubit will be denoted as multi-qubit gates. Using the fact that any two-level system is isomorphic to a spin-1/2 particle (e.g., an electron), we can always think of a qubit in terms of a certain pseudo-spin whose dynamics can be represented as rotation of the associated Bloch vector within the Bloch sphere.

For instance, as depicted in Figure 1, a qubit initially prepared in state $|1\rangle$, after experiencing a single qubit gate will be represented by certain Bloch vector $\vec{S}$, whose location on the Bloch sphere is a function of the gate parameters. Note that a classical system can only assume two positions (upwards and downwards), while a quantum system can explore the whole surface of the sphere.

It is also quite standard in quantum computation to use a diagramatic representation in terms of quantum circuits. Quantum circuits are built up of wires to denote the quantum bits and boxes to represent the gates, or quantum operations. Figure 2 shows two basics elements of a quantum circuit. The element on the left is the so-called Hadamard transformation, a particular example of single-qubit gate which transform each element of the computational basis as follows:

$$|0\rangle \rightarrow \frac{1}{\sqrt{2}}\left(|0\rangle + |1\rangle\right)$$
$$|1\rangle \rightarrow \frac{1}{\sqrt{2}}\left(|0\rangle - |1\rangle\right) \qquad [1]$$

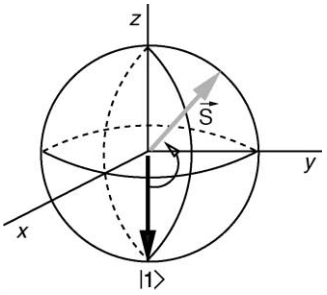

Figure 1 Geometrical representation of qubit systems using the Bloch sphere formalism. See the text for details.

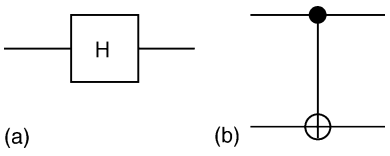

Figure 2 Examples of single qubit gates (a) Hadamard transformation and two qubit gates (b) CNOT gate as customarily represented in quantum circuits diagrams.

Part (b) of Figure 2 depicts a CNOT-gate. This is now an operation involving two qubits. The first one, the control qubit, remains unaltered after the gate operation while the second qubit, referred to as the target, undergoes a spin flip (logical NOT operation) only when the control is in the state $|1\rangle$. Specifically, the action of a CNOT-gate is defined by the following transformation rule:

$$\begin{aligned} &\text{CNOT} \\ &|00\rangle \rightarrow |00\rangle \\ &|01\rangle \rightarrow |01\rangle \\ &|10\rangle \rightarrow |11\rangle \\ &|11\rangle \rightarrow |10\rangle \end{aligned} \qquad [2]$$

We have already mentioned that single qubit rotations and CNOT gates provide a universal set of gates. Our aim now is to show how such operations can be built when the so far generic qubit are realized in terms of real atomic systems. In the two experimental scenarios we are going to analyze here, the CNOT operation will be achieved by means of a different type of gate, a controlled-phase gate supplemented by two one-qubit Hadamard gates on the target qubit. The arrangement is showed in Figure 3. The controlled-phase gate is again a two-qubit operation defined by the following transformation rule:

$$\begin{aligned} &\text{CNOT} \\ &|00\rangle \rightarrow |00\rangle \\ &|01\rangle \rightarrow |01\rangle \\ &|10\rangle \rightarrow |10\rangle \\ &|11\rangle \rightarrow -|11\rangle, \end{aligned} \qquad [3]$$

i.e., a global phase equal to π is acquired if, and only if, the two basis states are in the logical state 1. It is easy to check that when the target bit is rotated by a Hadamard gate prior and subsequently to the action

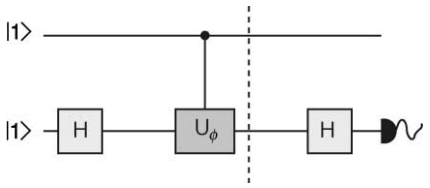

Figure 3 Controlled-phase gate with both inputs, control, and target qubits, in state $|1\rangle$. The first Hadamard gate rotates the target to state $(|0\rangle - |1\rangle)/\sqrt{2}$. The action of the controlled-phase gate with $\phi = \pi$ yields the joint state $|1\rangle + (|0\rangle - |1\rangle)/\sqrt{2}$ and a final Hadamard rotation on the target leaves the system in the product state $|1\rangle|0\rangle$.

of the joint phase gate, the resulting state is tantamount to the action of a single CNOT gate. Therefore, to prove that our atomic system allows for the implementation of a universal set of gates, it suffices to show that both single qubit rotations and controlled phase gates can be implemented with sufficient accuracy.

The next section analyzes a typical cavity QED setup and presents the basic physical ideas to understand how single and two-qubit gates can be implemented within atomic systems interacting with radiation fields. Subsequent sections will rely heavily in this analysis.

Quantum Computing with Atoms I: Cavity QED

A simplified cavity-QED arrangement for performing both single- and two-qubit gate operations is depicted in Figure 4. This configuration is well-known to quantum opticians and it is often referred to as a Ramsey interferometric setup. For concreteness, we will focus here in the experimental set up currently in operation at the ENS in Paris. There, the atomic system is a highly excited Rydberg atom initially prepared in a long-lived circular state. The relevant atomic states are represented in Figure 5, with the qubit being stored in levels $|i\rangle$ and $|g\rangle$ which will play the role of the general basis states $|0\rangle$ and $|1\rangle$.

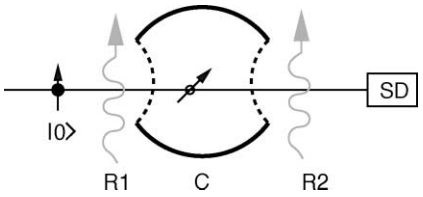

Figure 4 Cavity QED setup for single-qubit and two-qubit operations. Rotations of the atomic pseudo spin are performed via interation with classical radiation (Zone R), while the interaction with a resonant cavity field sustained in C allows the realization of a phase gate where the cavity photon acts as the control qubit.

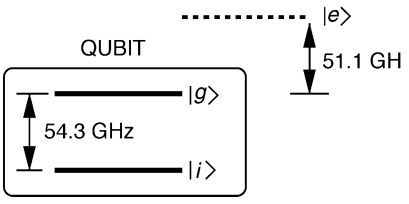

Figure 5 Circular Rydberg levels involved in the ENS experimental setup. The qubit is stored in levels $|i\rangle$ (logical value 0) and $|g\rangle$ (logical value 1). The radiative lifetime of these levels lies in the millisecond range. Dissipation can then be neglected along the 20 cm path inside the apparatus.

Regions denoted by R represent the interaction of the atomic system with classical microwave radiation. As detailed below, this interaction will allow arbitrary rotations of the atomic pseudo spin. Region C represents the interaction of the atomic system with a single mode cavity field resonant the atomic transition $g - e$. The highest Q value reported to date is of the order of 10^8, which corresponds to a photon storage time of a few milliseconds. Therefore, the relaxation time of the cavity field is much longer than the atom-cavity interaction time, which defines the two-qubit gate operation time and is of the order of a few tens of μs. The cavity field can be prepared in either of the Fock states $|0\rangle_\gamma$ or $|1\rangle_\gamma$ and will play the role of the control qubit for the realization of a phase gate, as detailed below. This set up is completed with a detection scheme (SD in the figure) that allows the selective detection of the atomic electronic state.

We will start our discussion showing how to perform an arbitrary single-qubit gate by means of irradiating the atomic system with classical radiation. We will keep the analysis in very general terms with the aim of using it later in the description of the implementation of quantum logic with trapped ions.

Single-Qubit Rotations

Let our qubit be a two-level atomic system with frequency separation ω_0. We will show that an arbitrary rotation can be achieved by means of irradiating the system with classical light, e.g., microwave radiation or a laser field, with tunable frequency ω_L. The radiation field will be specified by two controllable parameters, its Rabi frequency Ω and its phase ϕ. The atom-field Hamiltonian can be written as

$$H = \frac{\hbar\omega_0}{2}\left(|1\rangle\langle 1| - |0\rangle\langle 0|\right) + \hbar\left(g e^{i\omega_L t}|0\rangle\langle 1| + g^* e^{-i\omega_L t}|1\rangle\langle 0|\right) \qquad [4]$$

where the first term corresponds to the atomic internal energy and the second describes the coupling with the external field. The coupling constant g can be written in terms of the field parameters as

$$g = \frac{i\Omega}{2} e^{-i\phi} \qquad [5]$$

In order to write down a time-independent Hamiltonian, we will move to an interaction picture with

respect to $H_0 = \hbar\omega_L/2(|1\rangle\langle 1| - |0\rangle\langle 0|)$. In this frame,

$$H_{\text{int}} = \frac{\hbar\delta}{2}\Big(|1\rangle\langle 1| - |0\rangle\langle 0|\Big) + \hbar\Big(g|0\rangle\langle 1| + g^*|1\rangle\langle 0|\Big) \quad [6]$$

The interaction Hamiltonian can be readily expressed in terms of the Pauli spin operators

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad \sigma_y = \begin{pmatrix} 0 & i \\ -i & 0 \end{pmatrix} \quad \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad [7]$$

as

$$H_{\text{int}} = \frac{\hbar\delta}{2}\sigma_z + \frac{\hbar\Omega}{2}(\sin\phi\,\sigma_x - \cos\phi\,\sigma_y) \quad [8]$$

where $\delta = \omega_L - \omega_0$ denotes the detuning from the atomic transition and we have taken into account the explicit form of g as given by eqn [5]. We can now easily derive the time evolution operator by noting that H_{int} can be written in a compact form as $H_{\text{int}} = \vec{\sigma}\cdot\vec{n}$, where the vector $\vec{n}$ has cartesian coordinates $\vec{n} = (\Omega/2\sin\phi, -\Omega/2\cos\phi, \delta/2)$. Note that $|\vec{n}| \equiv \Omega_g = 1/2\sqrt{\Omega^2 + \delta^2}$. The time evolution operator can then be written as follows:

$$U = e^{-iH_{\text{int}}t} = \cos(|\vec{n}|t)1\!1 - i\sin(|\vec{n}|t)\vec{\sigma}\cdot\vec{n}/|\vec{n}| \quad [9]$$

In matrix form:

$$U = \begin{pmatrix} \cos\left(\frac{\Omega_g t}{2}\right) - i\frac{\delta}{\Omega_g}\sin\left(\frac{\Omega_g t}{2}\right) & \frac{\Omega}{\Omega_g}\sin\left(\frac{\Omega_g t}{2}\right)e^{-i\phi} \\ -\frac{\Omega}{\Omega_g}\sin\left(\frac{\Omega_g t}{2}\right)e^{i\phi} & \cos\left(\frac{\Omega_g t}{2}\right) + i\frac{\delta}{\Omega_g}\sin\left(\frac{\Omega_g t}{2}\right) \end{pmatrix} \quad [10]$$

In the limit of large Rabi frequency, where $\Omega \gg \delta$, we can write the following approximate expressions for the time evolution of the computational basis states

$$\begin{aligned} U|0\rangle &= \cos\left(\frac{\Omega_g t}{2}\right)|0\rangle - \sin\left(\frac{\Omega_g t}{2}\right)e^{i\phi}|1\rangle \\ U|1\rangle &= \sin\left(\frac{\Omega_g t}{2}\right)e^{-i\phi}|0\rangle + \cos\left(\frac{\Omega_g t}{2}\right)|1\rangle \end{aligned} \quad [11]$$

The transformed states by U are eigenstates of the spin operator along the direction $\vec{n}$ which is a function of the external field parameters. Therefore, by adjusting the Rabi frequency and the field's phase, it is possible to transform the basis states into spin eigenstates along any arbitrary direction, and to perform an arbitrary rotation of our qubit, we simply have to tailor appropriately the parameters of the driving field. For example, when the Rabi frequency and the interaction time are chosen such that $\Omega t/2 = \pi/4$, and the field's phase is taken equal to π, we get

$$\begin{aligned} U|0\rangle &= \frac{1}{2}\Big(|0\rangle + |1\rangle\Big) \\ U|1\rangle &= \frac{1}{2}\Big(|0\rangle - |1\rangle\Big) \end{aligned} \quad [12]$$

This relationship defines the Hadamard transformation H introduced before. Alternatively, using quantum optics jargon, we have performed a $\pi/2$-pulse. Note that using the Bloch sphere representation, we can visualize the action of a Hadamard gate on the computational basis states as a rotations that brings them to the equatorial plane of the Bloch sphere, the transformed states by H now lying in opposite directions along the x-axis.

The next step is to show that our system also allows the implementation of conditional dynamics and, in particular, allows to build a controlled-phase gate.

Conditional Dynamics: Controlled-Phase Gate

The interaction of the atomic system with the cavity field sustained by the microwave cavity is described by the Jaynes–Cummings (JC) Hamiltonian. We can see this Hamilton operator as a generalization of the operator defined by eqn [4], where the radiation field is now quantized and the terms $e^{\pm i\omega_L t}$ are replaced by the operators a and $a^\dagger$ corresponding to the annihilation and creation of a cavity photon of frequency ω. The interaction with the quantized cavity field couples levels $|e\rangle$ and $|g\rangle$, while the far detuned level $|i\rangle$ will now play the role of a passive spectator. Remember that our atomic qubit is stored in levels $|i\rangle$ and $|g\rangle$. To avoid confusion with the notation, we will write the Hamilton operator in terms of the atomic states e and g. Explicitly:

$$\begin{aligned} H_{\text{JC}} = &\frac{\hbar\omega_0}{2}\Big(|e\rangle\langle e| - |g\rangle\langle g|\Big) + \hbar\omega a^\dagger a \\ &- i\frac{\hbar\Omega}{2}\Big(a|g\rangle\langle e| - a^\dagger|g\rangle\langle e|\Big) \end{aligned} \quad [13]$$

where the coupling constant g has been taken to be $g = -i(\hbar\Omega/2)$, proportional to the Rabi frequency averaged over the mode structure, Ω. Using the same techniques employed in the previous section, we can derive the corresponding JC time evolution operator,

which yields, for exact resonance, the following transformation rules:

$$\begin{aligned} |g\rangle|0\rangle_\gamma &\rightarrow |g\rangle|0\rangle_\gamma \\ |g\rangle|1\rangle_\gamma &\rightarrow \cos\frac{\Omega t}{2}|g\rangle|1\rangle_\gamma - \sin\frac{\Omega t}{2}|e\rangle|0\rangle_\gamma \\ |e\rangle|0\rangle_\gamma &\rightarrow \cos\frac{\Omega t}{2}|e\rangle|0\rangle_\gamma + \sin\frac{\Omega t}{2}|g\rangle|1\rangle_\gamma \end{aligned} \quad [14]$$

where states $|\rangle_\gamma$ refer to the cavity field. Note that:

- The cavity field will play the role of our control qubit in the performance of a phase gate, the target qubit being the atomic system with computational states defined as before. The computational basis for the photonic qubit is provided by the Fock states $|0\rangle_\gamma$ and $|1\rangle_\gamma$.
- Strictly speaking, the time t entering in the equations above corresponds to an effective interaction time which accounts for the spatial variation of the coupling along the field mode.
- When the atom enters the cavity in state $|i\rangle$, it will acquire a global phase proportional to the ratio Ω^2/δ_i, where δ_i denotes the detuning between the atomic transition $e \leftrightarrow i$ and the mode frequency ω. In conditions of resonance, or quasi-resonance, this factor can be safely neglected, which justifies the term *passive spectator* used before.

We now have all the ingredients to understand how we can perform a controlled phase gate. Consider the situation where $\Omega t = 2\pi$, so the system experiences a full Rabi oscillation. According to the previous discussion, the basis states of two-qubit system atom-cavity field will transform as follows:

$$\begin{aligned} |i\rangle|0\rangle_\gamma &\rightarrow |i\rangle|0\rangle_\gamma \\ |i\rangle|1\rangle_\gamma &\rightarrow |g\rangle|0\rangle_\gamma \\ |g\rangle|0\rangle_\gamma &\rightarrow |g\rangle|0\rangle_\gamma \\ |g\rangle|1\rangle_\gamma &\rightarrow -|g\rangle|1\rangle_\gamma \end{aligned} \quad [15]$$

That is, whenever the atomic system enters the cavity in state $|i\rangle$, it will be left unaffected, irrespective of the photon state. However, if the atom enters the cavity in state $|g\rangle$, the system will undergo a phase shift equal to π conditional to the photon number. And that is precisely the dynamics required for a controlled phase gate as defined earlier.

A detailed account of the experiments in cavity QED, showing coherent gate operation, can be found in Further Reading. These experiments prove the working principle of a universal set of quantum logic gates with neutral atoms and provide the basic elements for the development of a cavity QED quantum register in the near future.

Quantum Computing with Atoms II: Ion Traps

Charged atomic particles, ions, provided the first atomic system where conditional dynamics was demonstrated experimentally. The theoretical proposal in 1995, by Cirac and Zoller, for performing a two-qubit controlled NOT gate between trapped ions cooled to their motional ground state, was followed a few months later by a pioneering experiment at NIST, in Colorado. While the physics involved in the description of laser cooled and trapped ions is conceptually more involved than the dynamics ruled by a purely JC Hamiltonian, we can review the rudiments of the Cirac–Zoller scheme on the basis of the techniques developed in the previous sections. Nevertheless, as discussed briefly at the end of this section, we should point out that the exact procedure followed in the actual experiments departs from the analysis presented here.

Figure 6 depicts a linear ion trap where a string of ions is confined in an essentially 1-D structure. Quantum bits are stored in two long-lived hyperfine states which can be driven with laser light of controllable Rabi frequency Ω and phase ϕ. Ideally, the separation d between ions exceeds the wavelength of the external field so that ions can be addressed individually. Detection of the atomic state relies on the well mastered quantum jump technique which provides an efficiency close to 100%. From our previous discussion, it is clear that we already have all the ingredients for performing arbitrary single qubits gates, but we still need to provide a procedure to achieve two-qubit gate operations. As detailed in the next section, this will be achieved using the motional degrees of freedom of the ions as a bus for information transfer between an arbitrary pair of ions.

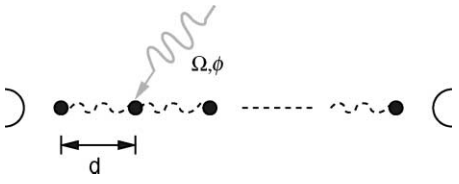

Figure 6 Schematic representation of a linear ion trap. Ions are individually addressed by external laser fields to perform single qubit operations, while two-qubit gates are mediated by the coupling to the motional degrees of freedom, depicted here as mechanical strings linking the chain of ions in the trap. The exact duration of a two-qubit gate operation and the characteristic decoherence time depend very much on the trap design, but orientative values are in the range of 50 μs and 100 − 1000 μs respectively.

The Cirac and Zoller Quantum Computer

At sufficiently low temperatures, the process of absorption and emission of photons produces a non-negligible recoil of the atomic system and the ion's motion can no longer be treated classically. In this regime, we can think of the string of ions as a system of coupled quantum harmonic oscillators whose normal mode configurations correspond to the collective motional states of the ions. The lowest energy solution corresponds to an oscillation where all ions are in phase (center of mass (CM) mode) and will be the one considered in our description. Figure 7 depicts the level scheme for ions initially cooled down to the motional ground state, illustrating both internal levels, $|e\rangle$ and $|g\rangle$, and motional (vibrational) states, denoted by $0, 1, \ldots$ Laser radiation can be tuned to be resonant with the $|g\rangle|0\rangle_{cm} \leftrightarrow |e\rangle|0\rangle_{cm}$ transition (carrier transition), but may also be tuned to drive transitions with different vibrational states (sideband transition), as represented by the external arrows in the figure. The realization of single qubit gates simply involves tuning the laser towards the carrier transition. The interaction is ruled by essentially the same Hamiltonian discussed above. Therefore, choosing appropriately the laser parameters, it is possible to induce an arbitrary rotation of the ion pseudo-spin.

To prove that the system allows the implementation of a universal set of gates, we will now show that it is possible to operate a controlled phase gate between two arbitrary ions. For that we need to couple internal and motional degrees of freedom which will be done by means of tuning the laser light to a sideband transition. The corresponding Hamiltonian will not be derived here in detail but it can be understood as describing a Jaynes–Cummings

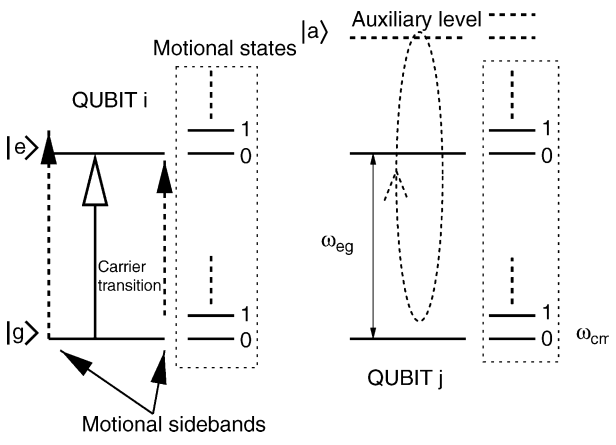

Figure 7 Relevant internal and motional atomic levels for the realization of a controlled NOT gate between two arbitrary ions within a chain. See the text for details.

form of dynamics where the quantized electromagnetic field within a cavity is replaced by the quantum mechanical oscillator describing the vibrational states of the ion. Explicitly:

$$H = \frac{\eta\Omega}{2}\left(c|e\rangle\langle g| + c^{\dagger}|g\rangle\langle e|\right) \qquad [16]$$

where c and $c^{\dagger}$ denote the annihilation and creation operators of vibrational quanta and η is the so-called Lamb–Dicke parameter, a measure of the recoil energy. The gate operation involves the following sequence:

- Mapping the internal state of the control ion into the collective motional state of the chain,
- performing an operation on the target ion conditional to the excitation number of the vibrational state and
- reverse the initial operation restoring the vibrational state to its ground state.

Imagine ion i, which will play the role of the control, and j, the target, initially prepared in arbitrary superpositions of the corresponding internal states, with the whole system cooled down to their motional ground state $|0\rangle_{cm}$. The joint state of the two particles can be written as a product state of the form:

$$\left(\alpha_i|g\rangle_i + \beta_i|e\rangle_i\right) \otimes |0\rangle_{cm} \otimes \left(\alpha_j|g\rangle_j + \beta_j|e\rangle_j\right) \qquad [17]$$

When ion i is irradiated by a laser tuned to the first motional side band $|g\rangle|1\rangle_{cm} \leftrightarrow |e\rangle|0\rangle_{cm}$, and the timing is such that the system undergoes a π-Rabi rotation, the internal state of the ion i is mapped onto the vibrational state (Note the transformation rules given in eqn [14]. As a result, the joint state of the system is still factorizable as

$$\left(|g\rangle_i \otimes \alpha_i|0\rangle_{cm} + \beta_i|1\rangle_{cm}\right) \otimes \left(\alpha_j|g\rangle_j + \beta_j|e\rangle_j\right) \qquad [18]$$

The second step of the protocol consists of applying an operation on ion j conditional on the vibrational state of the joint system. For that we apply a laser pulse resonant with the transition $|e\rangle_j|1\rangle_{cm} \leftrightarrow |a\rangle_j|0\rangle_{cm}$ with an auxiliary level $|a\rangle_j$ so that ion j undergoes a full Rabi oscillation. This results in acquiring a phase shift equal to π only if the system is state $|e\rangle_j|1\rangle_{cm}$ (see eqn [15]). This step entangles the internal and vibrational degrees of freedom of ion j, leading to a joint state of

the form:

$$|g\rangle_i \otimes \Big(\alpha_i|0\rangle_{cm}(\alpha_j|g\rangle_j + \beta_j|e\rangle_j) + \beta_i|1\rangle_{cm}(\alpha_j|g\rangle_j - \beta_j|e\rangle_j)\Big) \quad [19]$$

Applying a final laser pulse on ion i identical to the initial one, the state of the vibrational mode is transferred back to ion i and the atomic systems are left in the, generally, entangled state

$$\alpha_i\alpha_j|g\rangle_i|g\rangle_j + \alpha_i\beta_j|g\rangle_i|e\rangle_i + \beta_i\alpha_j|e\rangle_i|g\rangle_j - \beta_i\beta_j|e\rangle_i|e\rangle_j, \quad [20]$$

which completes the controlled-phase gate operation.

A simplified version of this scheme shortly followed the theoretical proposal by Cirac and Zoller, proving the working principle of the ions trap quantum processor. Since then, both theoretical and experimental progress have allowed the development of schemes for implementing faster gates as well as protocols which do not require cooling to the motional ground state. We will briefly revise the current state of the art and future prospects of this technology in the last section of this article.

Frequency Estimations as a Quantum Computation: Building Frequency Standards with Entangled States

Recently, it has been proposed to make use of entangled states of trapped ions for performing high-resolution spectroscopy beyond the shot noise limit. This boundary is the ultimate limit achievable when performing a frequency measurement using uncorrelated particles. Consider n atomic two-level systems with frequency separation ω_0 initially prepared in their ground state $|0\rangle$. The aim is to lock a certain oscillator of frequency ω_L to the atomic frequency. To do that, the currently employed protocols use the so-called Ramsey method of separate oscillating fields, where each atomic system undergoes two $\pi/2$-pulses (or Hadamard transformations) separated by a free time evolution of duration t, much larger than the duration of the pulse. Looking at the Hamiltonian describing the interaction between the ion and the field, eqn [1], one can easily see that the free time evolution can be understood as a controlled phase gate in the following sense. If we set $g = 0$ in eqn [1] and for simplicity re-scale the ion internal energies so that $H = \hbar\delta|1\rangle\langle 1|$, the free evolution operator can be written as $U = -\hbar\delta|1\rangle\langle 1|$, so that the atomic basis states evolve as:

$$\begin{aligned} U|0\rangle &= |0\rangle \\ U|1\rangle &= e^{-i\delta t}|1\rangle \end{aligned} \quad [21]$$

In other words, the ground state remains invariant, whereas the upper levels pick up a phase which is proportional to the detuning from the atomic transition. The state of each particle after the time evolution can then be written as

$$\frac{1}{\sqrt{2}}\Big(|0\rangle + e^{-i\delta t}|1\rangle\Big) \quad [22]$$

After the second pulse, which again mixes populations of levels $|0\rangle$ and $|1\rangle$, one measures the population of, say, level $|1\rangle$. The signal is therefore a sinusoidal function of the form

$$P_1 = \frac{1}{2}\Big(1 + \cos(\delta t)\Big) \quad [23]$$

which is symmetrical with respect to $\delta = 0$. This procedure is repeated a number of times to accumulate a sufficient data. Let us call T the total duration of the procedure, so that we accumulate $N = nT/t$ experimental data. Finally, whenever statistics in the populations are different from 50:50 at half maximum are detected, the oscillator frequency is steered to achieve exact resonance. The ultimate resolution $\Delta\omega_0$ achievable with this technique is limited simply by projection noise and can be written as

$$\Delta\omega_0 = \frac{1}{\sqrt{nTt}} \quad [24]$$

After time T, the oscillator's frequency is steered towards the resonance and new sequence starts. We will now illustrate how the use of entanglement can yield an uncertainty in the measurement beyond the shot noise limit eqn [24]. Consider the quantum network depicted in Figure 8. The n particles are now initially prepared in a maximally entangled state. This is achieved by means of subjecting the first ion to

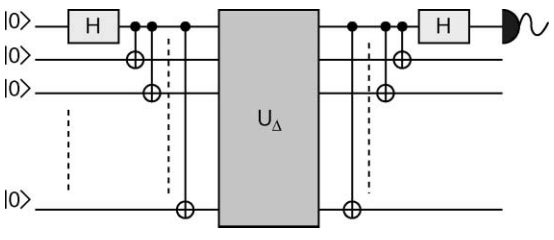

Figure 8 Quantum circuit representation for an experimental setup for a frequency estimation using maximally entangled states.

a Hadamard transformation followed by a cascade of CNOTs between the first ion, which acts as a control, and each of the remaining $(n-1)$ particles.

The resulting state is of the form

$$\frac{1}{\sqrt{2}}\Big(|0\ldots0\rangle + |1\ldots1\rangle\Big) \qquad [25]$$

The systems now evolve freely for a time t and, in light of the discussion above, we can represent this evolution in terms of a quantum gate which will leave state $|0\rangle$ invariant while introducing a phase factor proportional to the detuning if the system is in state $|1\rangle$. As a result, the joint state of the n particle after the free time evolution is given by

$$\frac{1}{\sqrt{2}}\Big(|0\ldots0\rangle + e^{-in\delta t}|1\ldots1\rangle\Big) \qquad [26]$$

with a phase factor amplified by a factor n as compared with the single particle state given by eqn [22]. The second part of the network disentangles the n particles, leaving the first ion in the state $(1/\sqrt{2})(|0\rangle + e^{-in\delta t}|1\rangle)$. If we now subject it to an additional Hadamard gate, the probability for the ion to be excited is

$$P_{1,ent} = \frac{1}{2}\Big(1 + \cos(n\delta t)\Big) \qquad [27]$$

which oscillates n times faster than the signal eqn [23]. The corresponding uncertainty for the estimation of the atomic frequency is now

$$\Delta\omega_0, ent = \frac{1}{n\sqrt{Tt}} \qquad [28]$$

This corresponds to an increase in the resolution of $\sqrt{n}$ beyond the shot noise bound. In practice, the achievable resolution using entangles states is limited by the decoherence time of the system t_{dec}, which sets the condition $T < t_{\mathrm{dec}}/2$ for the procedure to be valid. Remarkably, entanglement is still advantageous in a situation where T is chosen such that it exceeds the decoherence time. However, maximally entangled states should now be replaced by certain partially entangled ones to overcome the precision achievable with uncorrelated particles.

The application of entangled states in precision spectroscopy is a nice illustration of the potential of the ideas developed in quantum information beyond the ultimate task of building a large-scale quantum computer. The first experimental results showing the enhanced performance of entangled states have been reported by the NIST group in Boulder.

Conclusion and Perspectives

We have revised the fundamental concepts for the practical realization of quantum computation using atomic systems. We have showed how single qubit and two-qubit controlled-phase gates can be implemented using atoms interacting with the cavity field sustained by a microwave resonator and ion traps. We have illustrated how a very simple quantum computation can be used for the development of more precise frequency standards, emphasizing the potential of the ideas developed in quantum information beyond the implementation of large scale quantum computation.

Cavity QED technology has so far allowed the generation of entangled states of two and three particles and has demonstrated coherent gate operation. Ion trap technology has pushed controllable multi-particle entanglement to four particles and has showed the possibility of implementing forms of error correction. The combination of these two technologies offers interesting prospects for the near future. Surrounding traps by optical cavities and networking these devices via optical fibers is expected to allow the construction of the first prototypes for a quantum communication network.

Squeezed Phonons in Solids

Introduction

The reduction of noise is crucial for measurements requiring high accuracy and, often, for the observation of new phenomena. Among noise sources, noise inherently related to the quantum nature of an object persists even after all the classical sources of noise are removed. Quantum noise is a fundamental limitation, loosely related to the Heisenberg uncertainty principle, which imposes a lower limit to the fluctuations of any pair of conjugated variables, like position and momentum. For conjugated variables A_1 and A_2 we have

$$\Delta A_1 \Delta A_2 \geq \frac{\hbar}{2} \qquad [1]$$

where

$$\Delta A_i = \sqrt{\langle A_i^2 \rangle - \langle A_i \rangle^2} \qquad i = 1, 2 \qquad [2]$$

While quantum mechanics does not forbid reducing the noise in one of the conjugated observables down to zero, the noise for the other variable will increase according to eqn [1]. Squeezing refers to the reduction of noise of a quantum variable at the expenses of its conjugated variable. The term originates from quantum optics. Nonlinear interactions of the electromagnetic field with passive and active atomic media have been successfully used to generate squeezed photons, opening new possibilities for essentially noiseless optical communications and precision measurements. The electromagnetic field is not the only quantum object that can be squeezed. By performing appropriate manipulations of the internal quantum state of a system, it is, in principle, possible to squeeze an arbitrary variable. In the past few years, vibrational states have also been experimentally squeezed in molecules and solids, by exciting the system with ultrafast optical pulses. The concept of squeezing can also be extended to an ensemble of classical objects for which the fluctuations are of thermal origin.

Squeezing applies in particular to situations where the relevant variables are the position Q and momentum P of a harmonic oscillator. Consider the Hamiltonian of a particle of mass m in a harmonic potential of frequency Ω

$$H_0 = \frac{P^2}{2m} + \frac{m}{2}\Omega^2 Q^2 \qquad [3]$$

The ground state wavefunction is

$$\varphi_0 = \frac{1}{\left[2\langle Q_0^2 \rangle \pi\right]^{1/4}} \exp\left(-\frac{Q^2}{4\langle Q_0^2 \rangle}\right) \qquad [4]$$

where $\langle Q_0^2 \rangle = \hbar/2m\Omega$. The stationary probability, $|\varphi_0|^2$, is represented in Figure 1a. This state is also a minimal uncertainty state in that $\Delta Q \Delta P \equiv \hbar/2$. $\langle Q_0^2 \rangle$ gives a measure of the quantum noise and it is known as the vacuum noise level.

Let us now discuss the behavior of a harmonic oscillator that interacts with an external source. There are two types of quantum states for which the Gaussian shape of the wavefunction is preserved after interacting with an external driving force. These are the coherent state and the squeezed state. If the interaction places the system in a state of the same form as eqn [4] but displaced with respect to the center, the wavepacket will oscillate periodically, with period $\tau = 2\pi/\Omega$, without changing its shape as shown in Figure 1b. This quantum state is known as the coherent state. It has the same uncertainty as the ground state but the expectation value $\langle Q(t) \rangle$ depends on the time following the classical trajectory in the harmonic potential. If, instead, we introduce a sudden change in the spring constant at $t = 0$, the

wavepacket will begin to 'breathe' for $t > 0$, so that its width will vary periodically with a period given by $\tau/2$. This is the squeezed state. Here the noise of one of the variables is periodically reduced below the level of the vacuum noise (Figure 1c). A state that is a combination of a coherent and a squeezed state is shown in Figure 1d. The wavepacket follows the classical trajectory and breathes at the same time.

The results in Figure 1 apply only to harmonic oscillators. While the concept of squeezing can be extended to anharmonic potentials, there are additional features to consider such as, for example, wavepacket revivals.

Dynamics of a Parametrically Excited Crystal

Harmonic oscillators describe a wide range of physical systems. In particular, the dynamics of a crystal lattice can be described in terms of a set of independent harmonic oscillators, the quantum nature of which is described in terms of phonons. In this section we discuss interactions of a harmonic oscillator with external sources that produce squeezing.

The normal modes in a crystal obey equations of the form:

$$\ddot{Q}_q + \Omega_q^2 Q_q = 0 \qquad [5]$$

where Q_q and Ω_q are the phonon coordinate and frequency, and q is the wavevector.

As briefly mentioned in the previous section, a sudden change in the spring constant produces a squeeze state. To do this, we need what is known as time-dependent parametric coupling. As in the experiments on phonon squeezing, using ultrashort optical pulses, we consider an impulsive driving force proportional to Q. The relevant equation is:

$$\ddot{Q}_q + \Omega_q^2 Q_q = \lambda_q Q_q \delta(t) \qquad [6]$$

where $\delta(t)$ is the Dirac delta function, and λ accounts for the strength of the external impulsive force. This impulsive excitation induces a sudden change in momentum, proportional to the normal coordinate Q at $t = 0$, as can be shown by integrating eqn [6]. Explicitly, $\Delta\dot{Q}_q = \Delta P_q = \lambda_q Q_q(0)$. $\Delta P_q = P_q(0^+) - P_q(0^-)$, where $0^-(0^+)$ is the time immediately before (after) the excitation. This result is illustrated in Figure 2. The main effect of the interaction is to change the width of the Gaussian packet or variance of the distribution. This leads to a time-dependence of the noise defined in eqn [2], $\Delta Q^2(t) = \langle Q^2(t)\rangle$ reflecting the 'breathing' of the wavepacket. Since P_q is the conjugated variable of Q_q, $\langle P_q^2(t)\rangle$ shows the same time-dependent behavior as $\langle Q_q^2(t)\rangle$ but in quadrature with it, so as to fulfill eqn [2] at all time. Assuming an oscillator initially in its ground state, the solution of eqn [6] is

$$\langle Q_q^2(t)\rangle = \frac{\hbar}{2m\Omega_q}\left[1 + \left(\frac{\lambda_q}{\Omega_q}\right)\sin(2\Omega_q t) + \left(\frac{\lambda_q}{\Omega_q}\right)^2 \sin^2(\Omega_q t)\right] \qquad [7]$$

It is then clear that the fluctuations of Q_q periodically fall below the vacuum quantum noise level, determined by $\langle Q_0^2\rangle$, and that the oscillations have a frequency that is twice the frequency of the oscillator.

The considerations above apply to a quantum harmonic oscillator at temperature $T = 0$. In the classical case, we need to consider an ensemble of oscillators in equilibrium with a thermal bath at temperature T. It can be shown that eqn [7] also applies to the classical case, provided $\hbar/2m\Omega$ is replaced by $k_B T/\Omega^2 m$, where k_B is the Boltzman constant. In classical squeezing, the external perturbation is applied simultaneously to the ensemble, leading to a sudden change of the momentum of all the oscillators. The jump in momentum is proportional to the position of the particle at $t = 0$. After the interaction, the noise of the ensemble will fall periodically below the thermal noise at temperature T given by $k_B T/\Omega^2 m$. A pictorial representation of classical squeezing is shown in Figure 3.

To describe a more realistic situation, it is necessary to take into account effects due to dissipation. Theoretically, this is usually accomplished by considering the coupling with a continuum of external modes simulating a thermal bath. The solution to this type of problem is nontrivial even for the simplest case of linear coupling to the bath.

The impulsive excitation of eqn [6] is a parametric excitation containing all the frequencies. A more common way to parametrically excite an oscillator is to use a monochromatic source, as described by the equation

$$\ddot{Q} + [\Omega^2 + \varepsilon\cos(\Omega_0 t)]Q = 0 \qquad [8]$$

where the parametric excitation is characterized by the amplitude ε and the modulation frequency Ω_0. Notice that the excitation induces a time-dependent frequency $\omega^2(t) = \Omega^2 + \varepsilon\cos(\Omega_0 t)$, and, hence, it

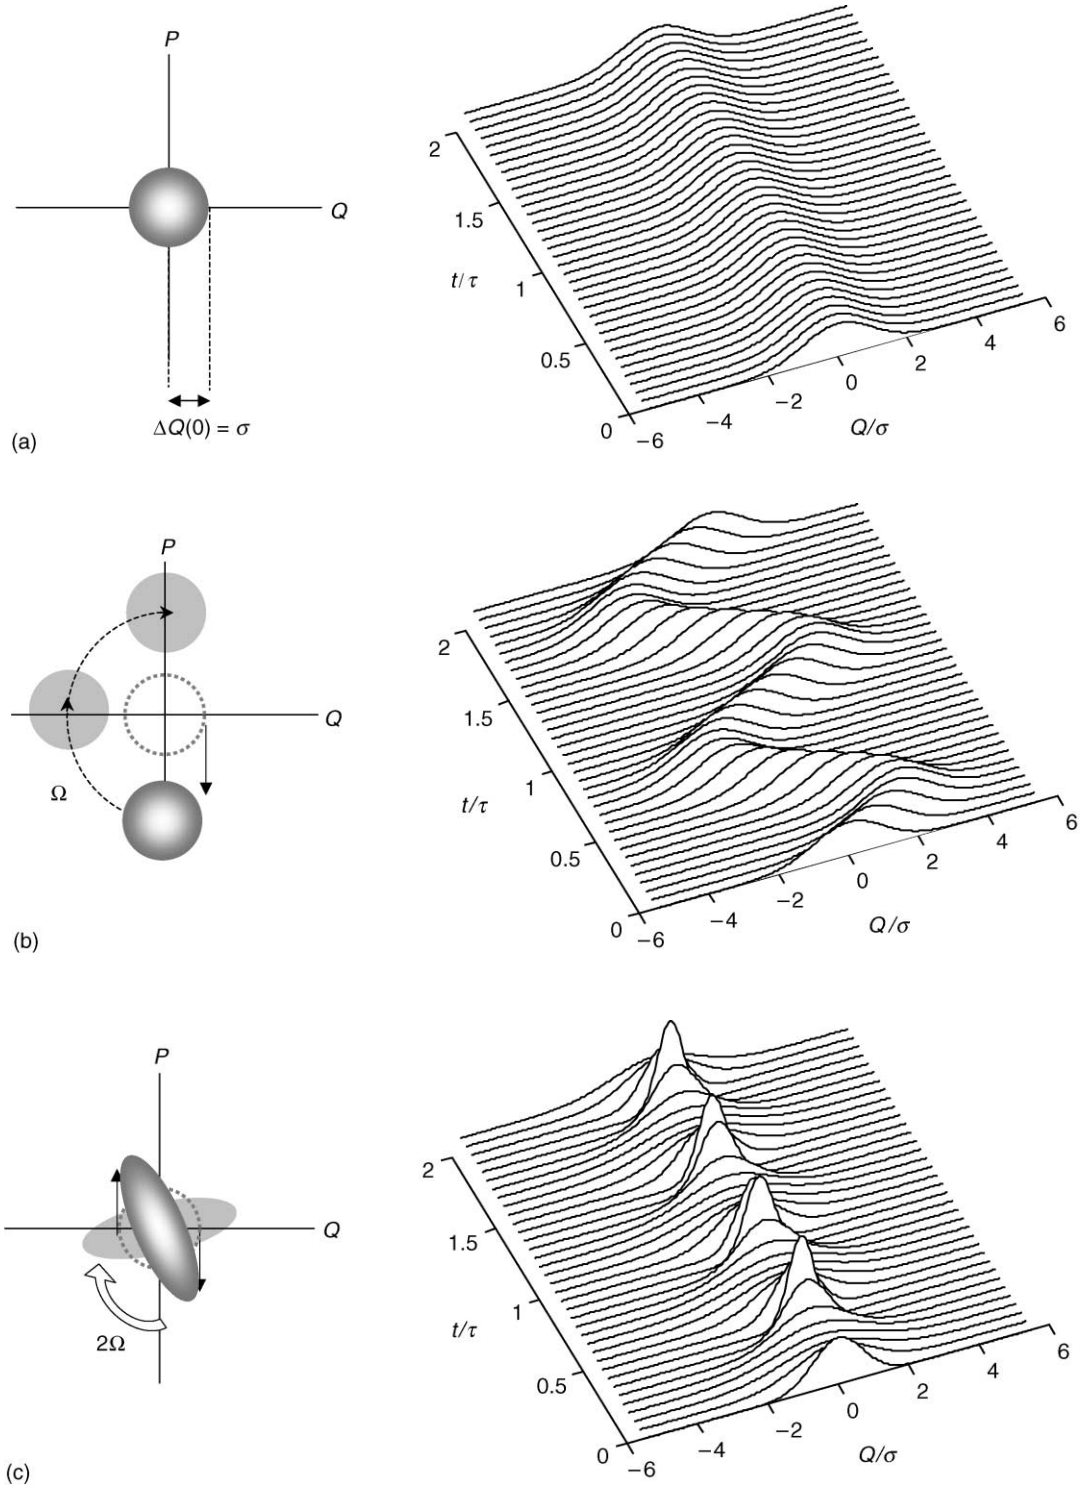

Figure 1 (a) Ground state probability density $|\varphi_0|^2$ for a quantum harmonic oscillator of frequency Ω. Q is the position, P is the momentum and σ is the standard deviation of the Gaussian wavepacket, or the square root of $\langle Q_0^2 \rangle$. The phase-space diagram on the left shows the uncertainty region for the ground state. (b) Coherent state. The uncertainty $\langle Q^2 \rangle$ does not change in time and it is always equal to $\langle Q_0^2 \rangle$, but the wavepacket oscillates with the period τ of the harmonic oscillator. The phase diagram shows the evolution of the uncertainty region, starting from the ground state (dashed line). A sudden constant change in momentum at time $t = 0$ produces a change in the equilibrium position and the wavepacket begins to oscillate. (c) Squeezed state. The wavepacket evolves by changing its width periodically with period $\pi/2$. The uncertainty, $\langle Q^2(t) \rangle$, takes values smaller than $\langle Q_0^2 \rangle$ for a fraction of the cycle. Due to the sudden change on momentum, proportional to Q, at $t = 0$, the distribution becomes ellipsoidal and rotates with frequency 2Ω. (d) Coherent-squeezed state. It is a combination of both (b) and (c). The wavepacket oscillates and breathes at the same time.

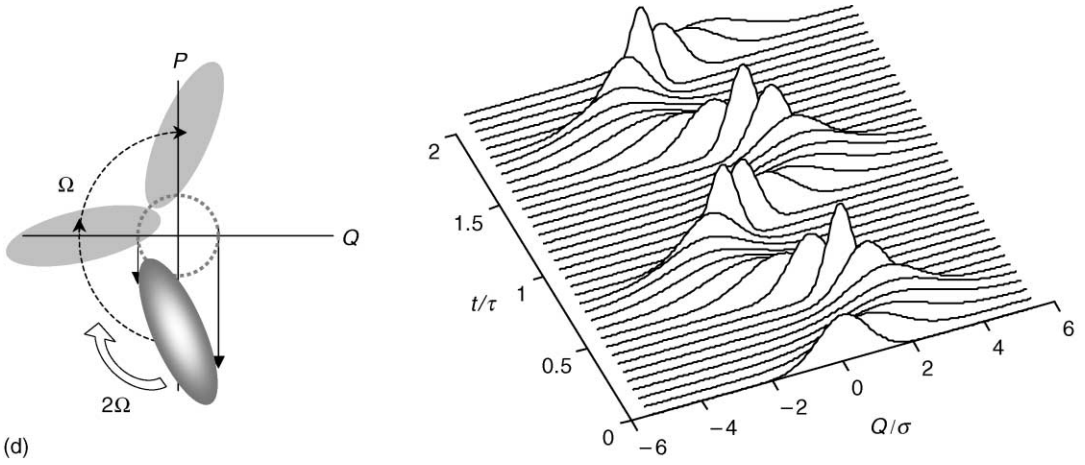

Figure 1 *Continued.*

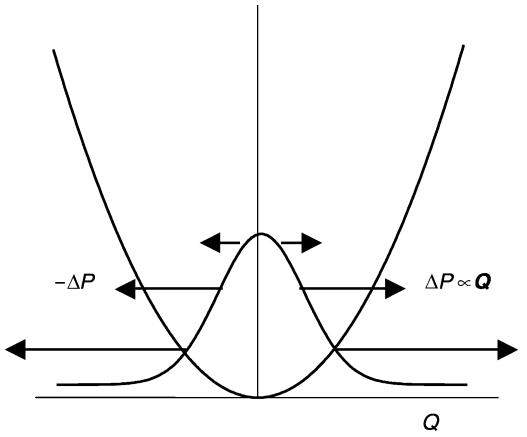

Figure 2 Schematic representation of the effect of an impulsive excitation on the ground state of the harmonic oscillator. At $t = 0$, the pulse induces a change in momentum P, proportional to the position Q. As a result, the wavepacket width in momentum space changes suddenly and starts to oscillate.

shows squeezing effects. The complete set of solutions with and without dissipation has been obtained by Zerbe and Hanggi for the quantum and classical cases.

Physical Interactions Giving Phonon Squeezing

The considerations above are rather general and specific to any physical system that behaves like a set of harmonic oscillators. Here, we consider proposals for phonon squeezing.

Equations [6] and [8] show that we need a driving force proportional to the phonon coordinate Q to achieve squeezing. One way to do this is for the external interaction to produce time-dependent correlations between two modes. Prior to the experimental achievement of phonon squeezing in 1997, using stimulated second-order Raman scattering, models based on (a) three-phonon parametric amplification and (b) polaritons had been proposed.

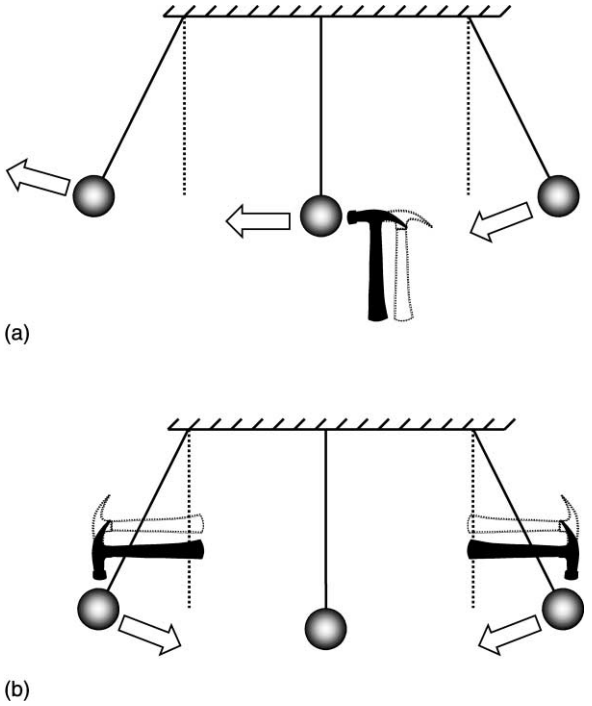

Figure 3 (a) Classical representation of a coherent phonon. An impulsive horizontal force acts on all members of a thermal distribution of pendula, displacing the group in phase space along the momentum axis. The ensemble precesses with an average position $\langle x \rangle \sim \sin(\Omega t)$. (b) Classical representation of a squeezed phonon. An impulsive vertical force produces an impulse proportional to the pendulum's displacement from equilibrium. Those pendula farthest from equilibrium receive the largest kick. The phase space distribution becomes elliptical and precesses with an ensemble averaged variance $\langle x^2 \rangle \sim \sin(2\Omega t)$.

These proposals have not yet been implemented experimentally.

The scheme proposed in (a) is based on three-phonon parametric amplification, similar to photon squeezed states that are generated by optical parametric amplification. Specifically, the proposal relies on a two-step process. First the generation by external excitation with two lasers of a 'pump' longitudinal optical phonon (LO) and, second, the decay of the optical phonon into two longitudinal acoustic phonons (LA), which will be squeezed. This is the kind of parametric oscillator described by eqn [8], for which the parametric control is driven by the coherent optical phonon field.

In case (b) it has been shown that mixed polarization modes known as phonon polaritons are intrinsically squeezed. These hybrid objects, sometimes referred to as dressed photons, are a mixture between phonons and photons that cannot be separated once they are formed.

Squeezing of vibrational states in molecules was confirmed experimentally earlier than in solids. Here, a molecule initially in the ground electronic and vibrational state is excited by an ultrafast optical pulse tuned with an electronic resonance. After the pulse arrives, the molecule is placed in a excited electronic state and the nuclei in a new (excited) potential with a new set of discrete vibrational modes. In Figure 4 we show, as an example of a diatomic molecule, the potential of a sodium dimer. For the sake of simplicity, we consider a single vibrational mode in the excited state and we disregard effects due to anharmonicity. If the optical pulsewidth is much shorter than any vibrational frequency, and the frequencies are different in the ground and excited state, the sudden change in frequency produces a vibrational squeezed state. On the other hand, even if the frequencies in the ground and excited state are equal, but the laser pulse is finite or chirped (frequency sweep on time), the final vibrational state may be squeezed. The formal demonstration of this is not trivial. Analytic solutions for the vibrational wavefunction for an arbitrary external field excitation are known for a very limited number of cases.

Squeezing of a wavepacket in an excited sodium diatomic molecule was achieved by Dunn and coworkers, measuring the time and frequency-resolved spectrum of the spontaneous emission. In this experiment, the molecule can return at any time to its electronic ground state by emitting light, the wavelength of which depends on the internuclear separation at that time. As shown in Figure 4, this is because the equilibrium position for the potential surfaces in the ground and excited states are different.

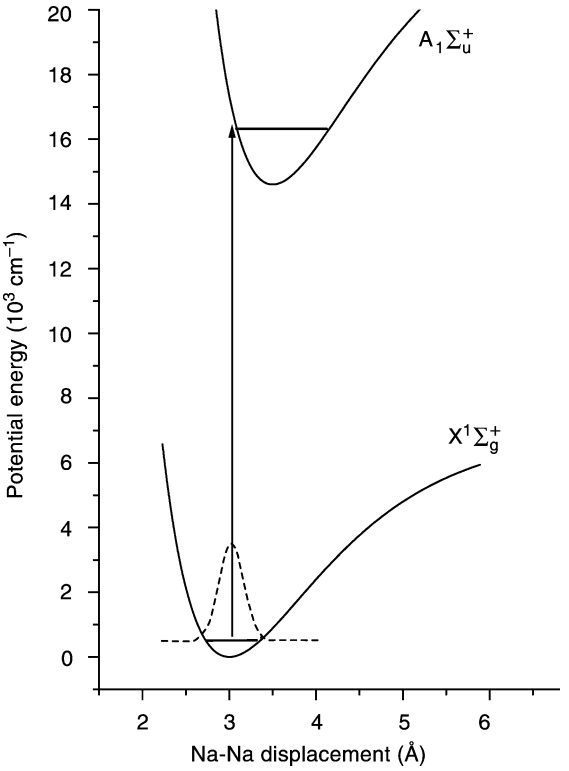

Figure 4 Potential curves for a Na_2 molecule, showing the ground and first excited states. The dashed line represents the ground state wave function. The equilibrium position of both potentials are shifted and the vibrational frequencies are different.

Thus, the time-dependent average wavelength of the emitted light oscillates as the atom vibrates, giving a signature of the dynamics of the wavepacket. Dunn observed oscillations in the signal strength that are consistent with a wavepacket expanding and contracting.

Experimental Generation and Detection of Squeezed Phonons by Second Order Raman Scattering

The first experimental demonstration of phonon squeezing was performed in 1997 by exciting a $KTaO_3$ (potassium tantalate) crystal with an ultrafast pulsed laser and coupling the light to the phonons through second order Raman Scattering. The squeezed phonon field produced by an intense optical pulse, referred to as the 'pump', is detected by a second low intensity pulse, known as the 'probe'. Phonon squeezing was also reported for $SrTiO_3$ (strontium titanate). In addition, correlations between pairs of phonons of different frequencies was reported in a closely related experiment on $KTaO_3$.

The simplest Hamiltonian describing this experiment contains the harmonic contribution from the lattice and a Raman-type interaction term. Raman scattering (RS) refers to light-crystal interaction in which the initial quantum of radiation energy, $\hbar\omega_i$, is divided into a vibrational excitation of the crystal with energy $\hbar\Omega$ and a scattered photon with energy $\hbar\omega_f$. Here, the total energy and momentum are conserved. The interaction energy is proportional to the second-order electronic susceptibility which can be expanded in terms of the atomic displacement Q. The nth term of the Taylor expansion is associated with RS of order n. Two phonons participate in the second order RS process. Although the absence of first-order RS is not required for achieving squeezing, $KTaO_3$ and SrTiO3 (above ~100 K) show no first-order Raman active modes. As a result, the leading contribution is

$$H_{\text{int}} = -\frac{1}{4}|E(t)|^2 \sum_q \chi_2(q) \qquad [9]$$

with $\chi_2(q) = (\partial^2\chi/\partial Q_q^2)Q_q^2$, where $\partial^2\chi/\partial Q_q^2$ is the second order Raman tensor, $E(t)$ is the magnitude of the light electric field, and χ is the linear electronic susceptibility. The Hamiltonian eqn [9], reflecting contributions from pairs of modes at $\pm q$, represents a change in the phonon frequency $\Delta\Omega_q(t) \approx -(1/4\Omega_q)(\partial^2\chi/\partial Q_0^2)|E(t)|^2$ that results in a time-dependent variance $\langle Q_q^2(t)\rangle$ and thus, squeezing. We note that, while individual scattering events produce a two-phonon state, the coherent ensemble of these correlated two-phonon states modulates the variance of Q. Notice that second-order RS excites phonons throughout the whole Brillouin zone instead of just the zone center at $q \approx 0$, as in first-order RS. This means that the light couples to a continuum of modes. The strength of the scattering at any particular frequency is proportional to the number of modes, i.e., the density of states, which is inversely proportional to the gradient $\nabla_q\Omega_q$ and thus, exhibits singularities at points where the gradient vanishes. These so-called critical points lead to associated singularities in the density of states referred to as van Hove singularities. $KTaO_3$ and $SrTiO_3$ show a sharp peak in the density of states at frequencies associated with certain van Hove singularities and, therefore, the continuum of modes becomes quasimonochromatic.

In the experiments, the period of the relevant phonons, $2\pi/\Omega_q$, is large compared with both the pulsewidth and the time the pulse takes for traversing the sample. Then, the time-dependent electric field can be approximated by the delta function $|E(t)|^2 \cong (4\pi I_0/nc)\delta(t)$, where I_0 is the pulse energy density, n the refractive index and c the speed of the light. Within this approximation, the dynamics of the system at $T = 0$ is described by eqn [6]. To lowest order in I_0, we have

$$\Delta Q_q = \langle Q_q^2(t)\rangle^{\frac{1}{2}} \approx \langle Q_q^2(0)\rangle^{\frac{1}{2}}\left[1 + \left(\frac{\lambda}{\Omega_q}\right)\sin(2\Omega_q t)\right] \qquad [10]$$

with $\lambda = 2\pi(I_0/nc)(\partial^2\chi/\partial Q_q^2)$.

As before, the variance drops below the quantum limit $\langle Q_q^2(0)\rangle$ for some fraction of the cycle. This zero-temperature description is only accurate for temperatures such that k_BT is very small compared with the phonon energies. For $T \neq 0$, the conditions overcoming the thermal contribution and produce quantum squeezing at low intensities are

$$n_q \ll 1 \qquad \text{and} \qquad \left(\frac{\lambda}{\Omega_q}\right) > 2n_q \qquad [11]$$

where $n_q = 1/[\exp(\hbar\Omega_q/k_BT) - 1]$ is the Bose factor.

Next we discuss the detection of the squeezed field. As mentioned earlier, the pump pulse creates the squeezed phonon state and the probe is affected by the changes in the material produced by the pump. The scattering of the probe by the squeezed phonon is also described by the nonlinear polarization of the material $P^{NL} = (2V)^{-1}E'(t)\sum_q \chi_2(q)$, where $E'(t)$ is the probe field, and V is the scattering volume. If the probe pulse is Gaussian-shaped of width τ_0 and centered at $\omega = \omega_0$, the total normalized change in the probe transmission ΔT is

$$\frac{\Delta T}{T}(\omega) \approx -\frac{l\pi\tau_0^2\omega(\omega-\omega_0)}{ncV}\sum_q \frac{\partial^2\chi}{\partial Q_q^2}|E'(t)|^2 \times \lambda\langle Q_q^2(0)\rangle\cos(2\Omega_q\Delta t)\exp(-2\Omega_q^2\tau_0^2) \qquad [12]$$

where l is the length of the sample. Equation [12] can be obtained from well-known results in coherent phonon detection. Comparing eqn [12] with eqn [10] it follows that the change in probe transmission is proportional to the derivative of the total time-dependent variance $\langle Q^2(t)\rangle = \sum_q \langle Q_q^2(t)\rangle$. Accordingly, the integral of $\Delta T/T$ probes $\langle Q^2(t)\rangle$.

$KTaO_3$

The perovskite $KTaO_3$ was the first material for which phonon squeezing was achieved. This compound has no first-order Raman active modes. The time-domain data in Figure 5a shows behavior

consistent with eqn [12]. The Fourier transform $\mathcal{F}_{FT}$ in Figure 5b, is dominated by a narrow peak, strongly dependent on temperature, that appears very close to twice the frequency of the TA (transverse acoustic) mode at the X point of the Brillouin zone. The comparison with the spontaneous Raman scattering data, Figure 5c, indicates that the $\mathcal{F}_{FT}$ peak is due to the 2TA overtone. The squeezing factor defined as $S = 1 - [\langle Q^2(t)\rangle / \langle Q^2(0)\rangle]^{1/2}$, is depicted in Figure 6. Notice that, whereas the squeezing factor in a quantum optics experiment can reach values as large as 70%, phonons in a solid can be squeezed by no more than, say, 0.01%. This is because larger values may lead to collapse of the solid since, according to the Lindemann criterion, solids melt when the root-mean-square displacement of an atom is a fraction of 0.2–0.25 of the lattice parameter.

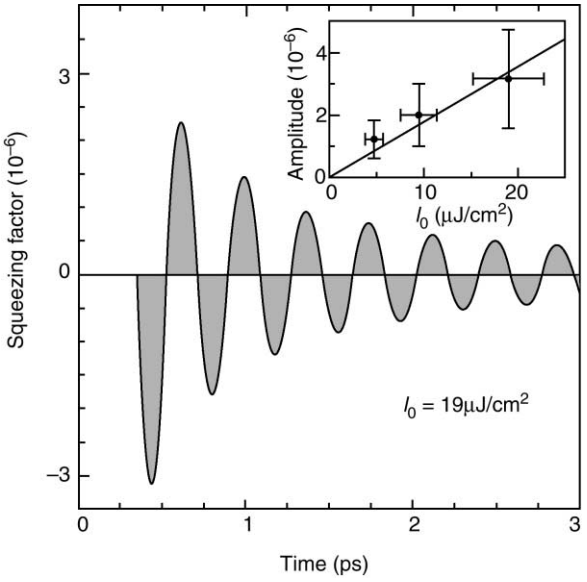

Figure 6 Experimental time dependence of the squeezing factor $S = 1 - [\langle Q^2(t)\rangle / \langle Q^2(0)\rangle]^{1/2}$. I_0 is the pulse intensity. In $KTaO_3$ it was also possible to induce a time-dependent covariance between two different independent modes by using second order RS to couple the two oscillators. In Figure 7 we show

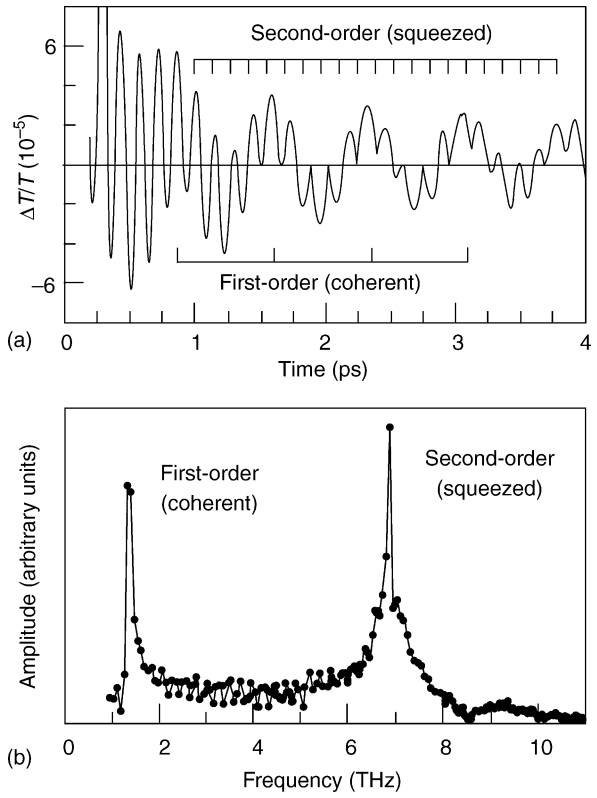

Figure 8 (a) The normalized transmitted probe intensity as a function of the probe delay for $SrTiO_3$ at $T = 7$ K. (b) Fourier transform of the time domain data. The 1.3 THz peak is the soft A_{1g}-phonon (coherent), and the 6.9 THz is the 2 TA overtone (squeezed). The second order feature is dominated by a sharp peak very close to twice the frequency of TA modes at X and M points of the Brillouin zone.

data revealing correlations between transverse optical (TO) and transverse acoustical (TA) modes.

$SrTiO_3$

This material undergoes a structural phase transition, called antiferro-distortive, at $T_C \approx 110$ K. Second-order RS is allowed at all temperatures, but first-order RS is only allowed for temperatures below T_C. Figure 8 shows data at low temperatures, revealing both first and second order features. From the comparison with spontaneous RS, the peak appearing in the $\mathcal{F}_{FT}$ at ~ 1.3 THz is due to first-order RS, while the peak at ~ 6.9 THz is due to second order RS (2TA overtone). The quantum state created by the utrafast pulse is then a mixture of a coherent and a squeezed state. Hence the phonon wavefunction will evolve qualitatively as in the picture shown in Figure 1d.

RELATIVISTIC NONLINEAR OPTICS

D P Umstadter, University of Michigan, Ann Arbor, MI, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Immediately after the invention of the laser in 1960, light could be focused to sufficient intensity to cause nonlinear optical effects in atomic media. In conventional nonlinear optics, where the electric field of a light wave E is much smaller than an atomic field, $E_{at} = 3 \times 10^9$ V/cm, various nonlinear phenomena, such as self-focusing, harmonic generation, and Raman scattering, arise due to the anharmonic motion of electrons in the combined fields of atom and laser. Approximate analytical solutions can be obtained by means of perturbation expansion methods, using E/E_{at} as the expansion parameter. At higher light fields, when E approaches E_{at}, this method breaks down and the medium becomes photo-ionized, creating a plasma, as illustrated by Figure 1. Further increases in light intensity enabled nonlinear optical effects of even these free plasma electrons (see Figure 2). The nonlinearity arises, in this case, because the electrons oscillate at relativistic velocities in laser fields that exceed 10^{11} V/cm, resulting in relativistic mass changes exceeding the electron rest mass and the light's magnetic field becomes important. The work done by the electromagnetic field (E) on an electron ($eE\lambda$) over the distance of a laser wavelength (λ), then approaches the electron rest mass energy ($m_e c^2$), where e is the elementary charge of an electron, m_e is the electron rest mass, and c is the speed of light. Effects analogous to those studied with conventional nonlinear optics – self-focusing, self-modulation, harmonic generation, and so on – are all found, but based on this entirely different physical mechanism. Thus, a new field of nonlinear optics, that of relativistic electrons, has been launched, as illustrated by Figure 1.

One outcome of accessing this new optical regime is the generation of frequency-shifted light in a spectral region where there are no other compact sources. Another is the acceleration of other types of particles, such as positrons, ions, and neutrons. These novel radiation sources have properties (femtosecond duration, micron source size, MeV energy) that make them suitable for numerous applications in imaging and spectroscopy in basic research, as well as medical diagnostics, cancer therapy, energy production, and space propulsion. Rapid advancement is underway and new research tools, subfields, and commercial products are on the horizon, e.g., compact and ultrashort pulse duration laser-based electron accelerators and X-ray sources.

Another physical regime will be encountered at even higher intensities ($I\lambda^2 \simeq 10^{24}$ W/cm^2), when even protons will quiver relativistically, i.e., the work done on a proton over the distance of a laser wavelength approaches its rest mass energy. This might be called the nuclear regime of laser–plasma interactions, because of the fusion and fission reactions and the generation of pions, muons, and neutrinos that should occur as nuclei collide in such energetic plasmas.

The recent dramatic increase in light intensity was partly made possible by the development, in the last decade, of compact lasers that have the ability to amplify shorter light pulses. For instance, solid-state lasers use the technique of chirped-pulse amplification to generate femtosecond duration pulses. To accomplish this, an ultrashort, low-energy laser pulse is first stretched in time before it is amplified and then recompressed. Gas or dye lasers, using solid-state switches, have produced picosecond duration pulses. Present day advanced laser systems now have multiterawatt peak powers and, when focused to micron spotsizes with adaptive optics, can produce electromagnetic intensities $I\lambda^2 \simeq 10^{21}$ W/cm^2, as illustrated by Figure 3. An example of a modern ultra-high-power (0.9 PW) solid-state (Ti:Sapphire) laser

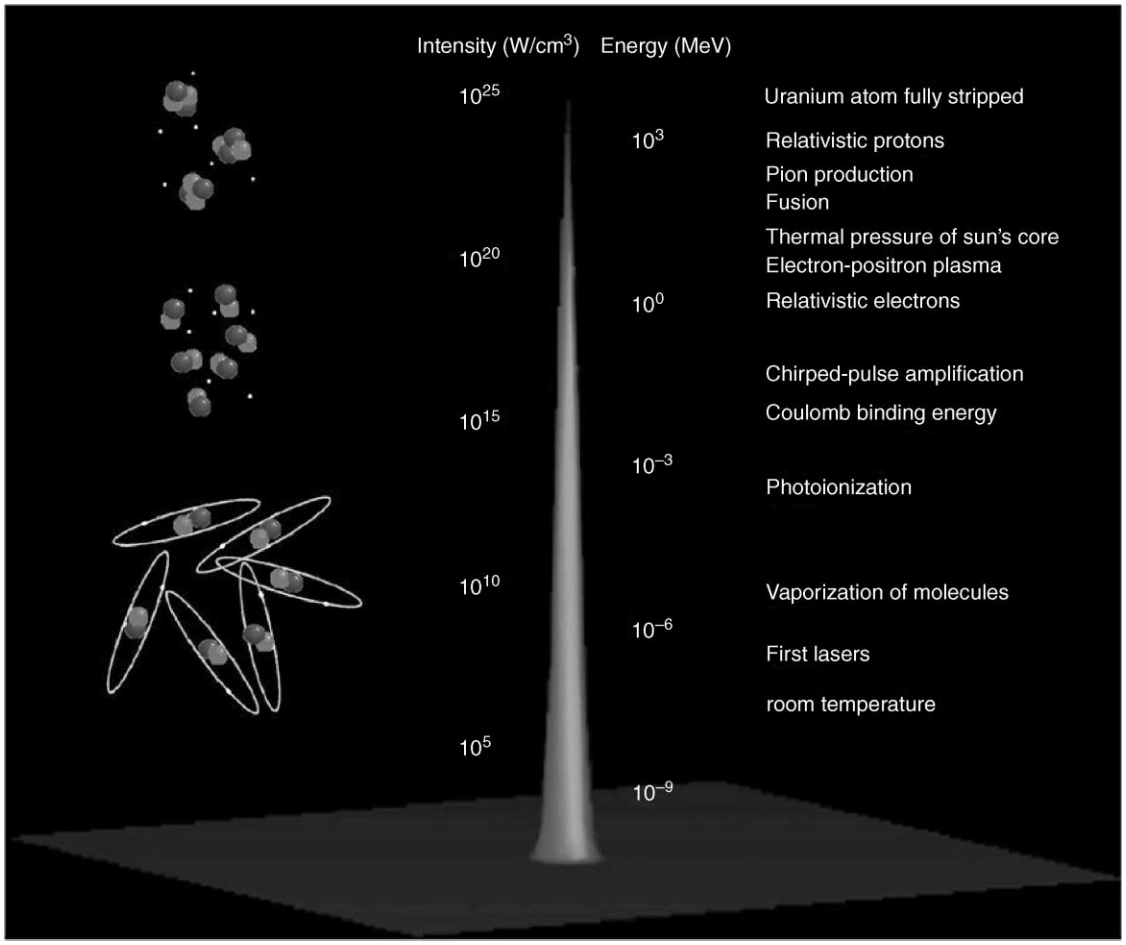

Figure 1 The various regimes of laser–matter interactions, represented by the ideal laser pulse. As the intensity of laser light increases, so does the energy of electrons accelerated in the light field and the regime of conventional nonlinear optics with electrons bound to atoms is replaced by the regime of relativistic nonlinear optics with free electrons in relativistic plasmas. At the highest intensities, even protons become relativistic, giving rise to what might be called the regime of nuclear optics, in which various nuclear processes, such as fusion, can take place. system, located at the Advanced Photon Research Center, Kansai Research Establishment, Japan Atomic Energy Research Institute (JAERI), can be seen in the photograph shown in Figure 4.

This paper will discuss the fundamental concepts underlying what might be referred to more broadly as the field of high-field science. For more detailed descriptions of recent progress in experiment or theory, several review papers have been published on related topics: (i) relativistic nonlinear optics; (ii) high-intensity laser development; (iii) laser accelerators; (iv) intense laser–plasma interactions; and (v) relativistic scattering.

Definitions

For an infinite plane wave for the light wave propagating in the $\hat{z}$ direction (shown in Figure 5), the fields may be described by

$$\mathbf{E} = \hat{e}_x E_0 \exp[\mathrm{i}(kz - \omega t)] = \hat{e}_x E_0 \, \mathrm{e}^{\mathrm{i}\psi} \qquad [1]$$

and

$$\mathbf{B} = \hat{e}_y B_0 \exp[\mathrm{i}(kz - \omega t)] = \hat{e}_y B_0 \, \mathrm{e}^{\mathrm{i}\psi} \qquad [2]$$

where ω and k are the frequency and wavenumber of the laser light, respectively. For the ultrashort pulse durations of the lasers typically used to produce high fields, it is assumed that the ions do not have time to move because of their greater inertia. In this case, $m(\mathrm{d}v/\mathrm{d}t) \approx -e\mathbf{E}$ and the term v/c can be used as an expansion parameter. At even higher fields, electrons can be accelerated to nearly the speed of light as they quiver in the oscillating fields of the light wave. In this case, the force due to the magnetic field can no longer be ignored and the mass of the electron

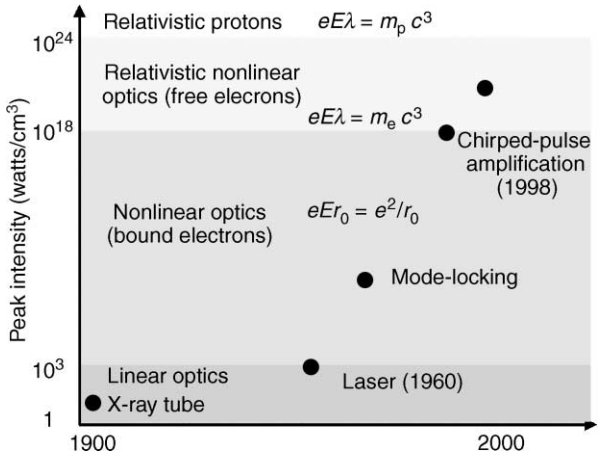

Figure 2 History of light sources over the last century. Each advance in laser power enables a new regime of optics. (Reproduced from Umstadter D (2003) Relativistic laser–plasma interactions. *Journal Physics D: Applied Physics* 36: R151–R165, with permission from IOP Publishing Ltd.)

can increase as $m = \gamma m_0$, where m_0 is the electron rest mass and the relativistic gamma factor is given by

$$\gamma = \frac{1}{\sqrt{1 - \left(\frac{v}{c}\right)^2}} \qquad [3]$$

The threshold for the relativistic regime of optics is crossed when the electron momentum p exceeds the product of the electron rest mass m_0 and c.

For problems involving charged particle motion in intense electromagnetic fields, it is often convenient to introduce the vector potential: $\mathbf{A}(\mathbf{r}, t) = \mathrm{Re}\{\mathbf{A}_0\, e^{i\psi}\}$. From Maxwell's equation $\nabla \cdot B = 0$, it can be seen that without loss of generality, the magnetic field can be written as the curl of a potential $B = \nabla \times A$. Further, from Faraday's law in vacuum:

$$\nabla \times E = -\frac{1}{c}\frac{\partial B}{\partial t} = -\frac{1}{c}\frac{\partial(\nabla \times A)}{\partial t} \qquad [4]$$

it is clear that $\mathbf{E} = -(1/c)\partial\mathbf{A}/\partial t$. To include the space–charge field of the plasma, as we will do in the section on collective plasma response below, we introduce the potential Φ, and the definition:

$$\mathbf{E} = -\nabla\Phi - \frac{1}{c}\frac{\partial}{\partial t}\mathbf{A} \qquad [5]$$

Assuming the Coulomb gauge:

$$\nabla \cdot \mathbf{A} = 0 \qquad [6]$$

or $A_z = 0$ in 1D, then $\mathbf{A}_\perp$ represents the laser field.

If we neglect Φ for now, then, by Fourier analysis:

$$\mathbf{E} = \mathrm{Re}\left\{\frac{i\omega}{c}\mathbf{A}_0\, e^{i\psi}\right\} \qquad [7]$$

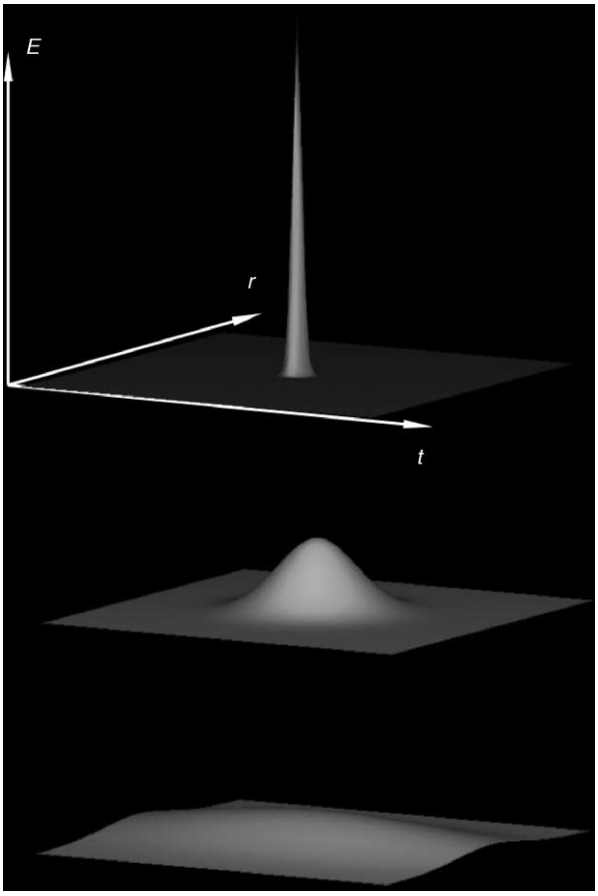

Figure 3 Laser light has become concentrated to ever-smaller regions of space (r) and time (t), dramatically increasing the peak electric field (E) at the laser focus. Prior to the development of chirped-pulse amplification (CPA), the energy of light was produced in long-duration pulses, as shown in the pulse of the bottom figure. After CPA, the pulse duration decreased dramatically as shown in the pulse in the middle. The latest improvement in laser technology has been the use of deformable mirrors, which has allowed lasers to be focused to a spatial dimension that is as small as the temporal dimension, a few laser wavelengths, as shown in the pulse on top. (Reproduced from Umstadter D (2003) Relativistic laser–plasma interactions. *Journal Physics D: Applied Physics* 36: R151–R165, with permission from IOP Publishing Ltd.)

$$\mathbf{B} = \mathrm{Re}\{ik\hat{z} \times \mathbf{A}_0\, e^{i\psi}\} \qquad [8]$$

The light intensity is given by the time-averaged Poynting's vector, which can be written for linear (LP), $\mathbf{A}_0 = A_0\hat{e}_y$ and circular polarizations (CP), $\mathbf{A}_0 = A_0(\hat{e}_x \pm \hat{e}_y)$ as:

$$I = \langle|\mathbf{S}|\rangle = \left\langle\left|\frac{c\mathbf{E} \times \mathbf{B}}{8\pi}\right|\right\rangle = \frac{\omega k}{16\pi}A_0^2 \qquad [9]$$

It is often the combination $I\lambda^3$ that matters, which has units of power and for linear polarization can be

Figure 4 Photograph of the 33-fs duration 0.9-PW-peak power laser system at JAERI. (Reproduced with permission from Yamakawa K (2004) Table-top lasers create ultrahigh peak powers. *OYOBUTURI* 73: 186–193.)

written as

$$I\lambda^2 = \frac{\omega k \lambda^2}{16\pi} A_0^2 = \frac{\pi}{2} c A_0^2 = \left[1.37 \times 10^{18} \frac{\mathrm{W}}{\mathrm{cm}^2} \mu\mathrm{m}^2\right] a_0^2 \qquad [10]$$

where the normalized vector potential is defined as

$$a_0 = \frac{eA_0}{mc^2} \qquad [11]$$

Relativistic effects become significant when a_0 approaches unity, which, as can be seen from eqn [10] occurs for 1 μm wavelength light at a laser intensity of $\sim 1.37 \times 10^{18}$ W/cm^2, corresponding to a electric field strength of 6×10^9 V/cm, which is four orders of magnitude greater than E_{at}.

Single-Particle Motion

The electron orbit, subject to a linearly polarized electromagnetic wave propagating in the $+z$ direction, is governed by the Lorentz equation:

$$m\frac{\mathrm{d}\mathbf{v}}{\mathrm{d}t} = -e\left(\mathbf{E} + \frac{\mathbf{v}}{c} \times \mathbf{B}\right) \qquad [12]$$

where v is the electron velocity, and E and B are the light's electric and magnetic field.

A zeroth order solution to eqn [12] is found by setting $v/c \ll 1$, which allows the term $(v/c) \times B$ to be neglected and γ from eqn [8] is set to unity. Integrating eqn [12] in this limit once over time (t) yields for the velocity:

$$\mathbf{v} = \mathrm{Re}\left\{\frac{e\mathbf{E}}{\mathrm{i}m\omega}\right\} = \frac{a_0}{c}\begin{cases} \hat{e}_y \cos\psi, & \mathrm{LP} \\ (\hat{e}_x \cos\varphi \mp \hat{e}_y \sin\psi), & \mathrm{CP} \end{cases} \qquad [13]$$

An electron in low-intensity light oscillates with this velocity in a straight line along the polarization vector ($\hat{e}_y$), which when normalized to c, is the normalized vector potential a_0. Integrating again yields for the

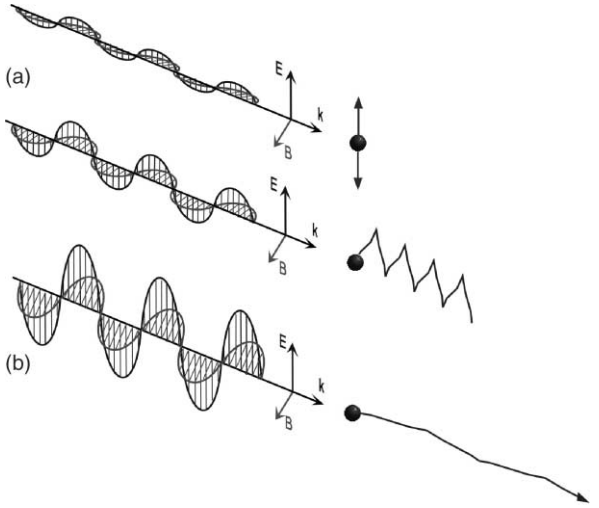

Figure 5 Classical optics versus relativistic optics. (a) In classical optics, the amplitude of the light wave is small, electrons oscillate in the direction of the electric field at the light's frequency, and there is no displacement along the light's propagation direction. Note that only the *E* field acts on the electron and the electron-oscillation velocity is very small compared with the speed of light. (b) In relativistic optics, the amplitude of the light wave is very large, the light's magnetic field becomes important and the combined action of the electric and magnetic fields push the electron forward. In this case, the electron velocity becomes close to the speed of light and its motion is a figure-eight superimposed upon a steady drift. (Reproduced from Umstadter D (2003) Relativistic laser–plasma interactions. *Journal Physics D: Applied Physics* 36: R151–R165, with permission from IOP Publishing Ltd.)

transverse displacement:

$$\mathbf{x} = \mathrm{Re}\left\{\frac{e\mathbf{E}}{m\omega^2}\right\} = \frac{a_0}{\omega c}\begin{cases}\hat{e}_y \sin\psi, & \text{LP}\\ (\hat{e}_y \sin\varphi \mp \hat{e}_z \cos\psi), & \text{CP}\end{cases} \quad [14]$$

Thus, for the $a_0 \sim 1$, the electron excursion during its oscillation is approximately λ.

A first-order approximation for the electron motion can be found by substituting the zeroth order velocity eqn [13] into the $v/c \times B$ term of eqn [12]. The latter then becomes proportional to

$$E \times B \propto \frac{a_0^2}{2}[1 + \cos(2\omega_0)]\hat{e}_z \quad [15]$$

In the frame in which the electron is on the average at rest, the relativistic motion of an electron is thus described by a figure eight, oscillating twice in the $\hat{e}_z$ or $\hat{k}$ direction for every once in the polarization direction ($\hat{e}_x$); i.e., a figure of eight motion. This originates from the fact that $v \times B \propto E \times B \propto E^2\hat{k}$, which is a product of two functions that vary sinusoidally at frequency ω and thus varies itself at frequency 2ω. In the lab frame,

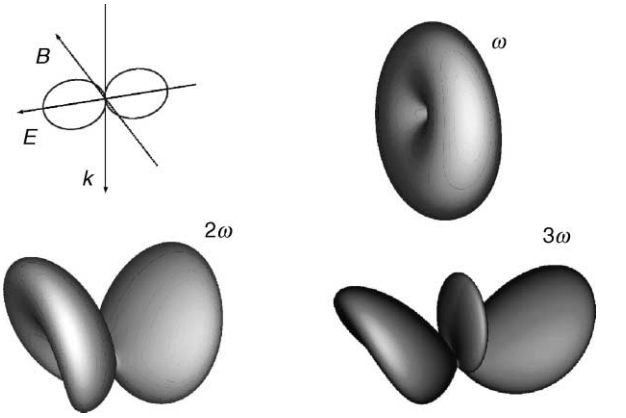

Figure 6 Harmonics driven by relativistic Thomson scattering as the electrons in high-intensity laser fields (a_0^2) undergo figure-eight motion display unique angular distributions. (Reproduced from Umstadter D (2003) Relativistic laser–plasma interactions. *Journal Physics D: Applied Physics* 36: R151–R165, with permission from IOP Publishing Ltd.)

this transverse motion is superimposed upon a steady drift in the ($\hat{e}_z$) direction (shown in Figure 5), originating from the DC term in eqn [15]. The next order approximation would include the mass shift $m = \gamma m_0$. As the field strength increases ($a_0^2 \gg 1$), the longitudinal motion ($\propto a_0^2$) begins to dominate the transverse motion ($\propto a_0$), as shown in Figure 5. This is described more formally below.

In the regime $a_0 \lesssim 1$, electrons radiate photons at harmonics of a modified laser frequency ω_0, with each harmonic order having its own unique angular distribution, as shown in Figure 6. The radiation at the fundamental is the usual donut pattern, with a maximum in the direction perpendicular, and a minimum along, the polarization vector ($\hat{e}_x$). The second harmonic has two emission lobes with maxima pointing at an angle between $\hat{e}_z$ and $\hat{e}_x$. An additional lobe is added for each additional harmonic order. This is referred to as nonlinear or relativistic Thomson scattering. The unique angular distributions of the second and third harmonics emitted from nonlinear relativistic Thomson scattering were observed experimentally and are shown in Figure 7. As will be shown in detail in the section on radiation from relativistic electrons, below, the situation is more complex for $a_0 \gtrsim 1$, and the scattered light is no longer simply harmonic.

Constants of the Motion

Several constants of the motion can be found from an exact treatment for the motion. The starting point is the relativistically correct Lagrangian, which is written as

$$L(\mathbf{r}, \mathbf{v}, t) = -mc^2\sqrt{1 - \frac{v^2}{c^2}} + \frac{q}{c}\mathbf{v}\cdot\mathbf{A} + q\phi \quad [16]$$

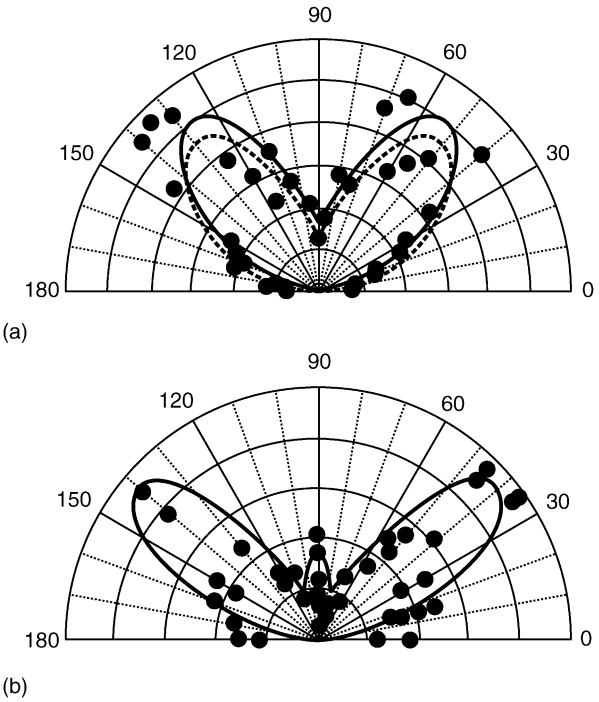

Figure 7 Angular pattern of higher-order harmonic light. Shown are polar plots of the intensity of the second-harmonic light (top) and third harmonic (bottom) as a function of azimuthal angle. Filled circles, experimental data; solid and dashed lines, theoretical results. (Reproduced with permission from Chen S-Y, Maksimchuk A and Umstadter D (1998) Experimental observation of relativistic nonlinear Thomson scattering. *Nature* 396: 653.)

where ϕ is the scalar potential associated with electrostatic fields. The Lorentz equation, eqn [12], is derived from the Euler–Lagrange equation:

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \mathbf{v}} - \frac{\partial L}{\partial \mathbf{r}} = 0 \qquad [17]$$

For an infinite plane wave, in which the Lagrangian is independent of space in the transverse direction, eqn [17] yields the conservation of transverse canonical momentum:

$$\frac{\partial L}{\partial \mathbf{v}_\perp} = \mathbf{p}_\perp + \frac{q}{c}\mathbf{A}_\perp = \text{constant} \qquad [18]$$

The sum of the transverse momentum and field strength remain constant. The next constant follows from $\mathrm{d}H/\mathrm{d}t = -\partial L/\partial t$, yielding the relation:

$$\frac{\mathrm{d}E}{\mathrm{d}t} = -\frac{\partial L}{\partial t} = c\frac{\partial L}{\partial z} = c\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial v_z} = c\frac{\mathrm{d}p_z}{\mathrm{d}t} \qquad [19]$$

where E is the time-dependent energy of the particle, which yields our second constant of the motion:

$$E - cp_z = \text{constant} \qquad [20]$$

For a particle initially at rest, the kinetic energy E_{kin} becomes

$$E_{\mathrm{kin}} = E - mc^2 = p_z c \qquad [21]$$

which yields

$$E_{\mathrm{kin}} = \frac{p_\perp^2}{2m} = p_x c = mc^2(\gamma - 1) \qquad [22]$$

Thus, the electron scattering angle θ is related to the transverse and longitudinal momenta or the kinetic energy by

$$\tan^2\theta = \left(\frac{p_\perp}{p_z}\right)^2 = \frac{2mE_{\mathrm{kin}}}{(E_{\mathrm{kin}}/c)^2} = \frac{2}{\gamma - 1} \qquad [23]$$

The angle of electrons produced by photo-ionization with intense lasers has been shown experimentally to obey the conservation of canonical momentum, as demonstrated in experiments that studied the angular distribution of relativistic electrons emitted from barrier-suppression ionization of atoms in intense laser fields (shown in Figure 8). The transverse normalized vector potential, $\mathbf{a} = e\mathbf{A}_\perp/mc^2$, is thus equal to the transverse normalized momentum:

$$\hat{\mathbf{p}}_\perp = \frac{\mathbf{p}_\perp}{mc} = \mathbf{a} = (0, a_y, a_x) \qquad [24]$$

The normalized kinetic energy can also be written in terms of a:

$$\hat{E}_{\mathrm{kin}} = \frac{E_{\mathrm{kin}}}{mc^2} = \gamma - 1 = \hat{p}_z = \frac{\hat{p}_\perp^2}{2} = \frac{a^2}{2} \qquad [25]$$

This can be rewritten as

$$\gamma = 1 + \frac{a^2}{2} \qquad [26]$$

From eqn [25], the normalized momenta in each direction can be found:

$$\hat{p}_z = \gamma\beta_z = \frac{\gamma}{c}\frac{\mathrm{d}z}{\mathrm{d}t} = \frac{a^2}{2} \qquad [27]$$

$$\hat{p}_y = \gamma\beta_y = \frac{\gamma}{c}\frac{\mathrm{d}y}{\mathrm{d}t} = a_y \qquad [28]$$

$$\hat{p}_x = \gamma\beta_x = \frac{\gamma}{c}\frac{\mathrm{d}x}{\mathrm{d}t} = a_x \qquad [29]$$

Note that the momentum in the longitudinal ($\hat{e}_z$) direction is proportional to a^2 while in the two

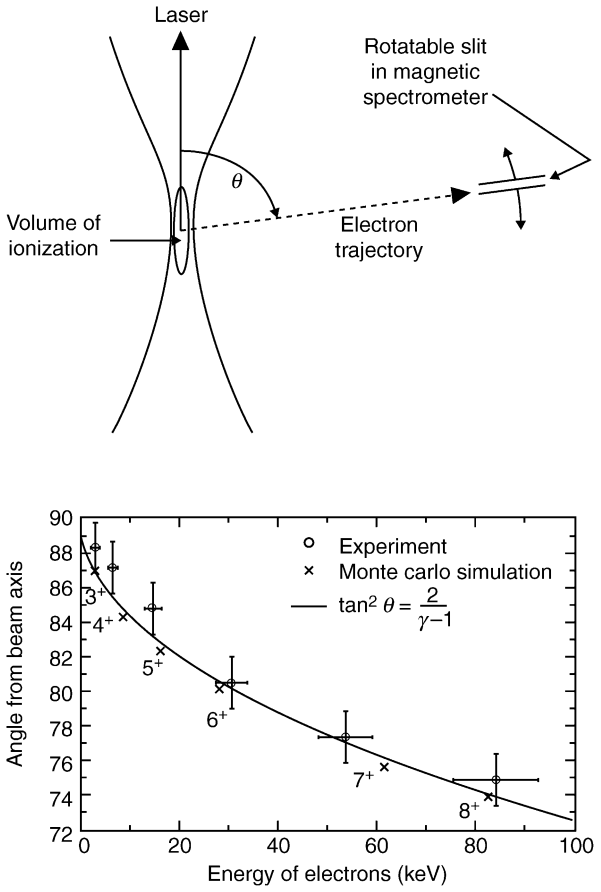

Figure 8 Top: Experiment to measure the angle of electron ejection during photo-ionization. Bottom: Kinetic energy versus angle during the production of 3^+ through 8^+ of neon. (Reproduced with permission from Moore CI, Knauer JP and Meyerhofer DD (1995) Observation of the transition from Thomson to Compton scattering in multiphoton interactions with low-energy electrons. *Physics Review Letters* 74: 2439. Copyright (1995) by the American Physical Society.)

transverse directions it is proportional to a. Equations [26]–[29] indicate that in the limit of large a, the normalized velocities are given by

$$\beta_z = \frac{a^2/2}{1+a^2/2} \to 1, \qquad \beta_y = \frac{a_y}{1+a^2/2} \to 0, \qquad \beta_x = \frac{a_x}{1+a^2/2} \to 0 \qquad [30]$$

This indicates that in the deeply relativistic regime, the electron is accelerated to near c in the longitudinal direction, while in the transverse directions its velocity goes to zero. It follows that, as a increases and the electron moves in phase with the light wave, relativistic Thomson scattering will be significantly reduced. Integrating eqn [29] in the variable $\tau = t - x(t)/c$ gives

$$\gamma\frac{\mathrm{d}}{\mathrm{d}t} = \gamma\frac{\mathrm{d}\tau}{\mathrm{d}t}\frac{\mathrm{d}}{\mathrm{d}\tau} = \gamma\left(1 - \frac{1}{c}\frac{\mathrm{d}z}{\mathrm{d}\tau}\right)\frac{\mathrm{d}}{\mathrm{d}\tau} = \left(1 + \frac{a^2}{2} - \frac{a^2}{2}\right)\frac{\mathrm{d}}{\mathrm{d}\tau} = \frac{\mathrm{d}}{\mathrm{d}\tau} \qquad [31]$$

which allows the equations for the displacement to be written simply as

$$\frac{\mathrm{d}z}{\mathrm{d}\tau} = c\frac{a^2}{2} \qquad [32]$$

$$\frac{\mathrm{d}y}{\mathrm{d}\tau} = ca_y \qquad [33]$$

$$\frac{\mathrm{d}x}{\mathrm{d}\tau} = ca_x \qquad [34]$$

For a box-shaped pulse, $a_x = a_0\cos(\omega\tau)$ for $0 < \tau < N(2\pi/\omega)$, $a_z = 0$, $a^2 = a_x^2\cos^2(\omega\tau)$, the trajectory for an electron initially at rest at $x = y = z = 0$ at $\tau = 0$ is then

$$x(\tau) = \frac{ca_0^2}{2}\int_0^\tau \cos^2(\omega\hat{\tau})\mathrm{d}\hat{\tau} = \frac{ca_0^2}{4}\left[\tau + \frac{1}{2\omega}\sin(2\omega\tau)\right] \qquad [35]$$

$$y(\tau) = ca_0\int_0^\tau \cos(\omega\hat{\tau})\mathrm{d}\hat{\tau} = \frac{ca_0}{4}\sin(\omega\tau) \qquad [36]$$

Thus, as we saw from the first-order appoximation above, eqn [15], the motion consists of a drift along $\hat{x}$:

$$x_\mathrm{d}(t) = \frac{a_0^2}{a_0^2+4}ct \qquad [37]$$

and a figure-eight motion in the drift frame of reference:

$$ky = a_0\sin(\omega\tau), \qquad k(z - z_\mathrm{d}) = \frac{a_0}{8}\sin(2\omega\tau) \qquad [38]$$

In the strongly relativistic regime, because the electron is strongly accelerated in the direction of the light wave, the harmonic emission from relativistic Thomson scattering loses its dependence on the laser frequency, ω, but instead depends only on the direction of observation, the amplitude a_0 and the initial phase of the electron, relative to the light wave. Electrons that do not begin their trajectories at zero or π phase with respect to the light wave can

drift in the transverse direction. For pulses with finite spatial width, such as a Gaussian pulse with field strength peaked on axis, the ponderomotive force of the light can also act to expel the electrons transversely from the axis.

For circular polarization:

$$\mathbf{a}(\mathbf{r}, t) = \mathrm{Re}\{a_0(\hat{e}_y \pm \mathrm{i}\hat{e}_x)\mathrm{e}^{-\mathrm{i}\omega\tau}\} \qquad [39]$$

the electron drifts as it did in the case of linear polarization and described in eqn [37] but orbits in a helical trajectory:

$$y(\tau) = \frac{ca_0}{\sqrt{2}\omega}\sin(\omega t/\gamma) \qquad [40]$$

$$x(\tau) = \mp\frac{ca_0}{\sqrt{2}\omega}\cos(\omega t/\gamma) \qquad [41]$$

Rather than oscillate in amplitude, the relativistic factor remains constant:

$$\gamma = 1 + \frac{a_0^2}{4} \qquad [42]$$

In either polarization case, the light pulse eventually overtakes the electron, leaving the latter at rest. However, net acceleration in vacuum can be obtained only under special circumstances, described by the Lawson–Woodward criterion, such as in the near field of metallic surfaces; with high-order focusing modes instead of infinite plane waves; or with mixed frequencies, or with optics to terminate the light but not the electrons. Regions of a tightly focused Gaussian pulse, where the accelerating field propagates at sub-luminal velocities also exist, but they are effective for only extremely large values of a and thus only very short acceleration lengths.

Role of Initial Phase

If we wish to understand the role of the electron's initial phase, the relativistic Lorentz equation (eqn [12]) may also be written, for an $\hat{x}$-polarized wave traveling in the $\hat{z}$ direction, as

$$\frac{\mathrm{d}}{\mathrm{d}t}(\gamma\beta) = (\hat{x} - \hat{z}\times\beta)a\cos(t - z) \qquad [43]$$

where we normalize time by $1/\omega_0$, velocity by c, and distance by c/ω_0. In eqn [43], $a = eE_0/m\omega_0 c$ is the dimensionless parameter measuring the electric field strength, $\gamma = (1 - \beta_x^2 - \beta_y^2 - \beta_z^2)^{-1/2}$ is the relativistic mass factor, and $\beta = (\beta_x, \beta_y, \beta_z)$ is the electron velocity (in units of c). The electron orbit, subject to the following general initial conditions at time $t = 0$:

$$x = 0, \qquad y = 0, \qquad z = z_{\mathrm{in}} \qquad [44]$$

$$\beta_x = \beta_{x0}, \qquad \beta_y = \beta_{y0}, \qquad \beta_x = \beta_{z0} \qquad [45]$$

$$\beta_{x0} = \beta_{y0} = 0 \qquad [46]$$

has a closed form solution when it is expressed parametrically: $t = t(\theta)$, $r = r(\theta)$, $\beta = \beta(\theta)$, where θ is the phase of the wave, defined by

$$\theta = t - z \qquad [47]$$

Note that $\beta_0 = (\beta_{x0}, \beta_{y0}, \beta_{z0})$ is the unperturbed velocity of the electron ($a = 0$ limit) and that the initial phase that the electron sees is $\theta_{\mathrm{in}} = -z_{\mathrm{in}}$ according to eqns [44] and [47]. This phase can be important in the ionization of the gas by an intense laser.

For the special case $\beta_{x0} = 0$, $\beta_{y0} = 0$, one finds $\beta_y = 0$, and the orbital equation yields the following closed form solution:

$$\gamma = \gamma_0 + \frac{a^2(\sin\theta - \sin\theta_{\mathrm{in}})^2}{2\gamma_0(1 - \beta_{z0})} \qquad [48]$$

$$\gamma\beta_z = \gamma - \gamma_0(1 - \beta_{z0}) \qquad [49]$$

$$\gamma\beta_x = \frac{1}{\gamma_0(1 - \beta_{z0})}a(\sin\theta - \sin\theta_{\mathrm{in}}) \qquad [50]$$

$$x = \frac{a[(\cos\theta_{\mathrm{in}} - \cos\theta) - (\theta - \theta_{\mathrm{in}})\sin\theta_{\mathrm{in}}]}{\gamma_0(1 - \beta_{z0})} \qquad [51]$$

$$t = \frac{(\theta - \theta_{\mathrm{in}})}{1 - \beta_{z0}}\left[1 + \frac{a^2}{2}\left(\frac{1}{2} + \sin^2\theta_{\mathrm{in}}\right)\right] + \frac{a^2(1 + \beta_{z0})}{2(1 - \beta_{z0})}\left[-\frac{\sin 2\theta}{4} + 2\cos\theta\sin\theta_{\mathrm{in}} - \frac{3\sin 2\theta_{\mathrm{in}}}{4}\right] \qquad [52]$$

In eqns [48]–[52], $\gamma_0 = (1 - \beta_{z0}^2)^{-1/2}$ and β_{z0} may either be negative (counter-propagating against the laser), or zero (Thomson scattering), or positive (co-propagating with the laser). Note that the velocity components β_x and β_z are given as explicit functions of θ according to eqns [49] and [50], upon using eqn [48]. They are periodic functions of θ of period 2π. The period, T, of this periodic (**Figure 8**) motion is thus equal to the increase in t as θ increases by 2π. Thus, we obtain from eqn [53]:

$$T = \frac{2\pi}{1 - \beta_{z0}}\left[1 + \frac{a^2}{2}\left(\frac{1}{2} + \sin^2\theta_{\mathrm{in}}\right)\right] \qquad [53]$$

The parametric solution for the z-coordinate of the electron orbit is given by $z = t - \theta$, in which t is given by eqn [52]. Over one orbital period, T, the electron undergoes a net displacement $r_0 = (x_0, 0, z_0)$ where x_0 is given by the increase in eqn [51] as θ increases by 2π, and z_0 is simply $T - 2\pi$:

$$\begin{aligned} z_0 &= T - 2\pi \\ &= \frac{2\pi}{1-\beta_{z0}}\left[\beta_{z0} + \frac{a^3}{2}\left(\frac{1}{2} + \sin^2\theta_{\text{in}}\right)\right] \end{aligned} \quad [54]$$

$$x_0 = \frac{-2\pi a \sin\theta_{\text{in}}}{\gamma_0(1-\beta_{z0})} \quad [55]$$

Note that the electron trajectory depends on a, β_{z0}, and θ_{in} in a rather complicated manner. Accordingly, the fundamental frequency ω_1 of the radiation spectrum depends on these three quantities. For backscattered radiation ($\hat{n} = -\hat{z}$), the dependence on electron beam and on the laser becomes decoupled.

Following is a useful formula relating the change of t with respect to θ:

$$\frac{\mathrm{d}\theta}{\mathrm{d}t} = 1 - \beta_z = \frac{\gamma_0(1-\beta_{z0})}{\gamma} \quad [56]$$

which may be verified from eqns [47] and [49]. Equation [56] is also valid for arbitrary values of β_{x0}, β_{y0}, β_{z0}, and θ_{in}, in which case γ_0 is the electron's relativistic mass factor in the absence of the laser.

Radiation from Relativistic Electrons

An electron with displacement $r(t)$ and velocity $v(t)$ carries a current density $J(r,t) = ev(t)\delta r - r(t)]$, whose Fourier transform $J_{\text{F}}(k,\omega)$ may easily be obtained. The total work done, W, in ergs, performed by the current $\mathbf{J}(\mathbf{r},t)$ on the electric field $\mathbf{E}(\mathbf{r},t)$ is given by

$$\begin{aligned} W &\equiv \int \mathrm{d}\omega\,\mathrm{d}\Omega \frac{\mathrm{d}^2 W}{\mathrm{d}\omega\,\mathrm{d}\Omega} \\ &= \int \mathrm{d}\omega\,\mathrm{d}\Omega \frac{\omega^2}{c^2}\left[|\mathbf{J}_{\text{F}}(\mathbf{k},\omega)|^2 - |\mathbf{n}\cdot\mathbf{J}_{\text{F}}(\mathbf{k},\omega)|^2\right] \end{aligned} \quad [57]$$

where the $\mathbf{k}$-space differential volume $\mathrm{d}^3\mathbf{k} = k^2\,\mathrm{d}k\,\mathrm{d}\Omega$ is expressed in terms of the solid angle (Ω) in the direction of the unit vector $\mathbf{n} = c\mathbf{k}/\omega$. We immediately obtain from eqn [56], under the far-field approximation:

$$\frac{\mathrm{d}^2 W}{\mathrm{d}\Omega\,\mathrm{d}\omega} = \frac{e^2\omega^2}{4\pi^2 c}|\mathbf{n}\times[\mathbf{n}\times\mathbf{F}(\omega)]|^2 \quad [58]$$

$$\mathbf{F}(\omega) = \int_{-\infty}^{\infty} \mathrm{d}t\ \beta(t)\mathrm{e}^{\mathrm{i}\omega[t-\mathbf{n}\cdot\mathbf{r}(t)/c]} \quad [59]$$

Equation [58] gives the energy radiated by the electron in the direction of the unit vector, per unit solid angle, per unit frequency ω. Radiation damping is ignored throughout.

Let us consider the simplest case where the electron orbit is strictly a periodic function of time with period T and a net displacement $\mathbf{r}_0$ per period. Thus, we have for all integers m (positive, negative, or zero):

$$\beta(t+mT) = \beta(t), \quad \mathbf{r}(t+mT) = m\mathbf{r}_0 + \mathbf{r}(t) \quad [60]$$

Equation [59] may then be written as, because of Thomson scattering the energy of the scattered photon is much less than the electron rest mass in the average rest frame of the electron, i.e.:

$$\frac{\hbar\omega_{\text{L}}}{mc^3} \ll 1 \quad [61]$$

$$\begin{aligned} \mathbf{F}(\omega) &= \sum_{m=-\infty}^{\infty}\int_{mT}^{(m+1)T} \mathrm{d}t\ \beta(t)\mathrm{e}^{\mathrm{i}\omega[t-\mathbf{n}\cdot\mathbf{r}(t)/c]} \\ &= \sum_{m=-\infty}^{\infty} f(\omega)\mathrm{e}^{\mathrm{i}m\omega[T-\mathbf{n}\cdot\mathbf{r}_0/c]} \end{aligned} \quad [62]$$

where

$$f(\omega) = \int_0^T \mathrm{d}t\ \beta(t)\mathrm{e}^{\mathrm{i}\omega[t-\mathbf{n}\cdot\mathbf{r}(t)/c]} \quad [63]$$

and we have used eqn [60]. Upon using $\sum_m \mathrm{e}^{\mathrm{i}mx} = \sum_m 2\pi\delta(x - 2m\pi)$ in the last infinite sum in eqn [64] and the property of the Dirac delta function, $\delta(ax) = (1/a)\delta(x)$, we obtain from eqns [62] and [63], the following expression for the spectrum:

$$\mathbf{F}(\omega) = \sum_{m=-\infty}^{\infty} \mathbf{F}_m \delta(\omega - m\omega_1) \quad [64]$$

$$\omega_1 = \frac{2\pi}{T - \mathbf{n}\cdot\mathbf{r}_0/c}, \quad [65]$$

$$\mathbf{F}_m = \frac{\omega_1}{2\pi}\int_0^T \mathrm{d}t\ \bar{\beta}(t)\mathrm{e}^{\mathrm{i}m\omega_1[t-\mathbf{n}\cdot\mathbf{r}(t)/c]} \quad [66]$$

Note from eqn [64] that the radiation spectrum is discrete, for strictly periodic motion of the electron. The base frequency of this spectrum, ω_1, depends on the periodicity (T) of the electron, on the electron's net displacement ($\mathbf{r}_0$) in one such period, and on the direction ($\hat{n}$) in which the radiation is observed. Thus, the radiation spectrum is, in general, not at the

harmonic frequency of the laser (nor at the harmonics of the electron orbital frequency, $2\pi/T$). It would thus be wrong to simply insert $\omega = n\omega_0$ in eqn [63] and to replace the electron's orbital period T there by the laser's optical period $2\pi/\omega_0$ and consider the resultant value of that integral to give the spectral amplitude of the radiation at the nth harmonic of the laser frequency. Erroneous conclusions regarding generation of high laser harmonics have appeared in the literature based on such an intuitive (but incorrect) substitution.

The power, p_m (in erg/s), radiated at the harmonic frequency $\omega = m\omega_1$ per unit solid angle in the direction of the unit vector $\hat{n}$ is then given by (from eqns [58] and [64]):

$$p_m = \frac{e^2 m^2 \omega_1^2}{4\pi^2 c} |\mathbf{n} \times \mathbf{F}_m|^2 \qquad [67]$$

where the dimensionless spectral amplitude $\mathbf{F}_m$ is given in eqn [66]. It is easy to show from eqns [60] and [65] that the integrand in eqn [66] is a periodic function of t of period T. Integrals of this type are readily evaluated by the Romberg method. The radiation spectrum observed *exactly* in the forward direction of the laser ($\hat{n} = \hat{z}$) always has only one discrete frequency, $\omega = \omega_1 = \omega_0$, which is easily shown from eqn [65] upon using the first equality of eqn [53]. This statement is true regardless of the velocity of the electron or the laser intensity, and may easily be deduced from eqn [66] for this case. However, for an energetic electron beam that is almost co-propagating with the laser, such as that produced by the laser itself, high harmonics at the laser frequency may be observed in the direction just slightly off the laser direction.

In the backscattering direction of the laser ($n = -z$), if we set $\theta_{\text{in}} = 0$, one obtains the following expressions for ω_1 and p_m, the backscatter power at $\omega = m\omega_1$ (from eqn [67]):

$$\frac{\omega_1}{\omega_0} = \left(\frac{2}{2+a^2}\right)\left(\frac{1-\beta_{z0}}{1+\beta_{z0}}\right) = \left(\frac{2}{2+a^2}\right)\gamma_0^2(1-\beta_{z0})^2 \qquad [68]$$

$$p_m = \frac{A}{\gamma_0^2(1-\beta_{z0})^2}\left(\frac{\omega_1}{\omega_0}\right)^4 s_m \qquad [69]$$

where $A = e^2\omega_0^2/4\pi^2 c = 0.69[\lambda(1\ \mu\text{m})]^{-2}$ erg/s, $s_m = 0$ for $m = 0, \pm 2, \pm 4, \ldots$, and for $m = \pm 1, \pm 3, \pm 5, \ldots$,

$$s_m = (a\pi)^2 m^2 \left[J_{\frac{(m-1)}{2}}(m\kappa) - J_{\frac{(m+1)}{2}}(m\kappa)\right]^2 \qquad [70]$$

$$\kappa = \frac{a^2}{2(a^2+2)} \qquad [71]$$

The $J_\nu(x)$ above are Bessel functions of the first kind of order ν. They also appear in the quantity '$[JJ]$' or '$F_m(K)$' in the FEL/synchrotron literature, where K is the undulator/wiggler parameter K. Setting $K = a$, one finds $s_m = \pi^2(1 + K^2/2)^2 F_m(K)$. It is easy to show that $s_m = s_{-m}$ for all odd integers m. Note that the relative spectral shape of s_m depends only on a, and is independent of the electron beam energy. The discrete spectrum for small a approaches a continuum for $a^2 \gg 1$.

The maximum values of s_m, occurring at $m = M$ with a value s_M, are shown in Figure 9. Note that the frequency component $\omega = M\omega_1$ contains the highest backscattered power. In terms of the laser frequency, the frequency component $\omega = N\omega_0$ would contain the highest backscatter power, where $N = M\omega_1/\omega_0$. The total backscatter power, P_{T} (in ergs/s), per unit solid angle in the $\mathbf{n} = -\mathbf{z}$ direction is then given by $P_{\text{T}} = \Sigma p_m$, where the sum is taken over all odd values of m:

$$P_{\text{T}} \approx \frac{\gamma_0^6(1-\beta_{z0})^6}{(\lambda/1\ \mu\text{m})^3} \times \begin{cases} 13.7a^3, & (a < 0.3) \\ 11.1/a, & (a \gg 1) \end{cases} \qquad [72]$$

To summarize, due to the rapid acceleration of electrons in the direction of the light wave and decrease of the oscillation frequency in the deeply relativistic regime, the photon energy from relativistic nonlinear scattering scales only linearly with laser field strength, $\sim a$. However, the relativistic motion of the electron results in a reduction in the angle of the scattered light, such that the harmonics are generated in a low-divergence-angle forward-propagating beam. There is also a relativistic Doppler shift ($\sim\gamma^2$). For instance, this mechanism will be used in high-energy physics experiments to cleanly make constituent particles in the gamma–gamma ($\gamma\gamma$) collider, in which gamma rays with energy 200 GeV will be generated by Compton scattering 1 eV photons from 250 GeV energy conventionally accelerated electron beams ($\gamma = 5 \times 10^{11}$).

Using a much smaller, laser-based accelerator (discussed in the following section), a 1 eV photon can be upshifted by this Doppler shift to an energy of 50 keV, corresponding to subatomic spatial resolution and of interest in medical diagnostics, by an electron beam with only $\gamma = 200$ (100 MeV). In this case, the maximum efficiency is obtained for laser fields a of order unity. When compared with conventional light sources based on cm-wavelength magnetostatic wigglers, the electromagnetic wigglers

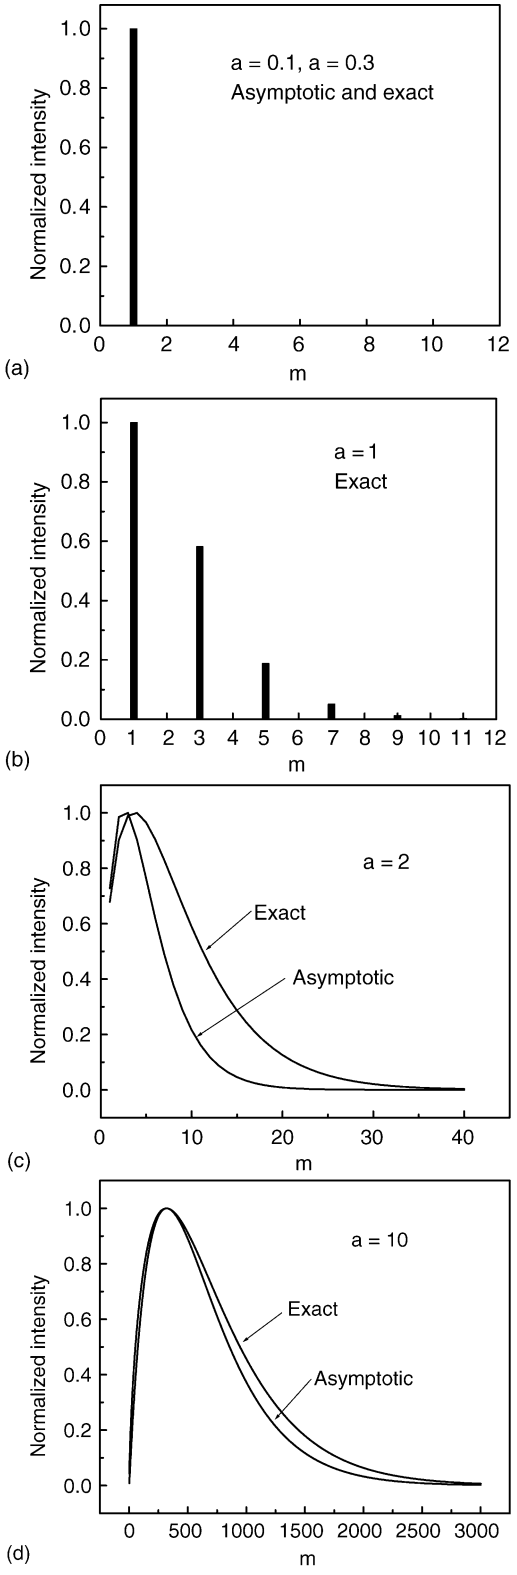

Figure 9 Normalized spectral distribution of s_m, at frequency $\omega = m\omega_1$. Here, s_m is normalized with respect to the maximum value s_M, occurring at $m = M$. (Reproduced from Lau Y, He F and Umstadter D (2003) Nonlinear Thomson scattering: A tutorial. *Physics Plasmas* 10: 2155, with permission from the American Institute of Physics.)

of such all-optical-laser-based EUV sources have ten-thousand times shorter wavelength (micron-scale). Thus, the total length of the wiggler region is correspondingly smaller (only mm in length). Another consequence of this is that the frequency upshift required to reach a given output wavelength is also ten thousand times smaller. Also, given that the required electron energy scales as the square root of the upshift, the required electron energy can be one-hundred-times lower (10–100 MeV). It follows from this, and the fact that the field gradients of these accelerators can be ten thousand times higher (1 GeV/cm) than convention RF-based accelerators, that the size of the accelerating region can, in principle, be a million times smaller (only mm in length). Besides its small size, this EUV source can produce femtosecond duration pulse and be synchronized with a relatively low jitter with another femtosecond light pulse having a different wavelength (by virtue of the possibility of deriving the two pulses from the same laser pulse); this is advantageous for the study of ultrafast pump-and-probe photo-initiated processes. The exceptionally low transverse emittance of laser-accelerated electron beams may even make it possible to generate coherent XUV radiation by means of the self-amplified spontaneous emission (SASE) free-electron lasing (FEL) mechanism.

Collective Plasma Response

The above equations apply to electron motion in vacuum. In the case of electrons in plasmas, the collective plasma electron response needs to be considered. A theory for the 1D nonlinear interaction of intense laser fields with electrons has been developed.

The variables are normalized such that

$$\mathbf{a} = e\mathbf{A}/mc^2, \qquad \phi = e\Phi/mc^2 \qquad [73]$$

$$\mathbf{u} = \mathbf{p}/mc, \qquad \beta = \mathbf{v}/c, \qquad \mathbf{u} = \gamma\beta \qquad [74]$$

$$\gamma = (1 + u^2)^{1/2} = (1 - \beta^2)^{-1/2} \qquad [75]$$

The relativistic force equation (Lorentz equation) is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbf{u} = \nabla\phi + \frac{\partial}{\partial t}\mathbf{a} - \bar{\beta}\times(\nabla\times a) \qquad [76]$$

The energy equation ($\mathbf{u}\cdot$ force equation) is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\gamma = \beta\cdot\left(\frac{\partial}{\partial z}\phi + \frac{\partial}{\partial t}\mathbf{a}\right) \qquad [77]$$

The transverse force equation (1D) is

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbf{u}_\perp = \left(\frac{\partial}{\partial t} + \beta_z \frac{\partial}{\partial z}\right)\mathbf{a}_\perp \qquad [78]$$

Since $\mathbf{a} = \mathbf{a}(z,t)$:

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbf{a}_\perp = \left(\frac{\partial}{\partial t} + \beta_z \frac{\partial}{\partial z}\right)\mathbf{a}_\perp \qquad [79]$$

hence:

$$\frac{\mathrm{d}}{\mathrm{d}t}(\mathbf{u}_\perp - \mathbf{a}_\perp) = 0 \qquad [80]$$

This is just conservation of transverse canonical momentum. Assuming $\mathbf{u}_\perp = 0$ prior to the laser interaction gives

$$\mathbf{u}_\perp = \mathbf{a}_\perp \qquad [81]$$

which is the same as eqn [24].

The electron response to the normalized scaler and vector potentials of the form $\phi = \phi(z - ct)$ and $\mathbf{a} = \mathbf{a}(z - ct)$, which are a function of only $\xi = z - ct$, is completely described by the following constants of the motion:

$$\beta_\perp - a_\perp/\gamma = 0, \qquad [82]$$

$$\gamma(1 - \beta_z) - \phi = 1, \qquad [83]$$

$$n(1 - \beta_z) = n_0, \qquad [84]$$

where $\gamma = (1 - \beta^2)^{-1/2}$ is the relativistic factor and n is the electron density. This allows the various electron quantities to be specified solely in terms of the potentials:

$$\beta_\perp = \frac{2(1+\phi)a_\perp}{(1+a_\perp^2)+(1+\phi)^2}, \qquad [85]$$

$$\beta_z = \frac{(1+a_\perp^2)-(1+\phi)^2}{(1+a_\perp^2)+(1+\phi)^2}, \qquad [86]$$

$$\gamma = \frac{(1+a_\perp^2)+(1+\phi)^2}{2(1+\phi)}, \qquad [87]$$

$$\frac{n}{n_0} = \frac{(1+a_\perp^2)+(1+\phi)^2}{2(1+\phi)^2} \qquad [88]$$

In the single particle limit, $\phi \equiv 0$, eqns [26] and [30] are retrieved. For a long pulse interacting with a dense plasma, $\tau_\mathrm{L} \gg \omega_\mathrm{p}^{-1}$ (i.e., neglecting wakefield effects) it can be shown that $(1+\phi) \simeq (1+a_0^2)^{1/2}$ for circular polarization and $(1+\phi) \simeq (1+a_0^2/2)^{1/2}$ for linear polarization.

Propagation

To understand the propagation of high-intensity light in plasma, we need to understand how the dielectric properties of a plasma medium are affected by the relativistic electron mass change. A wave equation is found by taking the curl of Faraday's law:

$$\nabla \times \mathbf{E} = -\frac{1}{c}\frac{\partial \mathbf{B}}{\partial t} \qquad [89]$$

and using Ampere's law:

$$\nabla \times \mathbf{B} = 4\pi \mathbf{J}/c + \frac{1}{c}\frac{\partial \mathbf{E}}{\partial t} \qquad [90]$$

gives

$$\nabla \times \nabla \times \mathbf{E} = -\nabla^2 \mathbf{E} + \nabla(\nabla \cdot \mathbf{E}) = \frac{1}{c^2}\left[4\pi \frac{\partial \mathbf{J}}{\partial t} - \frac{\partial^2 \mathbf{E}}{\partial t^2}\right] \qquad [91]$$

where $\mathbf{J} = \sum n_i q_i v_i$ and the summation over the index i is done over all charged species of electrons and ions. Using Coulomb's law:

$$\nabla \cdot \mathbf{E} = 4\pi\rho \qquad [92]$$

where $\rho = \sum n_i q_i$, and assuming a uniform plasma, the second term on the left vanishes. Substituting eqn [13] for the velocity, we find

$$\left(-\frac{\partial^2}{\partial t^2} + c^2\nabla^2 - \omega_\mathrm{p}^2\right)\mathbf{E} = 0 \qquad [93]$$

where

$$\omega_\mathrm{p} = (4\pi n_i q_i^2/m_i)^{1/2} \qquad [94]$$

is the plasma frequency. Assuming again plane waves and Fourier analyzing, yields the well-known dispersion relation for electromagnetic waves in plasma:

$$\omega^2 = \omega_\mathrm{p}^2 + c^2 k^2 \qquad [95]$$

The index of refraction can be written fully relativistically as

$$\eta^2 = \frac{c^2 k^2}{\omega^2} = \frac{c^2}{v_\phi^2} = 1 - \frac{\omega_\mathrm{p}^2}{\omega^2} \qquad [96]$$

where v_ϕ is the phase velocity of the light wave. Assuming infinitely massive ions, the plasma frequency can be written as

$$\omega_\mathrm{p} = \frac{\omega_{\mathrm{p}0}}{\gamma^{1/2}} = \left(\frac{4\pi n_\mathrm{e} e^2}{\gamma m_0}\right)^{1/2} \qquad [97]$$

where ω_{p0} is the plasma frequency in a quiescent plasma, e is the electron charge, m_0 is the electron rest mass, and n_e is the plasma electron density. A change in mass changes the plasma frequency, which in turn modifies the index of refraction and the velocity of the light wave. The light's phase velocity then depends on the laser intensity. This can be seen clearly if we expand the phase velocity for small field strength ($a_0 \ll 1$):

$$v_\phi = \frac{c}{\eta} \sim c\left[1 + \frac{\omega_{p0}^2}{2\omega^2}\left(1 - \frac{\langle a_0^2\rangle}{2}\right)\right] \qquad [98]$$

An on-axis minimum of the phase velocity [i.e., $v_\phi(r) > v_\phi(0)$] can be created by a laser beam with an intensity profile peaked on axis, such as with a Gaussian beam, causing the wavefronts to curve inward and the laser beam to focus, as shown in Figure 10. When this focusing effect just balances the defocusing caused by diffraction, the laser pulse can propagate over a longer distance than it could in vacuum, while maintaining a small cross-section. This mechanism is referred to as relativistic self-guiding.

Relativistic Self-Focusing

The threshold for relativistic self-focusing can be obtained using the fully relativistic formalism with the vector potential, as in our previous discussion of electron motion in vacuum. In this case, we can rewrite eqn [91] as

$$\nabla^2\mathbf{a} - \frac{1}{c^2}\frac{\partial^2\mathbf{a}}{\partial t^2} = \frac{\omega_p^2}{c^2}\frac{n_e\mathbf{a}}{n_0\gamma} \qquad [99]$$

where $n_0 = n_i$ is the uniform background density. For a Gaussian beam focused in vacuum, where

$$\mathbf{a}(\mathbf{r},t) = \mathrm{Re}\left\{\mathbf{a}_0(\mathbf{r},t)\exp[\mathrm{i}(\mathbf{k}\cdot\mathbf{r} - \omega t)]\right\} \qquad [100]$$

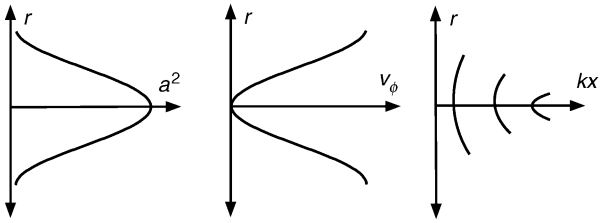

Figure 10 Relativistic self-focusing occurs when an on-axis peak in light intensity (left) produces an on-axis dip in the phase velocity (middle), which acts like a positive lens to cause the phase fronts to curve inward (right). (Reproduced from Umstadter D (2003) Relativistic laser–plasma interactions. *Journal Physics D: Applied Physics* 36: R151–R165, with permission from IOP Publishing Ltd.)

and the amplitude $\mathbf{a}(\mathbf{r},t)$ varies much less less in r and t than does the phase:

$$|\partial a_0/\partial t| \ll |\omega a_0|, \qquad |\partial a_0/\partial z| \ll |k a_0| \qquad [101]$$

then

$$a_0(r,z) = \frac{e^{-r^2/(r_0^2(1+z^2/L_r^2))}}{\sqrt{1+z^2/L_R^2}}\exp\left\{-\mathrm{i}\arctan\left(\frac{z}{L_R}\right) + \mathrm{i}\left(\frac{r}{r_0}\right)^2\frac{z/L_R}{1+z^2/L_R^2}\right\} \qquad [102]$$

satisfies the envelope equation (assuming second deriviatives are small compared to first derivatives), where L_R is the Rayleigh range and r_0 is the focal radius. In plasma, eqn [99] can then be written in this envelope approximation as

$$\left[\nabla_\perp^2 + 2\mathrm{i}k\frac{\partial}{\partial z}\right]a = -\frac{\omega_p^2}{c^2}\frac{|a|^2}{4}a \qquad [103]$$

The power at which the first and last terms of eqn [103] are in balance is

$$P = \frac{\pi R^2 I_0}{2} \qquad [104]$$

An equation for the beam radius R can thus be found:

$$\frac{\mathrm{d}^2R(z)}{\mathrm{d}z^2} = \frac{4}{k^2r_0^2}\left[1 - \frac{1}{22}\frac{\omega_p^2}{c^2}|a_0|^2 r_0^2\right] \qquad [105]$$

Self-focusing occurs when the two terms in the brackets in eqn [105] are equal, which gives for the critical power:

$$P_{crit} \simeq 17.4\cdot(\omega/\omega_p)^2\ \mathrm{GW} \qquad [106]$$

This corresponds to 1 TW for 1 μm light focused into a gas with electron density of $10^{19}/\mathrm{cm}^3$. Note that this is a power threshold, not an intensity threshold, because the tighter the focusing, the greater the diffraction (the first term in eqn [103]). Numerous recent experiments have confirmed this focusing mechanism when $P > P_{crit}$.

Any spatial variation of the laser intensity will act to push an electron to regions of lower intensity through the so-called ponderomotive force:

$$\mathbf{F} = \nabla\gamma = \nabla\sqrt{1+a^2} = (2\gamma)^{-1}\nabla a^2 \qquad [107]$$

$$\mathbf{F}_{\text{pond}} = -\frac{m_0 c^2}{8\pi} \frac{\nabla a_0^2}{\sqrt{1+\frac{a_0^2}{2}}} \cdot \left[\left(\frac{2}{a_0^2} + 1 \right) E(2\pi, \kappa) - \frac{2}{a_0^2} F(2\pi, \kappa) \right] \quad [108]$$

where

$$\kappa = \frac{a_0^2/2}{1 + a_0^2/2} \quad [109]$$

and F and E are the elliptic integrals of the first and second kind, respectively. In the low intensity limit, i.e., when $a_0^2 \ll 1$;

$$\mathbf{F}_{\text{pond}} = -\frac{m_0 c^2}{4} \nabla a_0^2 \quad [110]$$

That is, the laser ponderomotive force is roughly proportional to the gradient of laser intensity.

A Gaussian-shaped laser's ponderomotive force will tend to expel electrons radially from the region of the axis, so called 'electron cavitation.' If the ponderomotive force is high enough for long enough, the charge displacement due to expelled electrons (in either the lateral or longitudinal direction) will eventually cause the ions to move as well through the Coulomb electrostatic force, forming a density channel. Because $n_e(0) < n_e(r)$, and thus $v_\phi(0) < v_\phi(r)$, this enhances the previously-discussed relativistic self-guiding and can itself guide a laser pulse.

For plasmas created by photo-ionization of a gas by a Gaussian laser pulse, the density will be higher on the axis than off the axis. If we instead expand the phase velocity in terms of changes in density:

$$\frac{v_\phi}{c} \sim 1 + \frac{\omega_{p0}^2}{\omega^2} \frac{\Delta n_e}{n_e} \quad [111]$$

The phase velocity will thus be higher on axis, which will tend to defocus the light and increase the self-guiding threshold. In order to avoid this, gases with low atomic number and thus fewer available electrons, such as H_3, are commonly used as targets.

Raman Scattering, Plasma Wave Excitation and Electron Acceleration

The local phase velocity, described in eqns [98] and [111], can also vary longitudinally if the intensity and/or electron density does. Local variation in the index of refraction can 'accelerate' photons, i.e., shift their frequency, resulting in photon bunching, which in turn bunches the electron density through the ponderomotive force (F), and so on. When the laser pulse duration is longer than an electron plasma period, $\tau \gg \tau_p = 2\pi/\omega_p$, this photon and electron bunching grows exponentially, leading to the stimulated Raman scattering instability. Energy and momentum must be conserved when the electromagnetic wave $(\omega_0, \mathbf{k}_0)$ decays into a plasma wave $(\omega_p, \mathbf{k}_p)$ and another light wave $(\omega_0 - \omega_p, \mathbf{k}_0 - \mathbf{k}_p)$.

From an equivalent viewpoint, the process begins with a small density perturbation, Δn_e, which, when coupled with the quiver motion, eqn [13], drives a current $J = \Delta n_e e v_e$. This current then becomes the source term for the wave equation (eqn [91]), driving the scattered light wave. The ponderomotive force, due to the beating of the incident and scattered light wave, enhances the density perturbation, creating a plasma wave and the process begins anew. In three dimensions, a plasma wave can be driven when transverse self-focusing and stimulated Raman scattering occur together, a process called the self-modulated wakefield instability.

Two conditions must be satisfied for self-modulation to occur in the plasma. First, the laser pulse must be long compared to the plasma wave, $L \gg \lambda_p$. This allows the Raman instability time to grow, and it allows for feedback from the plasma to the laser pulse to occur. Second, the laser must be intense enough for relativistic self-focusing to occur, $P > P_c$, so that the laser can be locally modified by the plasma. Under these conditions, the laser can form a large plasma wave useful for accelerating electrons.

As the long laser pulse enters the plasma, it will begin to drive a small plasma wave due to either forward Raman scattering or the laser wakefield effect from the front of the laser pulse. This small plasma wave will have regions of higher and lower density with both longitudinal and radial dependence. That is, the plasma wave will be three-dimensional in nature with a modulation along the propagation direction of the laser and a decay in the radial direction to the ambient density (see **Figure 11**). The importance of this lies with how it affects the index of refraction in the plasma. In the regions of the plasma wave where the plasma density is lower, the radial change in the index of refraction is negative, $\partial n(r)/\partial r < 0$. This means that this part of the plasma acts like a positive lens and focuses the laser. Whereas regions of the plasma wave where the density is higher, $\partial n(r)/\partial r > 0$, the opposite occurs and the laser defocuses. This has the effect of breaking up the laser pulse into a series of shorter pulses of length $\lambda_p/2$ which will be separated by the plasma period. The instability occurs because of how the plasma responds to this. Where the laser is more tightly focused, the ponderomotive force will be

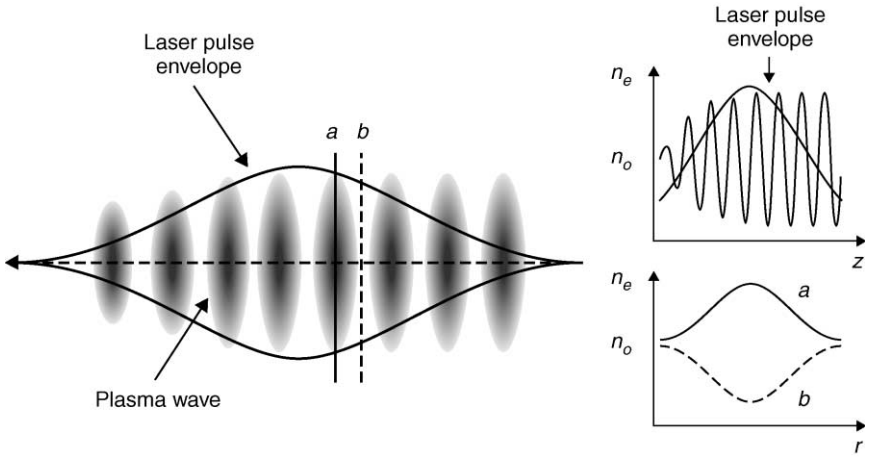

Figure 11 The plasma wave generated by a SMLWFA is three-dimensional in nature. Note that the darker regions correspond to areas of higher plasma density. The graphs to the right represent lineouts of the plasma density longitudinally and radially at the indicated points. (Reproduced with permission from Wagner R (1998) Laser–plasma electron accelerators and nonlinear relativistic optics. PhD thesis, University of Michigan.)

greater and will tend to expel more electrons. This decreases the density in these regions even further, resulting in more focusing of the laser. This feedback rapidly grows, hence the instability.

The phase velocity of the plasma wave in the case of forward scattering is equal to the group velocity of the beat wave, which for low-density plasma is close to the speed of light, as can be seen from the relation:

$$v_\phi = \omega_p/k_p = \Delta\omega/\Delta k = v_g = c\eta \sim c \qquad [112]$$

where eqn [94] and $\omega_p^2 \ll \omega^2$ were used to show that η is close to unity. Such relativistic plasma waves can also be driven by short pulses ($\tau \sim \tau_p$). In this case, the process is referred to as laser–wakefield generation, referring to the analogy with the wake driven by the bow of a boat moving through water, but the mechanism is similar (except it has the advantage that the plasma wave is driven linearly instead of as an instability).

In either case, the resulting electrostatic plasma wave can continuously accelerate relativistic electrons with enormous acceleration gradients. The gradient can be estimated from eqn [92] and the fact that because

$$\nabla \cdot \mathbf{E} \sim E\omega_p/c \propto E\sqrt{n_e} \qquad [113]$$

then

$$E \sim \sqrt{n_e}\ \text{eV/cm} \qquad [114]$$

corresponding to 1 GeV/cm for $n_e = 10^{18}\ \text{cm}^{-3}$. Because this gradient is four orders of magnitude greater than achieved by conventional accelerators (based on fields driven by radio-frequency waves pumped into metal cavities), laser-driven plasma accelerators have received considerable recent attention. They have been shown to accelerate an amount of electron charge (100 nC) comparable to that from conventional accelerators and to have superior transverse geometrical emittance (product of divergence angle and spotsize, similar to the $f/\#$ in light optics). However, their longitudinal emittance is currently much inferior, energy spreads of 100%. They have been shown to be useful for much of the same applications: radio-isotope production, radiation chemistry, as well as X-ray, proton, and neutron generation. Once the longitudinal emittance can be reduced, they may be advantageous for, among other applications, injectors (especially of short-lived unstable particles) into larger conventional accelerators for high-energy physics research and light sources, and, as discussed in the section on radiation from relativistic electrons about, as stand-alone all-optically driven ultrashort-pulse duration X-ray sources.

The SIMLAC code has been used to study wakefield generation and laser propagation in the limit $a^2 \ll 1$. It draws from nonlinear optics models and treats propagation in the group velocity frame. In this idealized model (which assumes perfect Gaussian beams), the pulse and wake are maintained over long enough propagation distances to accelerate an electron to GeV energy, as shown in Figure 12. A three-dimensional envelope equation for the laser field was derived that includes nonparaxial effects, wakefields, and relativistic nonlinearities.

The resonant wakefield has been characterized experimentally by temporal interferometry, as shown in Figure 13. However, this was done only for the tight-focusing case in which the laser spotsize is much

smaller than the plasma wave wavelength ($r_l \ll \lambda_p$) and thus the transverse wakefield was much greater than the longitudinal wakefield.

A typical experimental setup, used to study electron acceleration, is shown in Figure 14.

Dramatic reduction of the angular divergence of a laser accelerated electron beam was observed with increasing laser power above the relativistic self-focusing threshold, as shown in Figure 15.

Interactions with Solid-Density Targets

The generation of electrons by high-intensity laser light interacting with solid targets can generate energetic X-rays, accelerate other types of particles and induce nuclear reactions, as illustrated in Figure 16. For instance, high-order harmonics have been generated by the oscillation of the critical density surface, in the so-called moving mirror model. Bright X-rays, originating from Bremstrahlung caused by electron collisions with high-Z atoms in solid targets, have created isotopes by means of photofission. Laser-accelerated electron energies and

angular distributions have been inferred from analyzing (γ, n) and $(\gamma, 2n)$ reactions in composite Pb/Cu targets and in Ta/Cu targets. Positrons were created by colliding laser-accelerated electrons with a tungsten target.

When electrons are heated to high temperatures or accelerated to high energies, they can separate from plasma ions. Such charge displacement creates an electrostatic sheath, which eventually accelerates the ions. The ions are pulled by the charge of the electrons and pushed by the other ions' unshielded charges (similar to the 'Coulomb explosion' that can occur during the ionization of atoms). When the charge displacement is driven by thermal expansion, as in long-pulse (low-power) laser–plasma experiments, the maximum ion energies are limited to less than 100 keV. However, when the charge displacement is driven by direct laser heating, as in short-pulse high-power laser–plasma experiments, multi-MeV ion energies are possible. This was first shown with gas jet targets, in which case the ions were accelerated radially into 2π, and then later with thin solid-density-films, in which case the ions were accelerated into collimated beams. In the latter case, hydrocarbons and water on the surface of the film can become ionized and provide a source of protons to be accelerated.

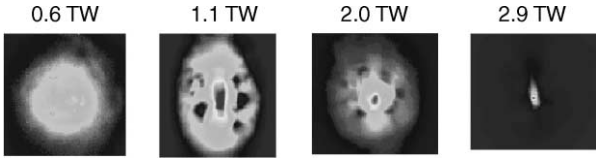

Figure 15 Images of the spatial profiles of the electron beam measured by a ccd camera imaging a LANEX screen at a distance of 15 cm from the gas jet for various laser powers. The divergence angle of the beam decreases to a value of $\Delta\theta = 1°$ at a power of 2.9 TW, corresponding to a transverse geomtrical emittance of just $\varepsilon_\perp \lesssim 0.06\pi$ mm-mrad. (Reproduced with permission from Umstadter D (2001) Review of physics and applications of relativistic plasmas driver by ultra-intense lasers. *Physics Plasmas* 8: 1774, with permission from the American Institute of Physics.)

An intense laser can ponderomotively heat electrons. If the laser contrast is high, vacuum heating can occur in the following manner. When light encounters a sharp interface between vacuum and solid density, the electromagnetic field becomes evanescent in the region above the critical density. The instantaneous '$v \times B$' force can push electrons in the direction of the light's propagation vector; it also has a frequency twice that of the pump and a magnitude proportional to the square of the normalized vector potential, a_0^3. Thus, electrons can only complete half of their figure-eight orbits, on the vacuum side, gaining relativistic energies; they move through the overdense region without the electromagnetic field to pull them back. An electrostatic sheath can thus form, which will accelerate the ions left behind. Another important heating mechanism is stochastic heating, which occurs when the light that is reflected from the critical surface beats with the incoming wave to create a standing wave. The motion of electrons in such a wave can become chaotic, resulting in a large increase in electron temperature (>100 keV).

As the heated electrons propagate through a solid, they can instantaneously field-ionize the neutral atoms of the solid. This will both modify the solid's

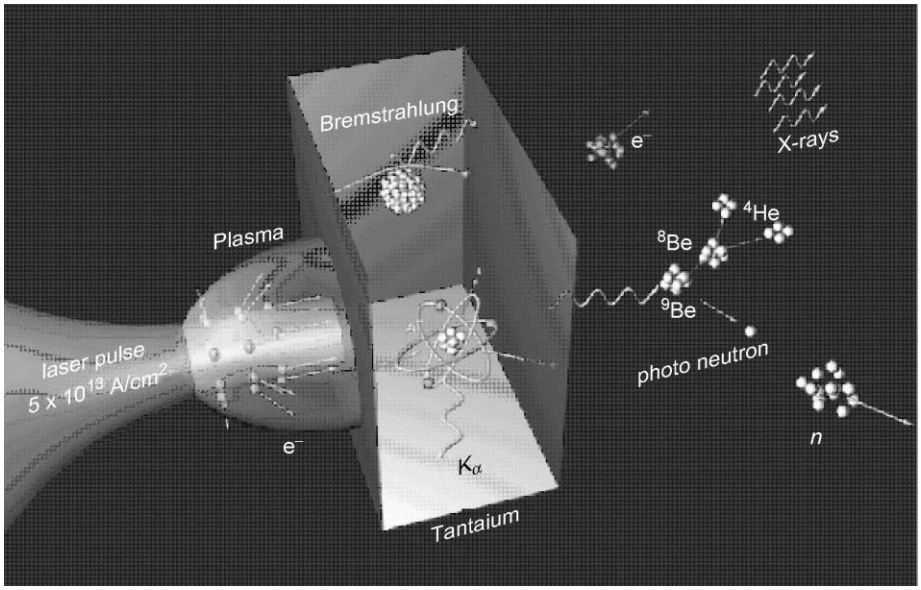

Figure 16 Illustration of the various mechanisms of particle acceleration and X-ray generation in high-intensity laser interactions with solid-density targets. (Courtesy of R. Sauerbrey.)

conductivity and provide a source of protons on the rear-side of the target. If the film is thin enough, the electrons can pass through, and create a sheath on the rear-side of the target. This latter mechanism has been dubbed the target normal sheath acceleration mechanism. The ions from thin foils have been claimed to originate from both the front and rear-side of the foil.

Several groups have reported the observation of ions originating from thin-film solid-density targets. Unlike previous long-pulse experiments, the ions were accelerated along the direction normal to the side of the target, that is opposite to that upon which the laser was incident. The ions generally originate from water or hydrocarbons on the surface of the material. The acceleration results from several different mechanisms, which may be occurring simultaneously. Charge-displacement is again common to all, with the electrons being heated ponderomotively, such as by Brunel, $J \times B$ or stochastic heating. In one case, the electrostatic sheath is formed at the backside of the ionization layer formed on the side of the target upon which the laser is incident (front side). In another case, the electrostatic sheath is formed by field ionization of the ion layer on the opposite side of the thin film target (back-side), the target normal sheath acceleration (TNSA) hypothesis. Numerical simulations show evidence for both front- and back-side acceleration.

The results of these experiments indicate that a large number of protons (10^{13} p) can be accelerated, corresponding to source current densities (10^8 A/cm^2) that are nine orders of magnitude higher than produced by cyclotrons, but with comparable, or even lower, transverse emittances ($\varepsilon_\perp \leq 1.0\pi$ mm-mrad). Proton energies up to 60 MeV have been observed in experiments at intensities exceeding 10^{20} W/cm^2 (using a petawatt power laser). The high end of the proton spectrum typically has a sharp cut-off, but is a continuum. In one experiment, protons were observed to be emitted in ring patterns, the radii of which depend on the proton energy, which was explained by self-generated magnetic fields.

A typical experimental setup used to observe the acceleration of ions is shown in Figure 17. The production of radionuclides have been used as an ion energy diagnostic. In another example of a nuclear reaction initiated by an intense laser, neutrons

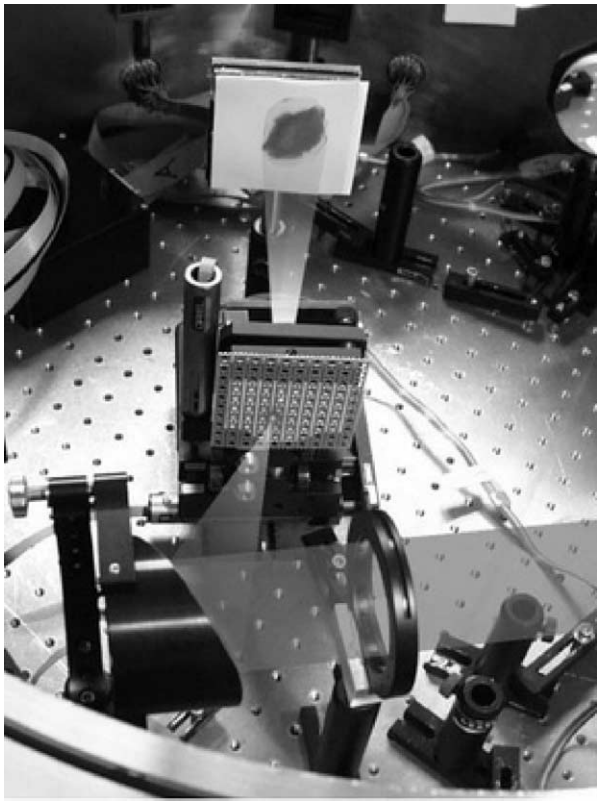

Figure 17 Artistically enhanced photograph of the typical setup used to observe the acceleration of ions. The laser (shown in the foreground) is focused with an off-axis parabola onto a thin-foil, held by a mesh that is positioned by a 3-axis micropositioner. have been produced by the He fusion reaction in the focus of 200 mJ, 160 fs Ti:sapphire laser pulses on a deuterated polyethylene target. Optimizing the fast electron and ion generation by applying a well-defined prepulse led to an average rate of 140 neutrons per shot. Neutrons have also been generated from cluster plasmas, which were produced by the cooled-nozzle depicted in Figure 18, but with significantly lower laser intensities than required with planar solid targets.

Concluding Remarks

The field of nonlinear optics, with electrons bound to atoms, has over the last forty years given rise to many scientific discoveries and technologies that are now commonplace. The relatively young field of relativistic nonlinear optics has already begun to do the same. Some of the exciting phenomena and applications that have already been identified have been discussed in this article. Others await discovery as ever higher laser intensities are reached, with no foreseeable limit.

When an electromagnetic wave passes over a small elastically bound charged particle, the particle will be set into motion by the electric field. Scattering takes place for frequencies not corresponding to the natural frequencies of the particles. If the particle is bound by a force obeying Hooke's law, this vibration will have the same frequency and spatial direction as that of the electric force in the electromagnetic wave. The phase, on the other hand, of the forced vibration will differ from that of the incident wave, which causes the basis of dispersion. If the charged oscillation is bound by a force which does not obey Hooke's law, but some more complicated law, it will reradiate not only the impressed frequency, but also various combinations of this frequency with the fundamental and overtone frequencies of the oscillator.

The Raman effect was discovered by C.V. Raman (1888–1971). Ordinary Raman spectroscopy is used as a tool for studying the vibrational energy levels of molecules and of lattice optical branch vibration in crystals. A spectroscopic measurement of the scattered light reveals the existence of frequencies shifted down by increments corresponding to vibrational frequencies of the material. This down-shifted scattering is referred to as Stokes scattering. Frequencies shifted up by the vibrational frequencies are also present in the scattered radiation, which are the so-called anti-Stokes scattering.

Stimulated amplification of scattered Stokes radiation occurs through a third-order nonlinear process. To introduce stimulated Raman scattering (SRS), first we describe the steady-state stimulated scattering theory.

In general, nonlinear optical processes are described by the classical Maxwell equation with the nonlinear polarization of a material $\mathbf{P}^{\mathrm{NL}}$:

$$\nabla \times \nabla \times \mathbf{E} + \varepsilon\mu_0 \frac{\partial^2 \mathbf{E}}{\partial t^2} = -\mu_0 \frac{\partial^2 \mathbf{P}^{\mathrm{NL}}}{\partial t^2} \qquad [1]$$

where ε and μ_0 are the linear dielectric constant of the material and the magnetic permeability of the vacuum. We consider a relatively intense excitation radiation $\mathbf{E}_{\mathrm{L}}$ (frequency ω_{L}) and a weak signal radiation $\mathbf{E}_{\mathrm{S}}$, having the carrier frequency ω_{s} corresponding to the scattered light frequency ($\omega_{\mathrm{s}} = \omega_{\mathrm{L}} - n\omega_0$);

$$\mathbf{E}_{\mathrm{L}} = \frac{1}{2}\{\bar{\mathbf{E}}_{\mathrm{L}}(\mathbf{r}, t) \exp \mathrm{i}(\mathbf{k}_{\mathrm{L}} \times \mathbf{r} - \omega_{\mathrm{L}} t) + \mathrm{c.c.}\} \qquad [2]$$

$$\mathbf{E}_{\mathrm{S}} = \frac{1}{2}\{\bar{\mathbf{E}}_{\mathrm{S}}(\mathbf{r}, t) \exp \mathrm{i}(\mathbf{k}_{\mathrm{S}} \times \mathbf{r} - \omega_{\mathrm{S}} t) + \mathrm{c.c.}\} \qquad [3]$$

where $\bar{\mathbf{E}}_L(\mathbf{r},t), \bar{\mathbf{E}}_S(\mathbf{r},t)$ are a slowly varying envelope of the complex electric fields. Assuming that the variation of the electric field during the time-scale shorter than the decay time of the induced oscillation in the material is negligible, nonlinear polarization induced by the excitation radiation is described as follows:

$$\mathbf{P}_S^{NL} = \frac{1}{2}\{\bar{\mathbf{P}}_S^{NL}(\mathbf{r},t)\exp i(\mathbf{k}_S\times\mathbf{r}-\omega_S t)+\text{c.c.}\} \quad [4]$$

$$\bar{\mathbf{P}}_S^{NL} = \varepsilon_0\chi^{NL}(-\omega_S,-\omega_L,\omega_L,\omega_S)\bar{\mathbf{E}}_L^*\bar{\mathbf{E}}_L\bar{\mathbf{E}}_S \quad [5]$$

where ε_0 is the vacuum dielectric constant and $\chi^{NL}(-\omega_S,-\omega_L,\omega_L,\omega_S)$ is the third-order nonlinear susceptibility, of which the real part corresponds to the variation of the dielectric constant depending on the optical radiation, whereas the imaginary part describes the stimulated scattering. In steady-state approximation, substituting eqns [3]–[5] into [1], we obtain

$$\frac{d\bar{\mathbf{E}}_S}{dz} = \frac{1}{2}\left(-a+i\frac{\omega_S}{cn_S}\chi^{NL}|\bar{\mathbf{E}}_L|^2\right)\bar{\mathbf{E}}_S \quad [6]$$

where we ignore the higher-order differential of amplitude. n_S is the refractive index at ω_S, and a is the linear absorption coefficient of the signal radiation. When ignoring the decay of the excitation radiation along the z direction in the material, for making the right-hand term of eqn [6] positive, the next condition must be satisfied:

$$I_L = \frac{1}{2}c\varepsilon_0 n_L|\bar{\mathbf{E}}_L|^2 \geq I_L^{th} = \frac{c^2\varepsilon_0 n_S n_L}{2\omega_S}\frac{a}{-\text{Im}\chi^{NL}} \quad [7]$$

The signal radiation is then amplified along the z direction at an amplification constant of g,

$$G = g(I_L - I_L^{th}) \quad [8]$$

$$g = \frac{\omega_S}{c^2\varepsilon_0 n_S n_L}(-\text{Im}\,\chi^{NL}) \quad [9]$$

Stimulated Raman Scattering

In SRS, the frequency difference $\omega_L - \omega_S$ corresponds to the resonance frequency of vibrational oscillation ω_V. Therefore, the vibrational oscillation mode is excited in the material as well as the generation of scattered radiation. In the following section, we consider the SRS by optical phonon. In general, nonlinear polarization under the optical excitation is described as follows:

$$\mathbf{P}^{NL} = N_0\alpha' q\mathbf{E}, \quad [10]$$

$$\ddot{q} = \Gamma_V\dot{q} + \omega_V^2 q = \frac{1}{2}\alpha'\mathbf{E}^2 \quad [11]$$

where q is the basic coordinate of molecular vibration, Γ_V is the decay rate of the vibrational oscillation, $\alpha' = (\partial\alpha/\partial q)_0$ is the Raman polarizability of a molecule, and N_0 is the molecule density. We can obtain the steady-state nonlinear polarization from eqns [4], [5], [10], and [11] as

$$\chi^{NL} = (-\omega_S,-\omega_L,\omega_L,\omega_S) = \frac{N_0(\alpha')^2}{4\varepsilon_0}\frac{1}{\omega_V^2-\omega^2+i\omega\Gamma_V} \quad [12]$$

where $\omega = \omega_L - \omega_S$. Thus, the gain coefficient can be obtained from eqns [9] and [12] under the assumption of $\omega_V \gg \Gamma_V$, as follows:

$$g_R(\omega_S) = \pm\frac{N_0(\alpha')^2\omega_S}{2c^2\varepsilon_0 n_S n_L\omega_V\Gamma_V} \times\frac{(\Gamma_V/2)^2}{(\omega_L-\omega_S\mp\omega_V)^2+(\Gamma_V/2)^2} \quad [13]$$

In general, Raman scattering is characterized by the scattering cross-section $d\sigma/d\Omega$, which is defined for one of the optical polarization directions in terms of the optical power density:

$$g_R(\omega_L-\omega_V) = \frac{16\pi^2c^2N_0}{\hbar n_S^2\omega_S^3\Gamma_V}\frac{d\sigma}{d\Omega}\left\{1-\exp\left(-\frac{\hbar\omega_V}{k_BT}\right)\right\} \quad [14]$$

The value of $(d\sigma/d\Omega)\Gamma_V^{-1}$ can be characterized as a peak intensity in the measured spontaneous Raman scattering spectrum.

When the conversion to the first Stokes wave is large, we must consider both pump depletion and conversion to higher-order Stokes waves (**Figure 1a**). Pump depletion in first Stokes generation can be accounted for by solving the following coupling

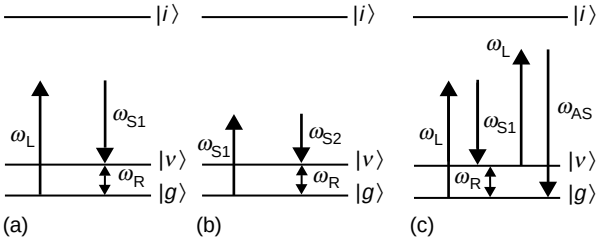

Figure 1 Energy diagrams of stimulated Raman scattering: (a) first Stokes scattering; (b) cascaded second Stokes scattering; and (c) first anti-Stokes scattering.

equations between pump power and Stokes power:

$$\frac{\partial I_L}{\partial z} + \frac{n_L}{c}\frac{\partial I_L}{\partial t} = -g_L I_L I_S \quad [15]$$

$$\frac{\partial I_S}{\partial z} + \frac{n_S}{c}\frac{\partial I_S}{\partial t} = g_R I_L I_S \quad [16]$$

where

$$g_L = \frac{\omega_L}{\omega_S} g_R$$

In SRS the power generated in the first Stokes serves as a pump for a second Stokes wave (Figure 1b). Cascade shifts of this type, in which the Stokes wave of order n serves as a pump for the generation of the Stokes wave order $n+1$, can result in the generation of radiation at several frequencies, each one shifted from the original pump frequency by a multiple of the vibrational mode frequency. In addition to the cascade higher-order Stokes generation, multiple Stokes orders can also be generated by four-wave mixing interactions (Figure 2), of the form:

$$\omega_{S,n+1} = 2\omega_{S,n} - \omega_{S,n-1} \quad [17]$$

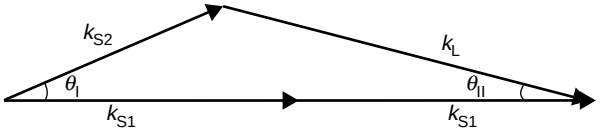

Figure 2 Vector diagram of multiple Stokes generation through four-wave mixing in positively dispersive media.

These interactions are important when the wavevector mismatch among the various waves is small. In most media exhibiting positive dispersion, the phase matching of the various interactions involves off-axis components of the generated waves. Thus, these four-wave mixing interactions are stronger for tightly focused beams than for collimated pump beams.

SRS can be realized in a variety of configurations, including single pass Raman generation, or using a variety of extra-cavity or intra-cavity Raman resonator. Variation of the Raman cross-section for the wavelength is shown in Figure 3 for various gaseous Raman media. The Raman gain coefficient simply increases with decreasing wavelength, as indicted by eqn [13]. Therefore, higher conversion efficiencies are obtainable with UV lasers such as rare-gas halide excimer lasers in a single pass configuration. Note that in some gases, such as H_2, the Raman gain becomes independent of pressure at higher pressures since the increase in linewidth, due to pressure broadening, cancels the increase in gain originated from number density. Typical SRS gains for some gas, liquid, and solid media are listed in Table 1.

Although SRS in high-pressure gases has been widely employed for frequency conversion, SRS in crystals is currently a growing area of research activity. Table 2 lists SRS frequency shifts of various crystals. Since a very high pump laser power ~1 GW/cm^2, which is already close to the laser damage threshold of many crystals, solid-state Raman lasers are

designed with an intra-cavity, coupled cavities, or an extra-cavity. Efficient Raman lasers have been demonstrated using external resonator configuration when the pumping pulse is intense enough. For example, $\sim 40\%$ conversion efficiency to S1 was reported with a Q-switched frequency doubled Nd:YAG laser in a $Ba(NO_3)_2$ crystal using a pump fluence of $1.4\,J\,cm^{-1}$ and a pulse repetition rate of 30 Hz. The resonator mirror characteristics can be designed to enhance the desired Stokes-order radiation by completely confining the lower-order Stokes radiation inside the cavity. For a lower power pump source, such as cw-pumped Q-switch lasers, a Raman crystal is placed inside a pump laser resonator to reduce the effective threshold for SRS. The resonator configuration has a significant influence on the Stokes output performance. The optimum spot size in the resonator and power density in the Raman crystal is a compromise between maximizing the conversion efficiency and avoiding optical damage. It is noteworthy that the thermal lens in the Raman crystal is caused by the energy dissipation of the phonon and thus depends on the power density of the Stokes field.

A fiber Raman laser is an optical fiber with pump light focused into one end and SRS light appearing at the output. By injecting a weak frequency-shifted signal light together with the pump light, the signal light experienced substantial amplification along the length of the fiber. This fiber Raman amplifier has been actively developed to extend the wavelength band for optical fiber communication. The fiber Raman lasers have utilized fused silica (SiO_2), germanosilicate, or phosphosilicate optical fibers for which the Raman frequency shifts are ~ 440–$490\,cm^{-1}$. In contrast to Erbium-doped fiber amplifier (EDFA), since the single mode fiber itself can act as an amplifier, the Raman amplifier can be distributed over optical transmission lines in lengths of >20 km, which can keep the transmission power always nearly constant and consequently reduce the signal noise. Moreover, by preparing multipumping wavelengths, the number of signal wavelengths can increase without the limitation of an amplification gain bandwidth. High-power light sources around 1480 nm developed for EDFA can be utilized by the fiber Raman amplifier. By tailoring the power levels among multiwavelength pump lights, a flat amplification gain spectral width of ~ 100 nm is obtainable.

Transient Effects

In the steady-state SRS analysis, we assume that the pump pulse duration is much longer than the vibrational mode dephasing time ($\Delta\nu_p \ll \Gamma_V$). In a transient regime, when the pump pulse duration is shorter than the dephasing time ($\Delta\nu_p \gg \Gamma_V$), the effect of the transient response of the medium reduces the gain and delays the Stokes pulse relative to the pump pulse. With no pump depletion, the analytical expression for the Stokes intensity for large

amplification gain is given as

$$I_S(\ell) \propto I_S(0)\exp\left(-\frac{\tau_p}{T_V}\right) \times \exp\left\{2\left[I_L\tau_p\ell\frac{16\pi^2c^2N_0}{\hbar n_S^2\omega_S^3}\left(\frac{d\sigma}{d\Omega}\right)\right]^{1/2}\right\} \quad [18]$$

Here, T_V is the dephasing time ($T_V = \pi\Gamma_V^{-1}$), and τ_p is the pump pulse width. One can see that the Raman gain is proportional to the square root of the multiplication of the pump pulse energy $I_L \times \tau_p$, the crystal length ℓ, and the total integral Raman scattering cross-section ($d\sigma/d\Omega$), but does not depend on the Raman linewidth Γ_V.

Anti-Stokes Raman Scattering

From eqn [13] the gain coefficient is negative at $\omega = \omega_L + \omega_S$. However, anti-Stokes scattering (Figure 1c) is stimulated through a four-wave mixing interaction of the form:

$$\omega_A = 2\omega_L - \omega_S \quad [19]$$

The equations describing anti-Stokes Raman scattering in the absence of pump depletion are:

$$\frac{d\bar{E}_S}{dz} + \frac{a}{2}\bar{E}_S = i\frac{\omega_S^2}{2c^2\varepsilon_0 k_{Sz}}\bar{P}_S^{NL} \quad [20]$$

$$\frac{dE_A^*}{dz} + \frac{a}{2}\bar{E}_A^* = -i\frac{\omega_A^2}{2c^2\varepsilon_0 k_{Az}}\bar{P}_A^{NL*} \quad [21]$$

$$\bar{P}_S^{NL} = \varepsilon_0\chi^{NL}\left\{|\bar{E}_L|^2\bar{E}_S + \bar{E}_L^2\bar{E}_A^*\exp(i\Delta kz)\right\} \quad [22]$$

$$\bar{P}_A^{NL*} = \varepsilon_0\chi^{NL}\left\{\bar{E}_L^{*2}\bar{E}_S\exp(-i\Delta kz) + |\bar{E}_L|^2\bar{E}_A^*\right\} \quad [23]$$

Here, Δk is the wavevector mismatch, given by

$$\Delta k = k_S + k_A - 2k_L \quad [24]$$

Then, power gain per unit length is obtained to give

$$G \cong -a \pm 2\,\mathrm{Im}\left\{\left(\frac{\Delta k}{2}\right)^2 - \frac{\omega_S}{2cn_S}\chi^{NL}|\bar{E}_L|^2\Delta k\right\}^{1/2} \quad [25]$$

The interaction of the anti-Stokes wave with the other waves is stronger when the wavevector mismatch is small. The exact value of the phase-matching angle depends on the dispersion of the medium. At the tightly focused pumping condition, strong anti-Stokes radiation is generated so that the wavevector mismatch is minimum. Just as in Stokes scattering, multiple anti-Stokes orders can be generated (Figure 4).

So far, Stokes and anti-Stokes Raman scattering have been used to generate radiation over much of the UV and VUV, ranging from 138 to 400 nm. The shortest wavelength achieved in this manner is at 138 nm, generated by a seventh-order anti-Stokes shift in H_2 using 139 nm radiation of an ArF laser. In general, the pump intensity used in experiments with rare-gas halide excimer lasers was in the range of 100 MW/cm^2 to 5 GW/cm^2. The conversion efficiency and the distribution of power among the various Stokes and anti-Stokes

components depend on the focal geometry, and the extent of the spectrum could be varied by changing the gas pressure.

Scattering from Surfaces and Thin Films

A Duparré, Fraunhofer Institut IOF, Jena, Germany

Introduction

The quality of optical components can be critically limited by light scattering. The majority of these components, such as lenses, mirrors, beamsplitters, and polarizers are covered with thin film optical coatings. To reduce scattering losses, their main sources and mechanisms must be known and, whenever possible, be controlled. Moreover, light scattering techniques have been widely recognized as a powerful tool for roughness and defect analysis as well as for general quality assessment.

Scattering can be divided into surface/interface scattering (SIS) and volume scattering (VS), attributed to the following scatter sources:

- roughness and surface defects of the substrate: SIS,
- surface/interface roughness and defects of the thin film coating: SIS,
- imperfections in the bulk substrate material: VS,
- intrinsic thin film morphology and defect structures: VS,
- surface contaminations: SIS.

Even though in particular cases and applications, VS can constitute the main scattering source, SIS largely dominates both substrate and thin film scattering losses. Studies into light scattering have widely focused on SIS effects from surface and interface micro-roughness. The theoretical outline given in the next section will also follow this concept in describing scattering from surface and interface roughness. It is emphasized, however, that volume scattering theories are accessible in the literature.

Light Scattering Models

Scattering from Rough Surfaces

A randomly rough surface can be considered as a Fourier series of sinusoidal waves with different amplitudes, periods, and phases. Following the grating equation, a single grating with spacing D causes scatter into the angle Θ according to

$$\sin\Theta = \lambda/D \qquad [1]$$

where λ is the wavelength of light. D represents one spatial wavelength in the Fourier series. Accordingly, $f = 1/D$ represents one single spatial frequency. A randomly rough surface contains many different spatial frequencies. This is quantitatively expressed by the power spectral density (PSD), giving the relative strength of each roughness component of a surface microstructure as a function of spatial frequency:

$$\mathrm{PSD}(\mathbf{f}) = \lim_{A\to\infty}\frac{1}{A}\left|\int_{\mathbf{A}}\zeta(\mathbf{r})\exp(-2\pi i\mathbf{f}\cdot\mathbf{r})\mathrm{d}\mathbf{r}\right|^2 \qquad [2]$$

where $\zeta(\mathbf{r})$ represents the height of the surface roughness profile, $\mathbf{r}$ is the position vector, and $\mathbf{f}$ is the spatial frequency vector in the x–y plane. A is the area of the measured region $\mathbf{A}$. We confine our discussion to isotropic surfaces, which represent the majority of cases in optical surface and thin film scattering studies. Thus, a PSD(f) independent of the surface direction Φ of vector $\mathbf{f}$ is obtained by averaging the two-dimensional function PSD($\mathbf{f}$) over all surface directions after transformation into polar coordinates:

$$\mathrm{PSD}(f) = \frac{1}{2\pi}\int_0^{2\pi}\mathrm{PSD}(f,\Phi)\mathrm{d}\Phi \qquad [3]$$

Well-established vector scattering theories developed, for instance, by Bousquet *et al.* or Elson provide the link between the PSD and the scattering intensity per solid angle of a surface:

$$\frac{dP}{P_0\, d\Omega} = F(\lambda, n, \Theta, \Phi)\mathrm{PSD}(f) \qquad [4]$$

This theory is valid for surfaces whose rms roughness is small compared to the wavelength. $dP/(P_0\, d\Omega)$ denotes the differential power scattered into the direction (Θ, Φ) per unit solid angle $d\Omega = \sin\Theta\, d\Theta\, d\Phi$ divided by the incident power P_0. Θ and Φ are the polar and azimuthal angles of scattering, respectively. The optical factor F contains all information on the corresponding perfect surface (without the roughness properties), i.e., the refractive index n, wavelength, and the conditions of illumination and observation. Both backscattering and forward scattering can be expressed by eqn [4], according to the illumination and observation conditions chosen. Without loss of generality, all formulas have been written here for normal incidence. The formalism, however, allows consideration of all possible cases, including oblique angles of incidence and arbitrary polarization properties. $dP/(P_0\, d\Omega)$ is called angle resolved scattering (ARS) which is related to the well-established term BRDF/BTDF (bidirectional reflectance/transmittance distribution function) by multiplication with $\cos\Theta$:

$$\frac{dP}{P_0\, d\Omega} = \mathrm{ARS} = \mathrm{BRDF\ (or\ BTDF)}\cdot\cos\Theta \qquad [5]$$

Total scattering (TS), which is defined as the power P scattered into the backward or forward hemisphere divided by the incident power P_0 (see also section on scattering measurement below), is obtained by integrating eqn [4] over the forward or backward hemisphere:

$$\mathrm{TS} = 2\pi \int_0^{\frac{\pi}{2}} \left(\frac{dP}{P_0\, d\Omega}\right) \sin\Theta\, d\Theta \qquad [6]$$

If the correlation length of surface roughness is much larger than the wavelength, scalar scattering theories like the one from Carniglia can also be employed. Moreover, in this case, the well-known simple approximate formula for total backscattering can be derived from both vector and scalar theories:

$$\mathrm{TS}_{\mathrm{back}} = R_0 \left(\frac{4\pi\sigma}{\lambda}\right)^2 \qquad [7]$$

where σ is the rms roughness and R_0 the specular reflectance.

It must be emphasized that this formula is only valid if the above-mentioned condition is met and as long as only single surfaces without coatings are considered.

Scattering from Dielectric Thin Films

For surfaces coated with a dielectric single layer or multilayer, ARS for a system of N layers is given by

$$\frac{dP}{P_0\, d\Omega} = \sum_{i=0}^{N} \sum_{j=0}^{N} F_i F_j^* \mathrm{PSD}_{ij}(f) \qquad [8]$$

where F_i is the optical factor at the i-th interface and F_j^* is the conjugate complex number of the optical factor at the j-th interface. The optical factors include both the conditions of illumination and observation and the characteristics of the ideal multilayer (refractive indices, film thickness). PSD_{ij} are the power spectral densities of the corresponding interfaces. For $i \neq j$, they describe the roughness cross-correlation between two interfaces.

From eqn [8] it becomes obvious that the scattering mechanism of coated surfaces is considerably more complex as compared to single surfaces.

The amplitudes of the scattered fields from all individual interfaces add up to the total scatter. In particular, the cross-correlation properties between the interface roughness profiles significantly determine the overall total scatter. So even for coatings having the same statistical roughness, the scatter losses can differ drastically when the cross-correlation between the interfaces is different. An example is demonstrated in a model calculation of total backscattering for $\lambda = 632.8$ nm in Figure 1.

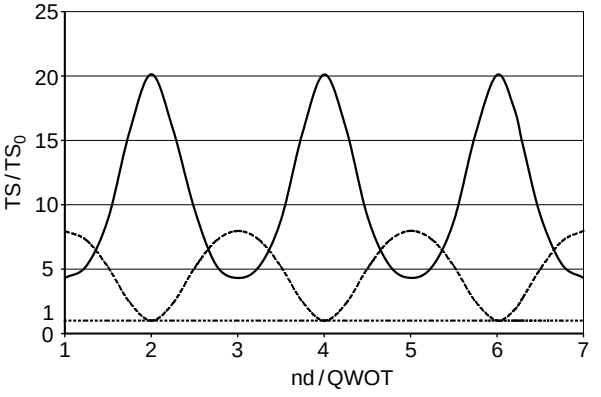

Figure 1 Calculated ratio of the total backscattering of a single high index layer ($n = 2.4$) on BK7 substrate ($n = 1.52$) to the scattering of the bare substrate as a function of optical thickness nd. (QWOT: quarter wave optical thickness). rms roughness was 1 nm, correlation length 1 μm for both the substrate–film and film–air interfaces. Full line: full interface cross-correlation. Dashed line: zero interface cross-correlation. Lower dashed line: bare substrate.

A thin film with refractive index $n = 2.4$ (typical for Titania films), and continuously increasing thickness, was modeled onto a BK 7 substrate ($n = 1.52$). Gaussian autocovariance functions with an rms roughness $\sigma = 1$ nm and a correlation length $\tau = 1$ μm were chosen for both the substrate–film and film–air interfaces. Only the cross-correlation function was varied. The two extreme cases of fully uncorrelated and fully correlated interfaces are depicted in the figure and related to the scattering of the bare substrate (TS_0). As a result of scattering interference effects, in both cases the scattering varies periodically with optical film thickness. The appearance of maxima and minima as well as the total amount of scattering crucially depends on the type of cross-correlation.

These effects have to be taken into careful deliberation whenever scattering in dielectric thin film coatings is considered. Otherwise, misinterpretation of the scatter loss origin is possible and may result in unsuitable technological attempts to minimize scatter losses.

Instrumentation for Light Scattering Measurement

Types of Measurements

Light scattering experiments on optical surfaces and thin films are, in most cases, either performed as ARS measurements using goniophotometers, or the scattering is collected over the backward and forward hemispheres yielding total integrated scattering (TIS) or TS. The latter can be measured either by using a Coblentz sphere or an integrating sphere (see schematic picture in Figure 2).

As Coblentz spheres image the scattered radiation directly onto the detector, they are much less sensitive to scattering by air particles than integrating spheres. So if super-smooth samples with scattering levels in the visible range of 1 ppm and lower shall be measured, integrating spheres require operation in vacuum or He-gas atmosphere whereas Coblentz spheres can still be used under usual clean room conditions.

Angle Resolved Scattering (ARS)

Sophisticated instruments for ARS measurements have been established in a number of laboratories. Most frequently the systems are operated at the He–Ne laser wavelength 632.8 nm, but also at 10.6 μm (CO_2 laser), 325 nm (He–Cd laser), and yet other wavelengths. These techniques are versatile and powerful, but rather unsuitable for routine measurements. For single surfaces, PSD can be calculated from such measurements. A standard procedure for ARS measurements is defined in ASTM standard E 1392 and was successfully verified in various round-robin experiments at different wavelengths. Figure 3 shows the photograph of a typical instrumentation.

The main parts of this setup are the illumination system and a double goniometer. The sample holder and the detector are each mounted on a precision goniometer. The detector head is located on the outer goniometer and can be revolved 360 degrees around the sample with an angular resolution of 0.01°. The performance of a scatterometer depends also considerably on the quality of the illumination system. Laser radiation passes several optical elements, such as a spatial filter, diaphragms, polarizers, and mirrors providing the high beam quality necessary for precision measurement.

Total Scattering (TS)

TIS measurements collect the light scattered into the backward hemisphere and are defined as the backscattered radiation divided by the total reflectance. The TIS measurement procedure is prescribed in ASTM standard F 1048 which applies to opaque reflective surfaces. Transparent or semi-transparent samples such as substrates, AR coatings, and beamsplitters cannot be measured without ambiguous additional assumption. The new international standard ISO 13696 defines TS as the backscattered and forward scattered radiation P divided by the incident radiation P_0. TS is hence equivalent to the scattering loss of the component. Opaque as well as transparent surfaces and coatings can be measured both in the backward and forward directions. TS and TIS can, however, be converted into one another, if the reflectance of the sample is known. This standard procedure was proved in an international round-robin experiment at 632.8 nm.

An example of a facility for TS measurements, in a wide range of wavelengths, is given in Figure 4. The apparatus for total backscattering and forward scattering measurements is operated from 193 nm to 10.6 μm by using several lasers. The setup is based on a Coblentz sphere imaging the light scattered into the backward or forward hemisphere within an angular range from 2° to 85° onto the detector unit. This angular range complies with the specification given in ISO 13696.

A special arrangement allows easy change from the backscatter to forward scatter operation modus. The detector unit consists of the detector (photomultiplier in the UV, VIS, NIR, and HgCdTe-element in the IR) and a small integrating sphere. The latter is used for homogeneously illuminating the detector. At all wavelengths, the light beam is modulated by a chopper and passes a beam-cleaning element. The incident radiation hits the sample surface at nearly zero degrees and the specular beam is guided back through the entrance/exit aperture of the Coblentz sphere. While performing the measurement, the sample is scanned across its surface by a positioning system, yielding one- or two-dimensional scattering diagrams. Calibration is performed with a commercial diffusing (Lambertian) standard. Filters are used for attenuating the beam during measurement of high-scatter samples and diffuse reflectance standards. Background levels smaller than 0.1 ppm at 632.8 nm were achieved without the necessity of He-gas flow or operation in vacuum.

Whereas in the past the majority of such facilities were designed for the visible, infrared, and near-ultraviolet spectral regions, the increasing demands for low-scatter optical components in the vacuum ultraviolet (VUV) region for application in photolithography has driven the development of scattering facilities for wavelengths as short as 157 nm. Because of the enhanced technical effort needed for the development of VUV scattering measurement instrumentation, only few setups exist that can be operated at 157 nm.

Applications

Fields of Applications

There exists a diversity of purposes for light-scattering investigations of surfaces and thin films, which requires proper selection of the particular method. For a number of purposes, routine measurements without detailed understanding of the scatter sources can be sufficient, while other problems need deeper insight into the scatter mechanisms and hence, require the combination of measurement with theoretical modeling. It is up to the engineer or scientist to decide in each particular case, to which level the

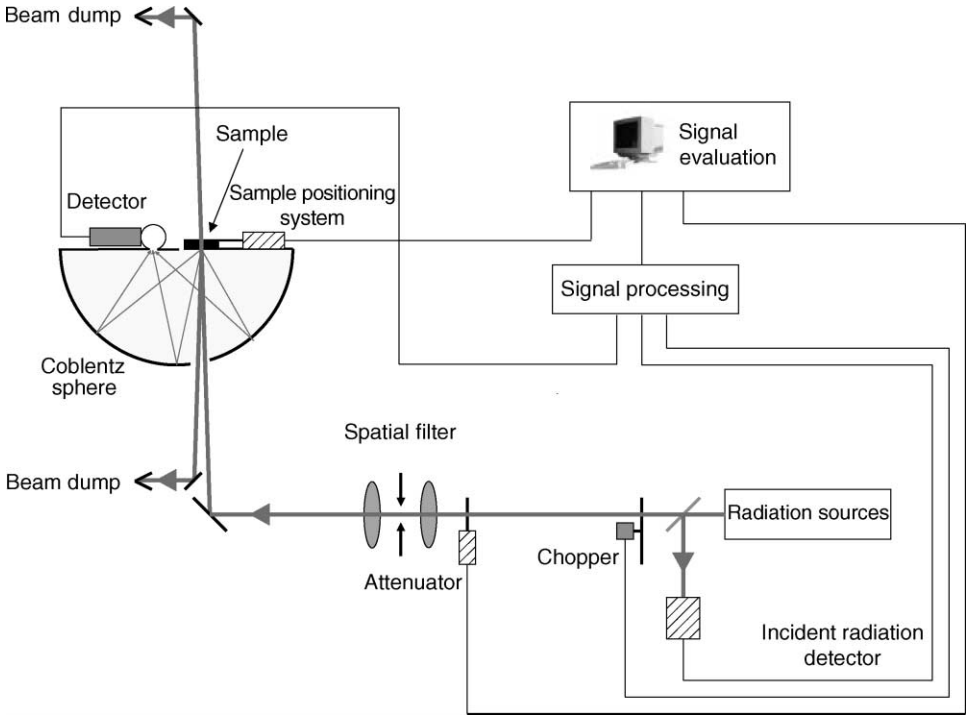

Figure 4 Schematic picture of an instrument for total scattering measurement (courtesy of Fraunhofer Institute for Applied Optics and Precision Engineering, Jena, Germany).

light-scattering study has to be extended. Examples for typical application tasks arising in industry and institutes are:

- determination of total scattering as an optical loss limiting the performance of a thin film component;
- surface finish assessment (roughness, defects) of optical substrates;
- study into the relation between scattering and the morphology and roughness of optical thin films as a precondition for optimizing deposition processes;
- assessment of cleanliness of coated components;
- detection of degradation effects in coatings and substrate materials;
- separation of interface scattering from the film and substrate;
- distinction of volume scattering from interface scattering in substrates and films.

Scattering measurements are noncontact, do not require sample preparation, enable rapid mapping of large sample areas, and are highly sensitive. This makes them usable for a large variety of applications extending from super-smooth substrates with surface roughness below 0.01 nm, thin film structures in the nanometer range, and small and large defect features up to rough engineering surfaces with micron roughness.

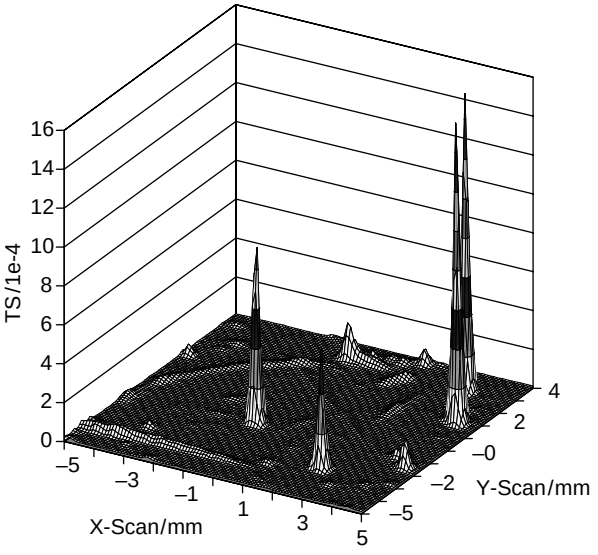

Figure 5 TS measurement (backscattering) on conventionally polished fused silica at 632.8 nm (2D-mapping) for surface quality assessment. Measurement performed with the TS instrument shown in Figure 4.

Examples of Measurements

Surface finish assessment

The result of a scattering measurement (TS, backscattering) at the He–Ne laser wavelength (632.8 nm), on conventionally polished fused silica, is shown in Figure 5. Symmetric defects, as well as

scratch-like features, can be recognized in this diagram. The minimum and averaged rms-roughness determined from the minimum (defect-free) and averaged (including defects) scattering levels are 0.51 and 0.72 nm, respectively.

Scattering from thin film components

Figure 6 shows a TS measurement (backscattering) performed on a polished CaF_2 sample. Half of the area of one surface of this sample was coated with a fluoride multilayer mirror system designed for 248 nm. The area mapping of the TS measurement at 248 nm delivers information of both the bare substrate quality and the increase in scattering after coating. According to the explanations in the first section, this increase has to be interpreted as a result of two influences: the increased reflectance (i.e., changed optical factors) and the roughness growth during deposition of the multilayer (i.e., changed PSD).

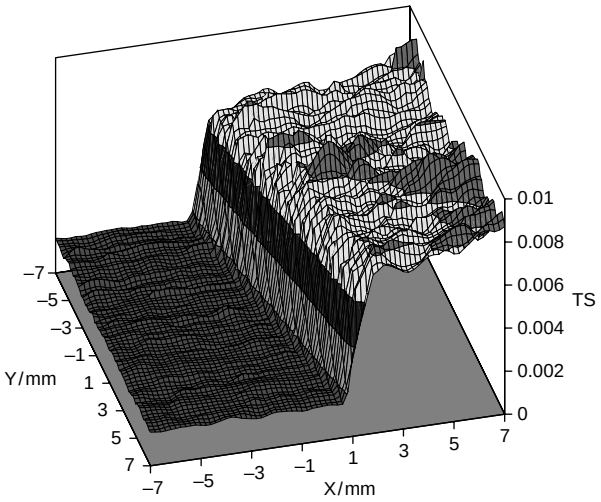

Figure 6 TS measurement (backscattering) at 248 nm on a CaF_2 substrate half of which was coated with a fluoride multilayer mirror system designed for 248 nm. Measurement performed with the TS instrument shown in Figure 4.

On the basis of such measurements, detailed interpretation can be accomplished by additional roughness analysis using scanning force microscopy, subsequent scattering modeling employing the formulas given above, and comparison of the modeled and measured results.

ARS techniques can, for example, be employed to compare the angular distribution of the scattering of a coating to that of the bare substrate. Figure 7 displays ARS measurements in the backward hemisphere at 325 nm (He–Cd laser) on a fused silica substrate before and after deposition (magnetron sputtering) of a Ta_2O_5/SiO_2 quarterwave multilayer mirror (325 nm design wavelength). As with the example discussed above, the higher scatter of the multilayer is caused by both the optical factors and increased roughness. The slight bump at large scatter angles in particular reveals high spatial frequency roughness attributed to the film morphology.

Figure 8 displays TS measurements at 157 nm. The diagram contains one-dimensional scans of forward scattering from an uncoated CaF_2 substrate and an antireflective (AR) coating on CaF_2. The background signal level is also included.

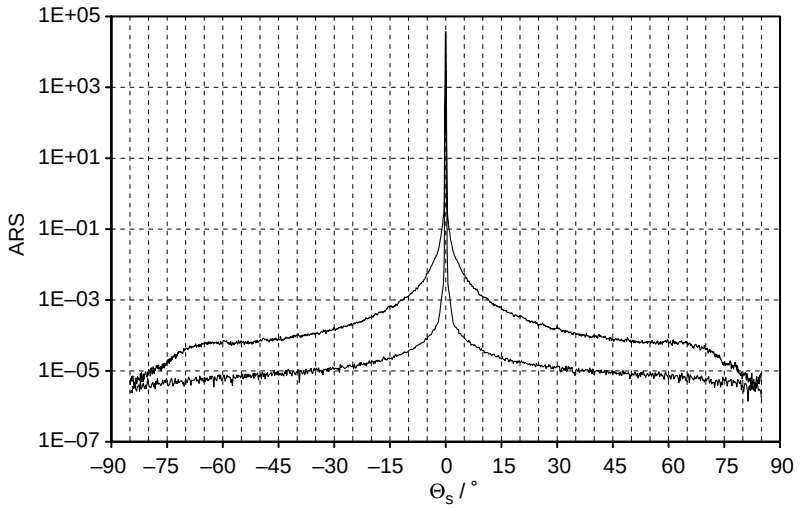

Figure 7 ARS measurement at 325 nm (backward hemisphere) on a fused silica substrate before (lower curve) and after (upper curve) deposition of a Ta_2O_5/SiO_2 quarterwave multilayer mirror with 325 nm design wavelength. Measurements performed with the ARS instrument shown in Figure 3.

Scattering Phenomena in Optical Fibers

P Tchofo-Dinda and G Millot, Université de Bourgogne, Dijon, France

Introduction

Nonlinear phenomena that result from interaction of intense light beams with dielectric media can be broadly divided into two main categories: namely, parametric effects and scattering phenomena. Parametric effects arise whenever the state of the matter is left unchanged by the interaction, whereas scattering phenomena imply transitions between vibrational or rotational energy levels in the medium. The two dominant scattering phenomena in optical fibers are stimulated Raman scattering (SRS) and stimulated Brillouin scattering (SBS), which are nonlinear processes in which a part of the energy propagating at a given frequency is converted into one or several down-shifted Stokes beams, through interaction with the vibrational modes of the materials. Although SBS and SRS phenomena are beneficial for developing all-optical fiber lasers and amplifiers for long-haul fiber transmissions, they are detrimental to transmission of ultrashort light pulses in silica fibers. In this article we describe the fundamental aspects of SBS and SRS.

General Features

Three well-known kinds of scattering phenomena in optical fibers are Rayleigh, Raman and Brillouin scattering. Although these three phenomena manifest themselves in qualitatively different ways, all of them originate fundamentally from the effects of a light wave on the atomic and molecular charges of the dielectric medium. The Raman and Brillouin scattering phenomena involve the vibrational modes of the material that are associated with the optical and acoustic branches of the dispersion curve of the material, respectively. Such vibrational modes, called phonons, are schematically represented in Figure 1 with the help of typical dispersion curves of a one-dimensional atomic lattice.

In standard silica fibers (SiO_2), the phonons associated with the optical branch correspond to intramolecular vibrations, which give rise to the Raman scattering phenomenon, whereas those associated with the acoustic branch correspond to intermolecular vibrations, which are responsible for Brillouin scattering. In either of these two scattering processes, part of the energy of the incoming light, which propagates at a given frequency ω, is converted into downshifted (Stokes) or upshifted (anti-Stokes) light waves, at frequencies $\omega - \Omega$ and $\omega + \Omega$, respectively. The frequency shift Ω is determined by the vibrational modes involved in the scattering process. Figure 2 represents schematically

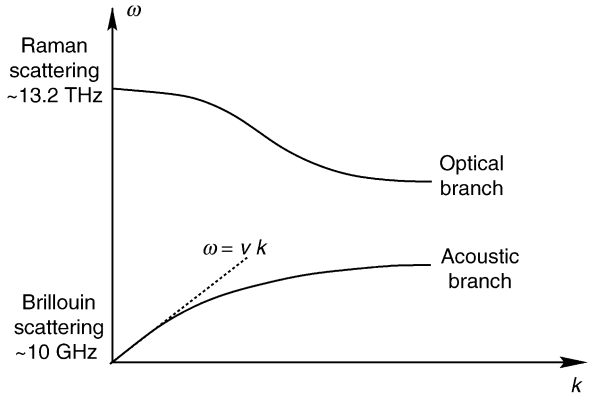

Figure 1 Schematic representation of the dispersion curves for material waves.

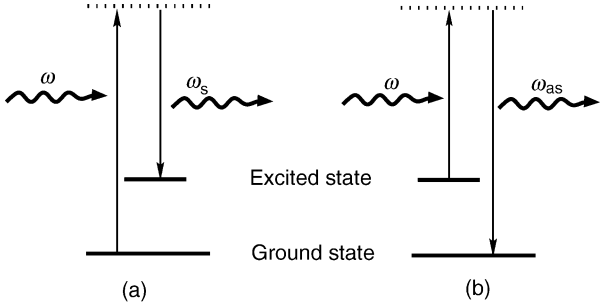

Figure 2 Schematic representation of the diagrams of energy transfer between incoming photons with frequency ω and the material, leading to (a) generation of the Stokes radiation ω_s, and (b) generation of the anti-Stokes radiation ω_{as}.

these energy conversion processes with the help of only two vibrational states, to simplify matters.

As Figure 2a shows, the material, which is initially in the ground state, absorbs a fraction $\hbar\Omega$ of the energy $\hbar\omega$ of incoming photons, to move up to the excited state. As a result, the frequency of the photons involved in this process is downshifted to $\omega_s = \omega - \Omega$. Those photons that are generated at frequency ω_s are commonly called 'Stokes radiation'. On the other hand, when a sufficiently large number of molecules is excited, they can interact with the incoming photons and return back to the ground state. As Figure 2b shows, in this process the energy is transferred from the material to the incoming photons, which thereby generates an upshifted anti-Stokes radiation at frequency $\omega_{as} = \omega + \Omega$. The Raman (Brillouin) frequency shift Ω is of the order of $\Omega_R \approx 13\,\text{THz}$ ($\Omega_B \approx 10\,\text{GHz}$).

In fact, the Raman and Brillouin effects may lead to so-called spontaneous processes, which occur in the limit of low-amplitude for all waves other than the incoming wave. For example, when a laser beam is injected in the fiber with a sufficiently low intensity, one can observe a spontaneous scattering process as schematically represented in Figure 3a.

One can clearly identify in Figure 3a the Raman and Brillouin radiation, as well as radiation scattered at the same frequency as the incoming wave, that is, Rayleigh radiation. Now, when the incoming wave propagates together with light waves whose intensity is no longer negligible with respect to that of the incoming wave, the Raman and Brillouin effects can lead to stimulated processes, in which energy is continually converted from higher to lower frequency photons. As a result, the number of Stokes photons is continually amplified at the expense of anti-Stokes photons, as schematically

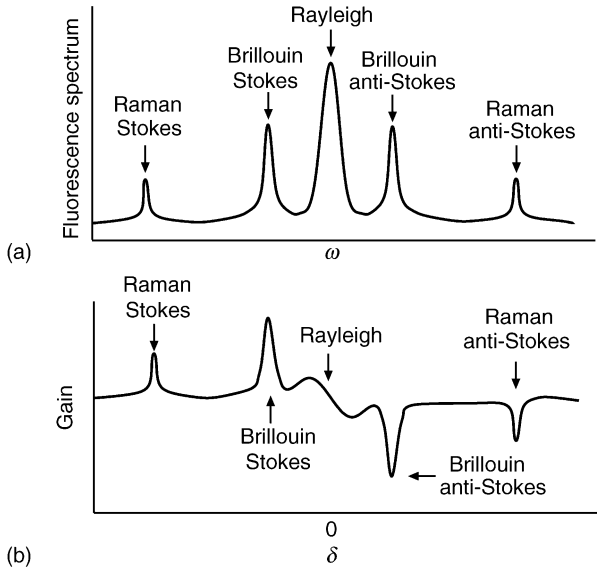

Figure 3 (a) Schematic representation of the frequency spectra for spontaneous and stimulated Raman and Brillouin scattering processes. (a) Fluorescence spectrum; (b) gain spectrum for stimulated Raman and Brillouin scattering processes. A pump and a probe waves are injected together in the fiber. δ is the frequency spacing between the pump and the probe wave.

represented in Figure 3b. The stimulated process can be obtained by either launching the incoming wave ω together with a probe wave at frequency $\omega - \Omega$ (which corresponds to the situation represented in Figure 3b), or by using a sufficiently intense incoming light beam. Indeed, above a certain power threshold (which depends strongly on the fiber length and the amount of dopants in the fiber), for which the gain corresponding to the Stokes amplification compensates for the linear fiber losses, the energy conversion from the incoming wave to the scattered waves can become sufficiently important for the scattering process to become stimulated. This process is commonly referred to as a self-stimulated process, as it does not require the use of a probe wave. Although the SRS and SBS exhibit some common general features as those mentioned above, there exist however some major differences between these two phenomena, from a fundamental point of view as well as for their practical applications to optical communication systems. We discuss separately these specific features for SRS and SBS.

Stimulated Raman Scattering

Under adiabatic following by the electrons of the optical-field-induced nuclear motions, the third-order nonlinear polarization in optical fibers may be

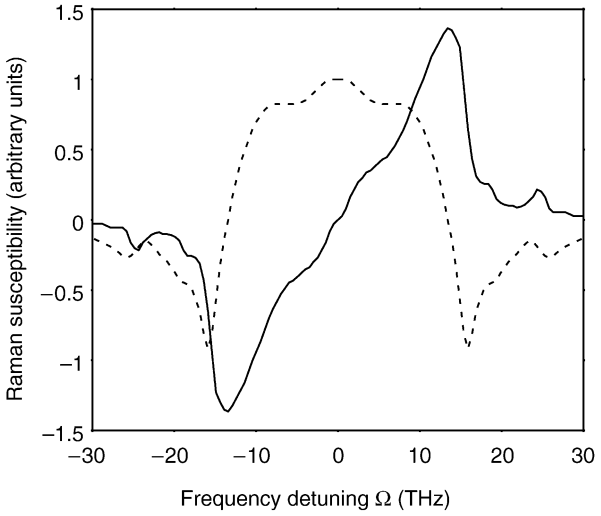

Figure 4 Schematic representation of the Raman susceptibility in an optical fiber. The solid curve represents the imaginary part of the susceptibility, that is, the Raman gain. The dashed curve represents the real part of the susceptibility.

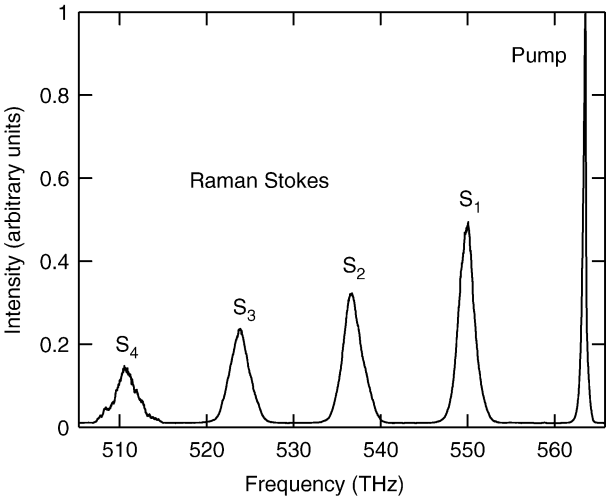

Figure 5 Self-stimulated Raman spectrum (i.e., amplified spontaneous noise), as recorded for a peak pump power $P_0 =$ 150 W and a fiber length $L = 10$ m.

written as

$$P(t) = \sigma|E(t)|^2E(t) + E(t)\int_{-\infty}^{t} \mathrm{d}s\sigma_{\mathrm{R}}(t-s)|E(s)|^2 \quad [1]$$

where σ and σ_{R} represent the instantaneous (Kerr) and noninstantaneous (Raman) parts of the fiber response, respectively. Here, we consider linearly polarized waves, for simplicity. Figure 4 shows schematically the Raman susceptibility of the fused silica, $\chi_{\mathrm{R}}(\Omega) = \sigma_{\mathrm{R}}(\Omega)/2$, which is quite close to that of standard silica fibers.

In Figure 4, the real and imaginary parts of χ_{R} are represented in solid and dashed curves, respectively. The imaginary part of the Raman susceptibility, which corresponds to the Raman gain $G_{\mathrm{R}} = \mathrm{Im}(\chi_{\mathrm{R}})$, is an experimentally measurable quantity. For example, at a pump wavelength $\lambda = 1\mu$m, the maximum value of the Raman gain in standard silica fibers is $\approx 10^{-13}\,\mathrm{mW}^{-1}$. In fact the Raman gain $G_{\mathrm{R}}(\Omega)$ depends on the type and amount of dopants used in the fabrication of the fiber. In contrast to crystalline silica where the Raman gain occurs at a well-defined frequency of 13.2 THz, the Raman gain of silica fibers extends over a large frequency range, as can be seen in Figure 4, with a broad prominent peak around 13.2 THz. In the absence of an input signal the broadband noise is amplified within the Raman Stokes components, which are centered about the frequency detuning of 13.2 THz.

If the power of the Stokes wave becomes large enough, the Stokes wave serves as a pump to generate a second-order Stokes wave. This process of cascade SRS can generate multiple Stokes waves whose number depends on the input pump power and fiber length. Figure 5 displays a typical experimental Raman spectrum generated from a Q-switched, frequency-doubled Nd:YAG laser, emitting 5 ns duration (30 GHz spectral width) pulses at 563.63 THz (532.26 nm). The laser output was injected along one birefringence axis of a 14 m length of polarization-maintaining single-mode fiber. At an estimated injected peak power of 200 W, several higher-order Raman Stokes orders S_j $(j = 1, 4)$ (separated by 13.2 THz) are generated between 510 and 550 THz (588 and 545 nm). The spectral profile of each resulting Stokes line is near-Lorentzian with a full width at half maximum ranging from about 2 THz for the first Stokes to about 3.5 THz for the fourth Stokes. The broadening of the Raman Stokes wave, as the Stokes order increases, is due to several competing nonlinear processes.

This broadband gain is due to the amorphous nature of fused silica, in which the molecular vibrational frequencies spread out into bands which overlap and create a continuum. This outstanding feature has been fully exploited to develop wide-band amplifiers for multichannel optical communications. Recent work demonstrated the achievement of a Raman amplifier with a bandwidth of 100 nm, by use of a set of height pumps and an appropriate choice of the frequency separations between the pumps. Another important application of the Raman gain in optical fibers lies in the development of fiber-Raman lasers, which can be

tuned over a wide frequency range (≈10THz). Such lasers can be obtained by inserting a piece of single-mode fiber inside a Fabry–Perot cavity formed by two partially reflecting mirrors. A rotating output mirror and an intracavity prism allow one to select the Stokes light that provides the laser wavelength. Another example is that the Raman gain can be used to assist non-phase-matched parametric interactions.

A large power-gain enhancement was recently demonstrated for nonphase-matched waves in a three-wave mixing interaction. The Raman-assisted three-wave mixing can be used to achieve wide-bandwidth frequency conversion processes without having to satisfy the strict conditions imposed by phase-matching conditions. The above discussion clearly illustrates some useful effects of the SRS in optical fibers. On the other hand, the SRS may represent a drawback for some optical communication systems, as we discuss below.

Let us consider a pump wave injected in the fiber at frequency ω_0. The total electric field in the fiber may be written as follows:

$$E = \frac{1}{2}\mathcal{A}(z,t)\exp[\mathrm{i}(k_0 z - \omega_0 t)] \qquad [2]$$

where $\mathcal{A}$ is a slowly varying field envelope. By expanding the wavevector k_0 of the electric field in a Taylor series around ω_0, the amplitude $\mathcal{A}$ of the electric field is found to satisfy the generalized nonlinear Schrödinger equation (NLSE):

$$\begin{aligned}&\frac{\partial\mathcal{A}}{\partial z}+\frac{\mathrm{i}}{2}\beta\frac{\partial^2\mathcal{A}}{\partial t^2}\\&=\mathrm{i}\gamma(1-\rho)|\mathcal{A}|^2\mathcal{A}+\mathrm{i}\gamma\rho\mathcal{A}\int_0^\infty \chi_R(s)|\mathcal{A}|^2(t-s)\mathrm{d}s\\&=\mathrm{i}\gamma|\mathcal{A}|^2\mathcal{A}+\mathrm{i}\gamma\rho C_1\mathcal{A}\frac{\partial|\mathcal{A}|^2}{\partial t}+\frac{\mathrm{i}}{2}\gamma\rho C_2\mathcal{A}\frac{\partial^2|\mathcal{A}|^2}{\partial t^2}\\&\quad+\frac{\mathrm{i}}{6}\gamma\rho C_3\mathcal{A}\frac{\partial^3|\mathcal{A}|^2}{\partial t^3}+\cdots\end{aligned} \qquad [3]$$

In eqn [3], $C_1\approx -7.9\times10^{-3}$ ps, $C_2\approx -1.28\times10^{-4}$ ps^2, $C_3\approx 9\times10^{-6}$ ps^3, and the parameter ρ, which measures the fractional contribution of Raman effects to the total nonlinearity, is ≈ 0.18 for standard silica fibers.

When the wave propagation involves only a relatively small frequency range around the pump frequency (less that 1 THz) then only the term proportional to C_1 in eqn [3], i.e., the leading term of the Raman contribution, plays a significant role. Most high-capacity transmission systems using a single channel fall into this situation, as long as picosecond pulses are used. The term proportional to C_1 induces a continuous frequency shift of the pulse frequency, as a result of a small transfer of energy from higher- to lower-frequency waves. This phenomenon, known as the soliton self-frequency shift, constitutes one of the undesirable effects of SRS in optical communications.

On the other hand, when the wave propagation involves a relatively large frequency region (of the order of a few THz), then higher-order terms that are proportional to C_2 and C_3 begin to play a significant role. In particular, the term proportional to C_3 indicates a strong transfer of energy from higher- to lower-frequency waves. In optical communications, this effect causes higher-wavelength channels of wavelength-division multiplexing systems to be amplified while depleting the lower-wavelength channels. This effect can be reduced by using filters and more amplification to compensate for the depletion at lower wavelengths (but this is achieved at the expense of a degradation of the signal-to-noise ratio).

Stimulated Brillouin Scattering

In optical fibers, the SBS occurs at input power levels that are much lower that those needed for SRS, and manifests itself through the generation of a backward-propagating Stokes wave. Although SBS is not (strictly speaking) a parametric process, the generation of the Brillouin Stokes radiation is commonly described as a parametric interaction between the pump wave, the Stokes wave and an acoustic wave (material wave). Indeed, one assumes that the annihilation of a pump photon creates simultaneously a Stokes photon and an acoustic phonon, with the following conservation laws for the energy and the momentum:

$$\Omega_\mathrm{B} = \omega_0 - \omega_\mathrm{s} \qquad [4]$$

$$K_\mathrm{B} = k_0 - k_\mathrm{s} \qquad [5]$$

where ω_0 and ω_s are the frequencies, and k_0 and k_s are the wavevectors of the incoming and Stokes waves, respectively. Then, assuming $|k_\mathrm{s}| \approx |k_0|$, the acoustic wave is found to satisfy the following dispersion relation

$$\Omega_\mathrm{B} = K_\mathrm{B}v = 2v|k_0|\sin(\theta/2) \qquad [6]$$

where v is the phase velocity of the acoustic wave, and θ is the angle between the pump and Stokes wavevectors. As eqn [6] shows, the frequency shift

Ω_B depends on the scattering angle. Ω_B is a maximum for $\theta = \pi$ (i.e., in the backward direction) and vanishes for $\theta = 0$ (forward direction). Thus, although eqn [6] predicts that Brillouin scattering should not occur in the forward direction, spontaneous Brillouin scattering can occur in the forward direction in optical fibers. But this phenomenon is quite negligible. In optical fibers, SBS occurs mainly in the backward direction with a frequency shift given by

$$\nu_B = \Omega_B/(2\pi) = 2v|k_0| = 2n_0 v/\lambda_0 \qquad [7]$$

where n_0 is the refractive index and λ_0 is the pump wavelength (incoming wave). In silica fibers, $v \approx 6\,\mathrm{km\,s^{-1}}$ and $n_0 \approx 1.45$; which leads to $\nu_B \approx 10\,\mathrm{GHz}$ at $\lambda_0 = 1.55\,\mu\mathrm{m}$. Thus, the Brillouin frequency shift is smaller by three orders of magnitude compared with the Raman frequency shift ($\approx$13 THz). The amorphous nature of fused silica leads to a Brillouin-gain coefficient $G_B(\nu)$ which extends over a frequency range of $\approx 10\,\mathrm{MHz}$, with a peak value at $\nu = \nu_B$. The Brillouin gain can be approximated by a Lorentzian profile given by

$$G_B(\nu) = \frac{(\Delta\nu_B/2)^2}{(\nu - \nu_B)^2 + (\Delta\nu_B/2)^2} G_B(\nu_B), \qquad [8]$$

$$G_B(\nu_B) = \frac{2\pi n_0^7 p_{12}^2}{c d_0 \lambda_0^2 v \Delta\nu_B}$$

where $\Delta\nu_B$ is the full width at half maximum, p_{12} is the elasto-optic coefficient and d_0 is the material density.

The Brillouin gain has been exploited to develop fiber-Brillouin lasers. Such lasers are obtained by inserting a piece of fiber inside a (ring or Fabry–Perot) cavity. Another useful application of the Brillouin gain of an optical fiber lies in the amplification of a weak signal. Fiber-Brillouin amplifiers allow one to amplify signals with a frequency shift that corresponds to the Brillouin frequency shift ν_B. Fiber-Brillouin amplifiers can provide up to 40 dB gain at pump powers of a few milliwatts. But the bandwidth of such amplifiers is relatively narrow.

Conclusion

In fact scattering phenomena can be beneficial as well as detrimental for optical communication systems. If signals are transmitted in a communication channel with a power above the threshold of a given scattering phenomenon, this phenomenon will induce a transfer of energy from the signal to the Stokes radiation. The resulting signal depletion would then require more amplification. In multichannel communications, the SBS (SRS) can induce cross-talk between two bidirectional channels if their frequency separation happens to be close to the Brillouin (Raman) shift, $\approx$10 GHz ($\approx$13 THz). However, those undesirable effects can be avoided by in-line control techniques for pulse transmission in fiber-optics communication systems. On the other hand, the Raman and Brillouin effects are useful for generating light at new frequencies as well as for amplifying weak light signals. In particular Raman amplifiers are one of the key devices for high-speed telecommunication systems.

Scattering Theory

Y A Eremin, Moscow State University, Moscow, Russia

© 2005 Published by Elsevier Ltd.

Lord Rayleigh (John William Strutt) (1842–1916)

In the nineteenth century, Lord Rayleigh offered the first explanation for the sky's blue color (on a clear day!). From Rayleigh's initial theory, representing a simplification of Maxwell's electromagnetic theory for the case of particles very small compared to the wavelength of the incident light, the theory was extended to describe the scattering of light by larger macromolecules in solution.

Scattering theory has played a central role in twentieth-century mathematical physics. From Rayleigh's explanation of why the sky is blue to modern medical application of computerized tomography, has attracted both scientists and mathematicians for over a hundred years. Scattering theory is concerned with the effect an inhomogeneous medium has on an incident wave. In particular, if the total field is viewed as sum of an incident field and a scattered field, then the direct scattering problem is to determine the scattered field from a knowledge of the incident one, obstacle properties, and the equations governing the wave motion. In contrast, the inverse scattering problem consists of reconstruction of the inhomogeneity from the knowledge of asymptotic behavior of the scattered field. An everyday example is human vision: from the measurements of scattered light that reaches our retinas, our brain reconstructs a detailed three-dimensional map of the world around us. In summary, the task of direct scattering theory is to determine the relation between the incident and scattered waves. The task of inverse scattering theory is to determine properties of the obstacle.

Light propagating can be described in terms of an electromagnetic field, which is composed of two related vector fields, the electric and the magnetic fields. This means that the vectors of electric ($\mathbf{E}$) and magnetic ($\mathbf{H}$) field have values defined at each point in space and time. The vector fields $\mathbf{E}$ and $\mathbf{H}$ interact through the material parameters: electric permittivity ε and magnetic permeability μ. The behavior of electromagnetic fields can be described by Maxwell's equations.

Maxwell Equations. James Clerk Maxwell (1831–1879)

Consider the electromagnetic wave (light) propagation in a homogeneous, isotropic medium with electric permittivity $\varepsilon > 0$, electric conductivity $\sigma \geq 0$, and magnetic permeability $\mu > 0$, containing a local obstacle. We assume that $\sigma = 0$ outside an obstacle. If J is a current density, the electric field $\vec{E}(x,t)$ and magnetic field $\vec{H}(x,t)$ satisfy the Maxwell equations:

$$\begin{aligned} \nabla \times \vec{E}(x,t) + \mu \frac{\partial \vec{H}}{\partial t}(x,t) &= 0 \\ \nabla \times \vec{H}(x,t) - \varepsilon \frac{\partial \vec{E}}{\partial t}(x,t) &= \vec{J}(x,t) \end{aligned} \qquad [1]$$

Also, in an isotropic conductor, the electric field satisfies Ohm's law:

$$\sigma \vec{E}(x,t) = \vec{J}(x,t) \qquad [2]$$

The speed of wave propagation for the electric and magnetic fields is $c = 1/\sqrt{\varepsilon\mu}$ and in free space $c = 1/\sqrt{\varepsilon_0\mu_0} = 2.99792458 \times 10^8$ m s^{-1}. Assume that the electromagnetic field is time-harmonic, i.e., of the form:

$$\begin{aligned} \vec{E}(x,t) &= \frac{1}{\sqrt{\varepsilon_0}} \mathbf{E}(x) \mathrm{e}^{-\mathrm{j}\omega t} \\ \vec{H}(x,t) &= \frac{1}{\sqrt{\mu_0}} \mathbf{H}(x) \mathrm{e}^{-\mathrm{j}\omega t} \end{aligned} \qquad [3]$$

where $\omega > 0$ is the frequency. Many phenomenon of light scattering can be described based on monochromatic wave propagation. Let us consider a local obstacle occupying a bounded domain D. Inside the obstacle we introduce relative complex permittivity:

$$\varepsilon = \frac{1}{\varepsilon_0}\left(\varepsilon + \mathrm{j}\frac{\sigma}{\omega}\right) \qquad [4]$$

Then $\mathbf{E}(x)$ and $\mathbf{H}(x)$ obey the time-harmonic Maxwell equations:

$$\nabla \times \mathbf{E}(x) = \mathrm{j}k\mathbf{H}(x), \quad \nabla \times \mathbf{H}(x) = -\mathrm{j}k\varepsilon\mathbf{E}(x) \qquad [5]$$

where $k^2 = \varepsilon_0\mu_0\omega^2$.

Helmholtz Equation. Herman Ludwig von Helmholtz (1821–1894)

A wave equation for vector $\mathbf{E}$ can be readily derived from the Maxwell equations. We obtain:

$$(\nabla^2 + k^2)\mathbf{E}(x) = 0 \qquad [6]$$

This is known as the homogeneous Helmholtz equation. A general planewave solution of the equation can be written as

$$\mathbf{E}(x) = \mathbf{E}_0 \, \mathrm{e}^{\mathrm{j}\vec{k}\cdot\vec{x}} \qquad [7]$$

here $\mathbf{E}_0$ is a constant vector independent of spatial coordinates and $\vec{k}\cdot\vec{x}$ is a scalar product of the vectors $\vec{x} = \{x_1, x_2, x_3\}$ and $\vec{k} = \{k_1, k_2, k_3\}$, the so called wavevector. Equations [6] and [7] yield the dispersion relation:

$$k^2 = \varepsilon_0 \mu_0 \omega^2 = k_1^2 + k_2^2 + k_3^2 \qquad [8]$$

For a given $\vec{k}$ vector, a constant phase front is determined by $\vec{k}\cdot\vec{x} = \text{const}$, which indicates that the front is perpendicular to the wavevector. So, the phase front is a plane and the amplitude of the electric field on the plane is a constant.

The Maxwell equations for the plane wave solution become:

$$\begin{aligned} &\vec{k}\times\mathbf{E}(x) = k\mathbf{H}(x), \quad \vec{k}\times\mathbf{H}(x) = -k\mathbf{E}(x) \\ &\Rightarrow \vec{k}\cdot\mathbf{E} = 0, \quad \vec{k}\cdot\mathbf{H} = 0 \end{aligned} \qquad [9]$$

Therefore, vectors $\mathbf{E}$ and $\mathbf{H}$ belong to the constant phase plane perpendicular to vector $\vec{k}$ and are orthogonal each other.

Poynting's Vector. John Henry Poynting (1852–1914)

For time-dependent fields, the Poynting vector is introduced as

$$\vec{S}(x,t) = \vec{E}(x,t)\times\vec{H}(x,t) \qquad [10]$$

It is interpreted as the power flow density with the dimension of watts/m^2. The time-average Poynting's vector power density is given by

$$\langle S\rangle = \frac{1}{T}\int_0^T \vec{S}(x,t)\mathrm{d}t \qquad [11]$$

For the time-dependent planewave fields:

$$\begin{aligned} \vec{E}(x,t) &= \mathbf{E}_0 \cos(\vec{k}\cdot\vec{x} - \omega t) \\ \vec{H}(x,t) &= \mathbf{H}_0 \cos(\vec{k}\cdot\vec{x} - \omega t) \end{aligned} \qquad [12]$$

The vector Poynting's power density shown in eqn [10], accepts the form:

$$\vec{S}(x,t) = |\mathbf{E}_0|^2 \cos^2(\vec{k}\cdot\vec{x} - \omega t) \qquad [13]$$

The time-average vector power density gives

$$\langle\vec{S}(x,t)\rangle = \frac{1}{2}|\mathbf{E}_0|^2 \qquad [14]$$

which shows that Poynting's power density is also propagating in the direction of the wave vector $\vec{k}$.

Boundary Conditions

Let us consider a bound obstacle D_i with a smooth closed surface S. The Maxwell eqn [5] has been written in differential form. It must be supplemented with boundary conditions enforced at the obstacle surface. The boundary conditions can be derived from the integral form of Maxwell equations. The field vectors $\mathbf{E}$, $\mathbf{H}$ are assumed to be finite but may be discontinuous across the obstacle surface S. In cases where there is no surface current density (which is so for a perfect conductor) the boundary conditions accept the following form:

$$\vec{n}\times(\mathbf{E}_\mathrm{i} - \mathbf{E}_\mathrm{e}) = 0, \quad \vec{n}\times(\mathbf{H}_\mathrm{i} - \mathbf{H}_\mathrm{e}) = 0 \qquad [15]$$

where subscripts i and e correspond to the total fields inside and outside the obstacle, respectively, and $\vec{n}$ is unit outward normal to S. Essentially the boundary conditions state that tangential components for electromagnetic fields are continuous across the boundary.

Silver–Müller Radiation Conditions

Analysis of a direct scattering problem on a local obstacle involves Maxwell eqn [10] and boundary conditions as in eqn [15] and some infinity conditions, which provide the uniqueness of the scattering problem solutions. Let us assume that a local obstacle is excited by an incident electromagnetic field $\{\mathbf{E}_0, \mathbf{H}_0\}$, given as entire solution to the Maxwell equations. Total field outside the obstacle can be represented as

$$\mathbf{E}_\mathrm{e} = \mathbf{E}_0 + \mathbf{E}_\mathrm{s}, \quad \mathbf{H}_\mathrm{e} = \mathbf{H}_0 + \mathbf{H}_\mathrm{s} \qquad [16]$$

where scattered field $\{\mathbf{E}_\mathrm{s}, \mathbf{H}_\mathrm{s}\}$ in the exterior domain $D_\mathrm{e} = \mathbb{R}^3/\bar{D}_\mathrm{i}$ satisfies the Silver–Müller radiation conditions:

$$\begin{aligned} &\frac{x}{|x|}\times\mathbf{H}_\mathrm{s} + \mathbf{E}_\mathrm{s} = \mathrm{o}\left(\frac{1}{|x|}\right) \\ &\frac{x}{|x|}\times\mathbf{E}_\mathrm{s} - \mathbf{H}_\mathrm{s} = \mathrm{o}\left(\frac{1}{|x|}\right) \end{aligned} \qquad |x|\to\infty \qquad [17]$$

uniformly for all directions $x/|x|$.

Scattering Amplitude

The following result is valid: every radiating solution $\{\mathbf{E}_s, \mathbf{H}_s\}$ to the Maxwell equations has the following asymptotic form:

$$\mathbf{E}_s(x) = \frac{e^{ik|x|}}{|x|}\left\{\mathbf{E}_\infty(\boldsymbol{\varpi}) + O\left(\frac{1}{|x|^2}\right)\right\}$$
$$\mathbf{H}_s(x) = \frac{e^{ik|x|}}{|x|}\left\{\mathbf{H}_\infty(\boldsymbol{\varpi}) + O\left(\frac{1}{|x|^2}\right)\right\} \qquad |x| \to \infty \qquad [18]$$

where the vector functions $\mathbf{E}_\infty$ and $\mathbf{H}_\infty$ defined on the unit sphere $\boldsymbol{\varpi} \in \Omega = \{0 \le \vartheta \le \pi; 0 \le \varphi \le 2\pi\}$ are known as the electric far field pattern (scattering amplitude) and magnetic far field pattern, respectively. They satisfy:

$$\mathbf{H}_\infty = \vec{\nu} \times \mathbf{E}_\infty, \quad \vec{\nu} \cdot \mathbf{E}_\infty = \vec{\nu} \cdot \mathbf{H}_\infty = 0 \qquad [19]$$

with the unit outward normal $\vec{\nu}$ on Ω. The latter means that $\mathbf{E}_\infty$ and $\mathbf{H}_\infty$ have only tangential components at the unit sphere.

Far field pattern represents real value analytic functions on a unit sphere. Reillich's lemma establishes one-to-one correspondence between radiating electromagnetic field and their far field pattern. It means that there exists only one scattered field $\{\mathbf{E}_s, \mathbf{H}_s\}$ corresponding to a given far field pattern $\mathbf{E}_\infty$.

Reciprocity Relations

Examine the set of far field pattern corresponding to the scattering problem including: Maxwell eqn [5], boundary conditions in eqn [15], and radiation conditions in eqn [17] at the infinity for the scattered fields. Let the incident electromagnetic field is given by the planewave:

$$\mathbf{E}_0(x) = \vec{e}_0\, e^{ik\vec{x}\cdot\vec{\kappa}}, \quad \mathbf{H}_0(x) = \vec{\kappa} \times \vec{e}_0\, e^{ik\vec{x}\cdot\vec{\kappa}} \qquad [20]$$

where $\vec{\kappa} \in \Omega$ is a unit vector giving the propagation direction and $\vec{e}_0 \in \mathbb{R}^3$ is a constant vector responsible for the polarization. From the previous consideration one can see that:

$$\mathbf{E}_s(x; \vec{\kappa}, \vec{e}_0) = \frac{e^{ik|x|}}{|x|}\left\{\mathbf{E}_\infty(\boldsymbol{\varpi}\vec{\kappa}, \vec{e}_0) + O\left(\frac{1}{|x|^2}\right)\right\}, \quad |x| \to \infty \qquad [21]$$

Furthermore, the following reciprocity relation for the scattering amplitude holds:

$$\vec{h}_0 \cdot \mathbf{E}_\infty(\boldsymbol{\varpi}; \vec{\kappa}, \vec{e}_0) = \vec{e}_0 \cdot \mathbf{E}_\infty(-\vec{\kappa}; -\boldsymbol{\varpi}, \vec{h}_0)$$

for all vectors $\boldsymbol{\varpi}, \vec{\kappa} \in \Omega$ and $\forall \vec{e}_0, \vec{h}_0 \in \mathbb{R}^3$.

Optical Theorem

Far field pattern enables us to evaluate scattering cross section, which is defined as

$$\sigma_s = \int_\Omega |\mathbf{E}_\infty(\boldsymbol{\varpi})|^2 d\boldsymbol{\varpi} \qquad [22]$$

For the planewave given by eqn [20] and excitation of nonabsorbing obstacle ($\sigma = 0$), the following relation holds:

$$\sigma_s = \frac{4\pi}{k} \mathrm{Im}\{\mathbf{E}_\infty(\vec{\kappa}) \cdot \vec{e}_0\} \qquad [23]$$

This is so-called optical theorem.

Huygen's Principle (Green's Theorem). Christian Huygens (1629–1695)

The Huygens' principle shows that a wavefield on the surface determines the wavefield off the surface. Let us introduce the scalar Green's function which satisfies the Helmholtz equation:

$$(\nabla^2 + k^2) g(x, y) = -\delta(x - y) \qquad [24]$$

where $\delta(x - y)$ is the Dirac delta function. For three-dimensional problems, the scalar Green's function $g(x, y)$ for isotropic media accepts the form:

$$g(x, y) = \frac{e^{jk|x-y|}}{4\pi|x - y|} \qquad [25]$$

Let electromagnetic fields $\{\mathbf{E}_s, \mathbf{H}_s\}$ be a radiating solution to the Maxwell eqn [5] in D_e. Then for any $x \in D_e$ we have the Stratton–Chu formulas:

$$\mathbf{E}_s(x) = \nabla \times \int_S g(x, y) \vec{\nu}_y \times \mathbf{E}_s(y) ds_y + \frac{j}{k} \nabla \times \nabla \times \int_S g(x, y) \vec{\nu}_y \times \mathbf{H}_s(y) ds_y$$
$$\mathbf{H}_s(x) = \nabla \times \int_S g(x, y) \vec{\nu}_y \times \mathbf{H}_s(y) ds_y - \frac{j}{k} \nabla \times \nabla \times \int_S g(x, y) \vec{\nu}_y \times \mathbf{E}_s(y) ds_y \qquad [26]$$

here S is a smooth closed surface, and $\vec{\nu}$ is the unit normal vector to S directed into D_e. Similar relations are valid for an electromagnetic field inside a bounded domain D_i. The Stratton–Chu

formulas are extensively employed to construct boundary integral equations for scattering problems investigating.

Homogeneous Obstacle

Consider a mathematical statement of the scattering problem by a bound homogeneous obstacle. Let external excitation be a planewave $\{\mathbf{E}_0, \mathbf{H}_0\}$: (eqn [20]). In this case the boundary-value scattering problem can be formulated in the form:

$$\begin{aligned} &\nabla \times \mathbf{E}_\tau(x) = \mathrm{j}k\mathbf{H}_\tau(x), \quad \nabla \times \mathbf{H}_\tau(x) = -\mathrm{j}k\varepsilon_\tau \mathbf{E}_\tau(x), \\ &\quad x \in D_\tau, \tau = \mathrm{i}, \mathrm{e} \\ &\qquad \vec{\nu} \times (\mathbf{E}_\mathrm{i} + \mathbf{E}_\mathrm{e}) = \vec{\nu} \times \mathbf{E}_0, \\ &\qquad \vec{\nu} \times (\mathbf{H}_\mathrm{i} + \mathbf{H}_\mathrm{e}) = \vec{\nu} \times \mathbf{H}_0 \ \text{ on } \ S \\ &\qquad \frac{x}{|x|} \times \mathbf{H}_\mathrm{e} + \mathbf{E}_\mathrm{e} = \mathrm{o}\left(\frac{1}{|x|}\right), \quad |x| \to \infty \end{aligned} \qquad [27]$$

where $\varepsilon_\mathrm{e} = 1$, $\varepsilon_\mathrm{i} = \varepsilon$ and $\{\mathbf{E}_\mathrm{e}, \mathbf{H}_\mathrm{e}\}$ corresponds to scattered field. For a smooth surface and the case $\mathrm{Im}\,\varepsilon \geq 0$, the problem has a unique solution.

Lippman–Swinger Integral Equation

Assume we deal with the local inhomogeneous obstacle that can be described by dielectric permittivity $\varepsilon(x)$, which is a continuous complex-valued ($\mathrm{Im}\,\varepsilon(x) \geq 0$) function in D_i. The correspondent scattering problem can be formulated as below in eqn [29]. In this case, the boundary-value scattering problem can be reduced to the solution of the Lippman–Swinger integral equation

$$\begin{aligned} \mathbf{E}_\mathrm{i}(x) = \ &\mathbf{E}_0(x) + \nabla \times \nabla \times \int_{D_\mathrm{i}} g(x, y) k^2 (\varepsilon(y) - 1) \\ &\times \mathbf{E}_\mathrm{i}(y) \mathrm{d}\nu_y, \quad x \in D_\mathrm{i} \end{aligned} \qquad [28]$$

Volume integral eqn [28] is equivalent to the corresponding scattering problem. Once the solution is found, the associated scattered field outside the inhomogeneous obstacle can be represented as

$$\begin{aligned} \mathbf{E}_\mathrm{s}(x) = \ &\nabla \times \nabla \times \int_{D_\mathrm{i}} g(x, y) k^2 (\varepsilon(y) - 1) \\ &\times \mathbf{E}_\mathrm{i}(y) \mathrm{d}\nu_y, \quad x \in D_\mathrm{e} \end{aligned} \qquad [29]$$

The Lippman–Swinger integral equation plays an important role under analysis of a wave scattering by local inhomogeneous obstacle.

Born Approximation

In the case where $k^2 |\varepsilon(x) - 1| mes D_\mathrm{i} \ll 1$, or where the second term on the right-hand part of the Lippman–Swinger integral eqn [28] is small compared to the first term, one can write $\mathbf{E}_\mathrm{i}(x) \simeq \mathbf{E}_0(x)$. Then the scattered field can be approximately evaluated as

$$\begin{aligned} \mathbf{E}_\mathrm{s}(x) = \ &\nabla \times \nabla \times \int_{D_\mathrm{i}} g(x, y) k^2 (\varepsilon(y) - 1) \\ &\times \mathbf{E}_0(y) \mathrm{d}\nu_y, \quad x \in D_\mathrm{e} \end{aligned} \qquad [30]$$

The above representation for the scattered field is known as the first-order Born approximation. It is also the first-order approximation in the Neumann series for the integral eqn [28]. The Born approximation plays an important role in diffraction tomography.

Rayleigh Scattering

Rayleigh scattering characterizes the scattering of electromagnetic waves by particles much smaller then an exciting wavelength. Consider a spherical particle with constant permittivity ε and radius a deposited at the origin of a coordinate system. Let linear polarized planewave be incident upon the particle $\mathbf{E}_0(x) = \vec{e}_x e^{\mathrm{j}kz}$, and $\vec{e}_x$ be unit vector Cartesian coordinate system. It is polarized in x-direction and propagates along z-axis. In this case, for the scattered intensity, we get:

$$I_\mathrm{s} = \left(\frac{\varepsilon - 1}{\varepsilon + 2}\right)^2 \frac{k^4 a^6}{r^2} \sin^2 \vartheta \qquad [31]$$

where r is distance from the origin and $\vartheta \in [0, \pi]$.

Corresponding scattering cross-section is calculated as

$$\sigma_\mathrm{s} = \frac{8\pi}{3}\left(\frac{\varepsilon - 1}{\varepsilon + 2}\right)^2 k^4 a^6 \qquad [32]$$

Thus the total scattered power is proportional to the fourth power of the wave number (minus fourth power of the wavelength – Rayleigh's Law). The scattered power is also proportional to the sixth power of the radius.

Mie Scattering

The Mie theory is a complete mathematical–physical theory of the scattering of electromagnetic wave by homogeneous spherical particles, developed by Gustav Mie in 1908. In contrast to Rayleigh scattering, the Mie theory embraces all possible ratios of the particle radius to wavelength. It relays

upon the exact solution to Maxwell equation for spherical homogeneous obstacle with planewave excitation. In the frame of Mie theory, the scattered field is represented as an infinite series of fields of spherical multipoles, which are orthogonal at a sphere surface. Mie solution plays an important role in light scattering by clouds of particles.

Stimulated Scattering

M Bashkansky and J Reintjes, Naval Research Laboratory, Washington, DC, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Scattering of light involves conversion of an incoming light wave in one mode to an outgoing wave in a different mode. Scattering can involve changes of wavelength, direction, and polarization, and can occur in all types of materials. Without scattering we would not be able to see objects in the world around us. Scattering processes involving particular physical interactions are often given distinctive names. Familiar examples include Rayleigh scattering from the random distribution of air molecules, which makes the sky blue, and Tyndall scattering from small suspended particles, which makes the sunset red. Other types of scattering, e.g., Raman, Brillouin and Rayleigh-wing scattering, are important spectroscopic tools that provide insight into atomic and molecular properties. In their most commonly encountered form, where the intensity of the scattered light is proportional to the intensity of the incident light, the scattering processes are termed spontaneous. With the intense radiation provided by lasers, however, the intensity of the scattered light can grow exponentially, and the processes are termed stimulated scattering.

Stimulated scattering is a subset of the larger discipline of nonlinear optics. The term was first used to describe nonlinear optical interactions (e.g., Raman, Brillouin, Rayleigh) in which the intensity of the scattered light grows exponentially, in a manner similar to the exponential growth of light intensity associated with lasers. These interactions involve exchange of energy with a second mode that is an internal mode of the scattering medium, and the scattered light wave is at a different wavelength from the incoming light. The use of the term stimulated has subsequently been expanded to include a wider class of nonlinear optical interactions, such as parametric fluorescence or certain aspects of self-focusing, in which the second mode is itself a light wave, with either a different frequency or direction of propagation.

In the wider sense, scattering of light occurs through interaction of the incoming light wave with an 'idler' mode in a material. Stimulated scattering occurs when the idler mode is itself driven by interference of the incoming and scattered light waves. Under these circumstances, exponential growth of the scattered wave results. Depending on the interaction, the idler mode may be an internal mode of the material or another light wave. Most linear scattering processes have stimulated counterparts. However, there are stimulated scattering interactions that have no spontaneous analogs.

The elements of stimulated light scattering can be summarized mathematically as follows. The scattering process is modeled as an incoming laser or pump, an outgoing scattered wave and an idler mode. The interaction of the laser with the idler mode to produce the scattered light wave is described by the equation

$$\frac{\partial}{\partial z}A_{\mathrm{S}}(z,t)+\frac{n}{c}\frac{\partial}{\partial t}A_{\mathrm{S}}(z,t)=\kappa A_{\mathrm{L}}b^{*} \qquad [1]$$

where A_{S} and A_{L} are the slowly varying amplitudes of the scattered and laser light waves whose electric fields are defined as

$$E_{\mathrm{S(L)}}=\frac{1}{2}\left\{A_{\mathrm{S(L)}}\mathrm{e}^{\mathrm{i}[\omega_{\mathrm{S(L)}}t-k_{\mathrm{S(L)}}z]}+\mathrm{cc}\right\} \qquad [2]$$

$\omega_{S(L)}$ is the frequency of the scattered (laser) light, $k_{S(L)}$ is the corresponding wavevector, κ is a coupling coefficient, cc denotes complex conjugate, and b is the amplitude of the idler mode given by

$$B = \frac{1}{2}\left\{b e^{i[\omega_b t - k_b z]} + \text{cc}\right\} \quad [3]$$

The interaction of the laser and scattered wave to drive the idler mode is described by the equation

$$\mathcal{L}(b^*) = \kappa' A_L^* A_S \quad [4]$$

where $\mathcal{L}$ is a differential operator that describes the dynamics of the idler mode, e.g., a damped oscillator or a propagating wave, and κ' is a second coupling coefficient. For the class of stimulated processes that involve excitation of an internal mode of the medium, $\mathcal{L}$ has the form

$$\mathcal{L} = \frac{\partial}{\partial t} + \frac{1}{T_2} - v\frac{\partial}{\partial z} \quad [5]$$

where T_2 is the damping time of the coherence of the internal mode. When interaction times are long compared to internal response and decay times,

$$b^* \sim \kappa' A_L^* A_S$$

and the scattered wave obeys an equation of the form

$$\frac{\partial}{\partial z} A_S(z,t) = \frac{g}{2}|A_L|^2 A_S(z,t)$$

which has an exponential-gain solution for the scattered wave intensity:

$$I_S(z,t) = I_S(0,t)e^{I_L g z}$$

When the idler mode is a light wave, as in stimulated parametric fluorescence, [4] has the same form as [1] and they can be solved as a coupled pair, leading to transcendental or hyperbolic solutions. Within the framework of nonlinear optics, interactions of these types can be expressed as arising from a nonlinear optical polarization, which forms the right-hand side of [1]. The dynamics of the nonlinear polarization are then described by [4].

Stimulated processes are often associated with pumping thresholds. When these processes are configured with cavity resonators, they possess a threshold in pumping intensity just as with lasers or other oscillators. When they are operated in single or multipass scattering cells, they have no true threshold. However, they still have a practical useful threshold when the growth from quantum noise raises the scattered signal to a level comparable to the pump. By convention, this is taken to be the incident light intensity at which the scattered intensity reaches approximately 1% of the pump intensity, typically involving gains of the order of e^{23}–e^{30}. At this level, a small increase in pump intensity raises the scattered intensity to levels at which the pump starts to be depleted.

Attenuation of the scattered light can be accounted for by replacing $I_L g$ in the above expression by $I_L g - \alpha$, where α is the attenuation coefficient. Exponential gain is now experienced when the pump intensity exceeds the level given by

$$I_L > \frac{\alpha}{g}$$

This value can serve as an estimate of threshold pumping in cavity configurations, although in free propagation situations, net gain must still approach e^{23} to exhibit threshold behavior.

A list of stimulated scattering interactions is given in Table 1.

Stimulated Raman Scattering

Stimulated Raman scattering (SRS) involves conversion of an incoming light wave at one frequency, termed the laser or pump wave, into a scattered wave of different frequency, along with excitation or de-excitation of an internal mode of the medium. The frequency difference between the pump and scattered waves is equal to the frequency of the material mode and is characteristic of the material. When the frequency of the scattered wave is lower than that of the incident wave, the scattered wave is termed a Stokes wave, and the internal mode of the medium is excited in the scattering process. When the frequency of the scattered wave is higher than that of the incident wave, the scattered wave is termed an anti-Stokes wave, and the internal mode of the medium is de-excited in the scattering process.

The internal mode of the medium that is involved in Raman scattering is a nonpropagating collective mode. Many different types of internal modes in all types of materials can be involved in Raman scattering. Examples include molecular vibrations and rotations in gases, liquids, or solids, electronic states that are of the same parity as the ground state in gases or solids, optical phonons or polaritons in solids, and Langmuir waves in plasmas. Raman frequency shifts can range from tens of wavenumbers for lattice vibrations to tens of thousands of wavenumbers for electronic transitions.

Spontaneous Raman scattering was first described theoretically by Smekal in 1923 from a quantum mechanical study of light scattering, and was

Table 1 List of stimulated scattering interactions

Stimulated scattering process	*Internal material mode*	*Light mode change*
Stimulated Raman scattering	Nonpropagating internal energy mode: molecular vibrations and rotations, same parity electronic states, optical phonons and Langmuir waves	Change in wavelength, polarization, direction
Stimulated Brillouin scattering	Propagating sound waves	Change in wavelength, polarization, and direction
Stimulated Rayleigh scattering	Temperature and density fluctuations due to light absorption	Change in direction
Stimulated Rayleigh wing scattering	Molecular distribution and orientation fluctuations	Change in wavelength and direction
Stimulated concentration scattering	Fluctuations of concentration in gas mixtures	Change in direction
Photorefractive stimulated scattering	Diffusion of photo-excited carriers	Change in direction
Stimulated Thomson/Compton scattering	Momentum changes in bunched free electrons	Change in wavelength and direction
Stimulated parametric fluorescence	Nonresonant nonlinear polarization	Change in wavelength and direction
Self-focusing	Nonresonant nonlinear polarization	Change in direction

demonstrated experimentally by Raman, and shortly after by Landsberg and Mandelstamm in 1928. Stimulated Raman scattering was first observed in 1962 by Woodbury and Ng, and Eckhardt *et al.* soon after the development of pulsed lasers.

Stimulated Raman scattering can be observed in many different configurations including cavity resonators, single or multiple-pass generator cells or amplifiers. It can be observed as forward scattering, with the scattered light propagating in the same direction as the pump light, or backward scattering, with the scattered light propagating in the opposite direction to the pump light. Its most widespread use is for generation of coherent light at frequencies different from the pump light. Other applications include phase conjugation, optical gating, beam cleanup, and pulse compression.

The equations describing SRS when depletion of the pump light and diffraction of the optical beams are neglected are:

$$2ik_{\mathrm{S}}\left(\frac{\partial A_{\mathrm{S}}}{\partial z}\pm\frac{1}{v_{\mathrm{gS}}}\frac{\partial A_{\mathrm{S}}}{\partial t}\right)=-\frac{N}{2}\frac{\omega_{\mathrm{S}}^2}{c^2}\left(\frac{\partial\alpha}{\partial Q}\right)_{\mathrm{S}}Q^*A_{\mathrm{L}} \quad [6]$$

$$\frac{\partial Q^*}{\partial t}+\Gamma Q^*=-\frac{\mathrm{i}}{4\omega_{\mathrm{o}}m}\left(\frac{\partial\alpha}{\partial Q}\right)_{\mathrm{S}}A_{\mathrm{L}}^*A_{\mathrm{S}} \quad [7]$$

Here A_{S} and A_{L} are the slowly varying optical field amplitudes of the Stokes and laser waves as given in [2], $\omega_{\mathrm{S(L)}}$ are the optical frequencies, $k_{\mathrm{S(L)}}$ are the corresponding k vectors, $v_{\mathrm{S(L)}}$ are the group velocities, and Q is the amplitude of the idler mode, in this case the normal mode coordinate of the material excitation, defined by:

$$\mathbf{Q}(x,y,z,t)=\frac{1}{2}(Q(x,y,z,t)\mathrm{e}^{-\mathrm{i}(\omega_{\mathrm{o}}t-k_{\mathrm{o}}z)}+\mathrm{cc}) \quad [8]$$

$(\partial\alpha/\partial Q)_S$ is the Stokes hyperpolarizability, $\omega_0=\omega_{\mathrm{L}}-\omega_{\mathrm{S}}$ is the Raman transition frequency, and k_0 is the k vector of the material excitation. The phase matching relation $k_{\mathrm{S}}=k_{\mathrm{L}}-k_0$ is automatically satisfied for SRS because the material mode that is involved is nonpropagating. Γ is the half width at half maximum of the Raman linewidth given by $\Gamma=1/\mathrm{T}_2$, where T_2 is the dephasing time. N is the number of molecules in the ground state and m is the effective reduced mass of the material oscillation.

When the fields are constant or vary slowly compared to the response time of the material, the Stokes intensity is given by

$$I_{\mathrm{S}}(z)=I_{\mathrm{S}}(0)\mathrm{e}^{I_{\mathrm{L}}g_{\mathrm{ss}}Z} \quad [9]$$

where the intensity I is given by

$$I_{\mathrm{S(L)}}=\frac{1}{2}(cn_{\mathrm{S(L)}}\varepsilon_0)|A_{\mathrm{S(L)}}|^2$$

and

$$g_{\mathrm{ss}}=\frac{N\omega_{\mathrm{s}}}{4\Gamma n_{\mathrm{S}}n_{\mathrm{L}}m\omega_0c^2\varepsilon_0}\left(\frac{\partial\alpha}{\partial Q}\right)^2 \quad [10]$$

where $n_{S(L)}$ is the index of refraction of the Stokes (laser) in the material and ε_0 is the dielectric permittivity of the vacuum.

The Stokes wave grows exponentially with z at a rate that depends on the pump intensity. If the Stokes wave becomes intense enough, its power can become comparable to that of the original pump wave. In that case depletion of the pump wave must be taken into account with an equation for the pump wave amplitude similar to [6]. The Stokes intensity is now given by

$$I_S(z) = \frac{I_S(0)e^{I_L(0)gz}}{1 + \dfrac{\omega_L}{\omega_S}\dfrac{I_S(0)}{I_L(0)}e^{I_L(0)gz}} \qquad [11]$$

which is valid when $I_S(0) \ll I_L(0)$.

In the limit of strong interactions all of the laser energy can be depleted. The maximum Stokes energy is given by $I_S = I_L(\omega_S/\omega_L)$, where ω_S/ω_L is termed the Manly–Rowe ratio. The energy that is removed from the laser but not converted to Stokes radiation is transferred to the material.

For each photon produced in the scattered wave, a corresponding quantum of energy is given to the material mode and a photon is removed from the laser. In principle, 100% of the laser photons can be converted to Stokes photons, but complete conversion is not achieved in practice. Photon conversion efficiencies greater than 90% have been reported in some pulsed laser experiments.

SRS frequency shifts and gains of some materials are shown in Table 2.

When pulses are used with durations comparable to or shorter than the response time of the material, ranging from picoseconds to femtoseconds depending on the material, the interaction is transient and the effects of the time derivatives in [6] and [7] must be accounted for. Under these conditions the Stokes intensity is given as a temporal integral with Bessel function dependence on the laser intensity. When the pulse duration is much shorter than the material dephasing time and the incident Stokes functional form is the same as the pump, the amplified Stokes intensity is given by the expression

$$I_S(z,\tau) = I_S(0,\tau)I_0^2\left(\sqrt{2g_{ss}\Gamma z\int_{-\infty}^{\tau} I_L(\tau')d\tau'}\right) \qquad [12]$$

where I_0 is a modified Bessel function. In this regime, the Stokes intensity depends only on the integrated pump energy. The Stokes gain is reduced from its steady state value for pulses of constant intensity, but for pulses of constant energy the highest Raman gain is obtained in the limit of transient interactions.

One of the most important applications of Raman scattering is the generation of new coherent waves at frequencies shifted from the pump. In this case, an incident Stokes wave is not supplied as the starting term in [9] or [12]. Rather, the process is initiated by the vacuum fluctuations in the Stokes and material oscillator fields. Quantum field creation and annihilation operators must replace the classical field amplitudes of [6] and [7]. The intensity of the generated Stokes wave is given by the expectation value of the normally ordered number operator and in the extreme transient regime is given by:

$$I_S(z,d\tau) = \frac{1}{2A}\hbar\omega_S\Gamma g_{ss}I_L(d\tau)z \times\left\{I_0^2\left(\sqrt{2\Gamma g_{ss}z\int_{-\infty}^{\tau} I_L(\tau')\tau'}\right) - I_1^2\left(\sqrt{2\Gamma g_{ss}z\int_{-\infty}^{\tau} I_L(\tau')\tau'}\right)\right\} \qquad [13]$$

where A is the cross-sectional area of the interaction geometry. The Stokes light generated in this fashion has all the characteristics of amplified spontaneous emission of lasers operated below threshold until the Stokes intensity becomes high enough to deplete the laser.

The stochastic nature of the SRS quantum mechanical source is manifest in the macroscopic Stokes light when the Stokes generator is operated well below pump depletion levels. For a single spatial mode the probability density distribution of

Amsterdam, The Netherlands: North Holland and Reintjes J and Bashkansky M (2001) Stimulated Raman and Brillouin Scattering. In: Bass M (ed.) *Optical Society of America Handbook of Optics*, Ch. 18, 2nd ed., vol. IV, New York: McGraw-Hill.

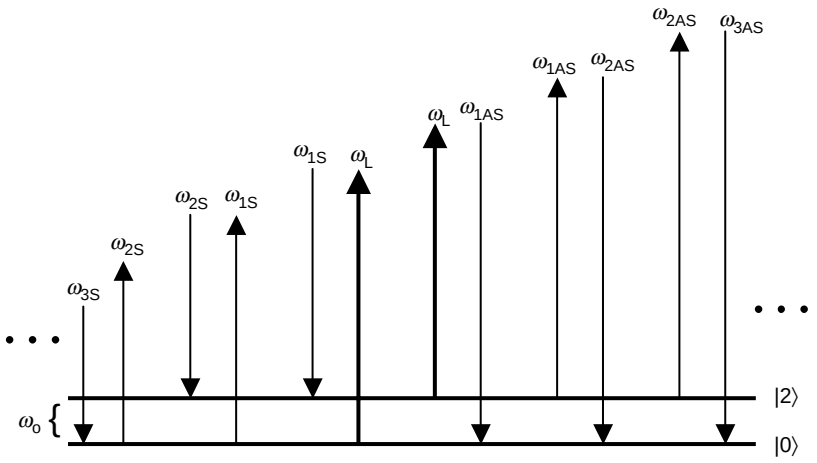

Figure 1 SRS level diagram showing generation of multiple Stokes and anti-Stokes frequencies.

the Stokes energy has the form of a negative exponential:

$$P(W) = \frac{1}{\langle W \rangle} \exp\left[- \frac{W}{\langle W \rangle} \right]$$

Statistical fluctuations in pulse energy, spatial profile, pointing, and in the spectral and temporal structure of the Stokes signal have all been observed.

If the intensity of the generated Stokes light becomes comparable to the pump intensity, it can serve as a pump wave for its own Raman interaction, producing a wave termed the second Stokes wave, shifted from the pump by frequency $2\omega_o$. If the process is driven hard enough third- and higher-order Stokes waves can be produced.

In addition to the interaction between the pump and Stokes beams described above, stimulated Raman scattering can also involve an anti-Stokes wave whose frequency is given by $\omega_{AS} = \omega_L + \omega_o$. The relationship of various Stokes and anti-Stokes waves is depicted in Figure 1. If a population inversion exists between the energy levels of the Raman process, then the anti-Stokes wave experiences exponential gain in a manner similar to that described above for the Stokes gain.

When all the population is in the ground state, which is usually the case, the anti-Stokes wave has exponential loss. The anti-Stokes wave can still grow without population inversion if the phase-matching condition

$$\Delta k = k_{AS} + k_S - 2k_L = 0$$

is approximately satisfied. Because of normal dispersion in the material this condition is usually not satisfied for collinear beams. However, if the Stokes and anti-Stokes beams propagate at small angles as shown in Figure 2, then the phase-matching condition can be met. For angles near but not exactly at phase matching the anti-Stokes wave grows exponentially as part of a mixed Stokes/anti-Stokes mode with a gain given by:

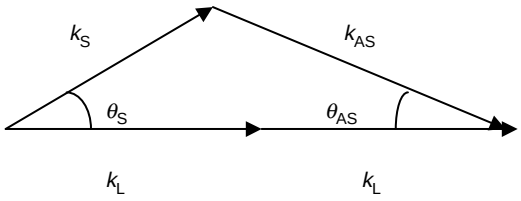

Figure 2 Phase matching diagram for Stokes–anti-Stokes coupling in a medium with positive dispersion.

$$g = \mathrm{Re}\left\{ \tfrac{1}{2}(K_3 - K_1)|A_L|^2 - \tfrac{i}{2}\sqrt{\Delta k^2 + 2i\Delta k(K_3 + K_1)|A_L|^2 - (K_1 - K_3)^2|A_L|^4} \right\} \quad [14]$$

At exact phase matching the interaction of Stokes and anti-Stokes waves serves to suppress the exponential gain of either wave.

As with Stokes waves, multiple-order anti-Stokes waves can be generated. Stokes and anti-Stokes orders up to at least 13 have been reported.

Stimulated Brillouin and Rayleigh Scattering

Light scattering can also occur through interaction with material density variations. Spontaneous

scattering through interaction with this type of internal mode produces a triplet of spectral lines. The up- and down-shifted lines are known as Brillouin anti-Stokes and Stokes lines, respectively, and are due to interaction with acoustic waves. The central peak is termed Rayleigh, or thermal Rayleigh scattering and is due to stationary density fluctuations arising from light absorption. A broad skirt around the central peak, which can be observed in anisotropic media, is due to the fluctuation of molecular distribution and orientation and is termed Rayleigh wing scattering. Each of these processes can give rise to stimulated scattering in the presence of intense radiation.

Density fluctuations are induced directly by light intensity through electrostriction, and indirectly by temperature fluctuations when optical absorption is important. A general classical model of the interaction, including both electrostriction and absorptive heating effects, is described by three equations:

The Navier-Stokes equation:

$$\rho_0\frac{\partial \mathbf{v}}{\partial t}+\frac{v^2}{\delta}\nabla(\Delta\rho)+\frac{v^2\beta\rho_0}{\delta}\nabla(\Delta T)-\eta\nabla^2\mathbf{v} = 2\gamma\varepsilon_0\nabla(\mathbf{E}_\mathrm{L}\cdot\mathbf{E}^*_\mathrm{R/B})-2\varepsilon_0\left(\frac{\partial\varepsilon}{\partial T}\right)_\rho(\mathbf{E}_\mathrm{L}\cdot\mathbf{E}^*_\mathrm{R/B})\nabla(\Delta T) \quad [15]$$

The continuity equation:

$$\frac{\partial}{\partial t}\Delta\rho+\rho_0\nabla\cdot\mathbf{v}=0 \quad [16]$$

The energy transport equation:

$$\left(\rho_0 C_v\frac{\partial}{\partial t}-\lambda_\mathrm{T}\nabla^2\right)\Delta T-\frac{C_v(\delta-1)}{\beta}\frac{\partial}{\partial t}\Delta\rho = 4nc\alpha\varepsilon_0(\mathbf{E}_\mathrm{L}\cdot\mathbf{E}^*_\mathrm{R/B})+4\varepsilon_0\left(\frac{\partial\varepsilon}{\partial T}\right)_\rho\left(T_0\mathbf{E}_\mathrm{L}\cdot\frac{\partial}{\partial t}\mathbf{E}^*_\mathrm{R/B}\right) \quad [17]$$

Here $\rho=\rho_0+\Delta\rho$, $T=T_0+\Delta T$, $\mathbf{v}$ is the volume element, v is the acoustic wave velocity, $\delta=C_p/C_v$ is the ratio of heat capacities at constant pressure and at constant volume, $\eta=(2\eta_\mathrm{s}+\eta_\mathrm{d})$ where η_s is the shear viscosity and η_d is the dilational viscosity, $\gamma=\rho_0(\partial\varepsilon/\partial\rho)_T$, λ_T and β are the thermal conductivity and thermal expansion coefficients, ε is the dielectric constant, and α is the linear absorption coefficient. $\mathbf{E}_\mathrm{L}$ is the pump field and $\mathbf{E}_\mathrm{R/B}$ is either the Rayleigh or Brillouin field.

Equations [15] and [16] can be combined to eliminate the $\mathbf{v}$ dependence:

$$\left[-\frac{\partial^2}{\partial t^2}+\left(\frac{v^2}{\delta}+\frac{\eta}{\rho_0}\frac{\partial}{\partial t}\right)\nabla^2\right]\Delta\rho+\frac{v^2\beta\rho_0}{\delta}\nabla^2(\Delta T) = 2\gamma\varepsilon_0\nabla^2(\mathbf{E}_\mathrm{L}\cdot\mathbf{E}^*_\mathrm{R/B})-2\varepsilon_0\left(\frac{\partial\varepsilon}{\partial T}\right)_\rho\nabla\cdot[(\mathbf{E}_\mathrm{L}\cdot\mathbf{E}^*_\mathrm{R/B})\nabla(\Delta T)] \quad [18]$$

Together with the equations describing the effect of the medium on the optical fields [19a,b], this coupled set of equations describes simultaneously stimulated Brillouin and Rayleigh scattering:

$$\left(\frac{\partial}{\partial z}+\frac{1}{v_\mathrm{g}}\frac{\partial}{\partial t}+\frac{1}{2}\alpha\right)A_\mathrm{L} = \mathrm{i}\frac{\omega_\mathrm{L}}{4cn_\mathrm{L}}\left[\frac{\gamma}{\rho_0}\Delta\rho A_\mathrm{R/B}+\left(\frac{\partial\varepsilon}{\partial T}\right)_\rho A_\mathrm{R/B}\Delta T\right] \quad [19a]$$

$$\left(\frac{\partial}{\partial z}-\frac{1}{v_\mathrm{g}}\frac{\partial}{\partial t}-\frac{1}{2}\alpha\right)A_\mathrm{R/B} = -\mathrm{i}\frac{\omega_\mathrm{R/B}}{4cn_\mathrm{R/B}}\left[\frac{\gamma}{\rho_0}\Delta\rho^* A_\mathrm{L}+\left(\frac{\partial\varepsilon}{\partial T}\right)_\rho A_\mathrm{L}\Delta T^*\right] \quad [19b]$$

where the slowly varying envelope approximation [2] is used for the waves described by A_L, $A_\mathrm{R/B}$, $\Delta\rho$, and ΔT. The nonlinear polarization term is related to density and temperature wave amplitudes in the following way:

$$P^\mathrm{NL}=\varepsilon_0 E\left[\left(\frac{\partial\varepsilon}{\partial\rho}\right)_T\rho+\left(\frac{\partial\varepsilon}{\partial T}\right)_\rho T\right] \quad [20]$$

Without the driving terms involving the optical fields, [17] and [18] describe broadband damped fluctuations in the variables $\Delta\rho$ and ΔT. When the optical driving terms are included, resonant behavior emerges. Steady state solutions can be obtained assuming strongly damped material excitations, allowing neglect of $\Delta\rho$ and ΔT derivatives. Separate contributions of the Rayleigh and Brillouin interactions to $\Delta\rho$ can be identified:

Rayleigh contribution:

$$\Delta\rho_\mathrm{R}=\left[\frac{\gamma(\Omega+\frac{1}{2}\mathrm{i}\delta\Gamma_\mathrm{R})-\mathrm{i}\gamma_\mathrm{a}\Omega_\mathrm{B}}{\Omega+\frac{1}{2}\mathrm{i}\Gamma_\mathrm{R}}\right]\frac{\varepsilon_0}{4v^2}A_\mathrm{L}A^*_\mathrm{R} \quad [21]$$

where γ_a is the absorptive coupling constant given by

$$\gamma_\mathrm{a}=\frac{2\alpha n v^2\beta}{C_p\Omega_\mathrm{B}}$$

The Brillouin contribution is:

$$\Delta\rho_B = \left[\frac{-(\gamma - i\gamma_a \nu q/\Omega)q^2\varepsilon_0}{4(\Omega^2 + i\Omega\Gamma_B - \nu^2 q^2)}\right] A_L A_B^* \qquad [22]$$

In [21] and [22] the frequencies and wavevectors satisfy the following relations:

$$\omega_L = \omega_{R/B} + \Omega \qquad [23a]$$

$$k_L = k_{R/B} + q \qquad [23b]$$

where ω_L is the incident laser frequency, $\omega_{R/B}$ is the frequency of the scattered Rayleigh or Brillouin wave, and k_L, $k_{R/B}$ are the corresponding wavevectors. Ω and q are the frequency and wavevector of the density fluctuation. Equations [23a,b] can also be described as energy and momentum conservation relations among incident and scattered photons and a phonon in the quantum mechanical picture.

The Rayleigh and Brillouin contributions exhibit resonant behavior at different frequency shifts. The Rayleigh contribution has its resonant frequency at $\Omega_R = 0$, resulting in typical diffusion behavior. The Rayleigh linewidth $\Gamma_R = 2\lambda_T q^2/\rho_0 C_p$ is the inverse of the decay time of the isobaric density fluctuations. The Brillouin contribution has its resonance at a frequency shift given by

$$\Omega_B = q\nu$$

where ν is the sound velocity. Thus at resonance the density fluctuations associated with the Brillouin effect correspond to sound waves. The Brillouin linewidth

$$\Gamma_B = \frac{q^2}{\rho_0}\left[\eta + \frac{\kappa}{C_p}\left(\frac{C_p}{C_\nu} - 1\right)\right]$$

is the inverse of the phonon lifetime τ_B.

In general Brillouin and Rayleigh interactions involve noncollinear scattering with the outgoing wave propagating at an arbitrary angle to the incident wave. In this case [23b] is a vector relation and the interaction geometry can be represented as shown in Figure 3.

The resulting relations among the k-vectors and frequencies of the various waves can place restrictions on the values of frequency shifts that are observed under various circumstances.

The coupled equations for the optical intensities in the steady state take the following form:

$$\frac{dI_L}{dz} = -g_{R/B} I_L I_{R/B} - \alpha I_L \qquad [24a]$$

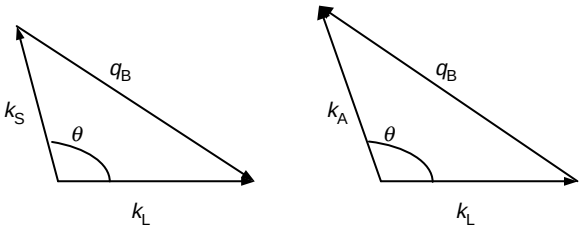

Figure 3 SBS phase matching diagram depicting relations between laser, k_L, sound wave, q_B, and Stokes and anti-Stokes, k_S, k_A k-vectors.

$$\frac{dI_{R/B}}{d\zeta} = g_{R/B} I_L I_{R/B} - \alpha I_{R/B} \qquad [24b]$$

where z is the direction of propagation of the incoming wave, ζ is the direction of propagation of the scattered wave, and $g_{R/B}$ is the gain coefficient of the Rayleigh or Brillouin effect. Equations [24a,b] describe interactions that have exponential gain. Stimulated Brillouin and Rayleigh scattering can be used in both a self-generator and an amplifier mode, but are used most often in a self-generator mode. Because the frequency shifts are small in these interactions, the starting signals for self-generators are thermal excitations of the internal modes rather than vacuum fluctuations.

Stimulated Brillouin Scattering

Stimulated Brillouin scattering (SBS) occurs through interaction with acoustic waves in solids, liquids, and gases and with ion-acoustic waves in plasmas. The Stokes or anti-Stokes frequency shifts for SBS are much smaller than for SRS, with typical values on the order of 0.1–100 GHz, depending on the excitation wavelength and interaction geometry as well as on material properties. Because the internal mode in SBS is a propagating wave, the phase matching condition shown in Figure 3 places restrictions on the frequency of the sound wave that is involved at various scattering angles. SBS is used most often for pulse compression and for correction of phase distortion in propagating light beams through phase conjugation. Although SBS is normally associated with high-power lasers in laboratory experiments, it is also a major factor in limiting the intensity of low-power lasers that can be used in optical fibers because of the long interaction lengths. SBS is also a prominent source of damage in solids and crystals caused by high-power lasers. It can also be used for generation and study of coherent hypersonic waves.

The SBS gain coefficient has both electrostrictive and absorptive contributions, $g_B = g_B^e + g_B^a$ where

$$g_B^e = \frac{\omega_B \gamma^2 \Omega_B}{2n_B n_L c^2 v^2 \rho_0 \Gamma_B} \frac{1}{1 + (2(\Omega - \Omega_B)/\Gamma_B)^2} \quad [25]$$

and

$$g_B^a = \frac{\omega_B \gamma \gamma_a \Omega_B}{4n_B n_L \rho_0 v^2 c^2 \Gamma_B} \frac{4(\Omega - \Omega_B)/\Gamma_B}{1 + (2(\Omega - \Omega_B)/\Gamma_B)^2} \quad [26]$$

The SBS gain from electrostriction has a maximum value of

$$g_B^e = \frac{\omega_B \gamma^2 \Omega_B}{2n_B n_L c^2 v^2 \rho_0 \Gamma_B} \quad [27]$$

at the resonant frequency shift

$$\Omega = \Omega_B = qv \quad [28]$$

For this condition the interaction is with a sound wave in the material. The frequency of the sound wave, and the gain, depend on the angle between the incident and scattered light. Using the vector relation

$$\mathbf{k}_B = \mathbf{k}_L - \mathbf{q}$$

depicted in Figure 3 and the approximations $\Omega_B << \omega_B, \omega_L, |k_B| \approx |k_L|$ we obtain

$$q = 2|k_L| \sin(\theta/2) \quad [29]$$

The Brillouin frequency shift is then given by

$$\Omega_B = 2n_L \omega_L (v/c) \sin(\theta/2) \quad [30]$$

and the Brillouin linewidth is given by

$$\Gamma_B = \frac{4}{\rho_0}\left[\eta + \frac{\kappa}{C_p}\left(\frac{C_p}{C_v} - 1\right)\right]\frac{\omega_L^2 n_L^2}{c^2} \sin^2(\theta/2)$$
$$= \Gamma'' \sin^2(\theta/2) \quad [31]$$

The peak Brillouin electrostrictive gain is then given by

$$g_B^e = \frac{\omega_B \gamma^2 \omega_L}{n_B c^3 v \rho_0 \Gamma_B} \sin(\theta/2) \quad [32a]$$

$$g_B^e = \frac{\omega^2 \gamma^2}{n_B c^3 v \rho_0 \Gamma'' \sin(\theta/2)} \quad [32b]$$

where we have used the approximation $\omega_B \approx \omega_L = \omega$.

The maximum electrostrictive SBS gain is independent of the laser frequency because the Brillouin linewidth is proportional to the square of the laser frequency.

As a function of angle the maximum Brillouin gain is usually observed in the backward direction. This is consistent with the form of the gain coefficient given in [32a], which indicates that the gain is proportional to $\sin(\theta/2)$. However, when the angular variation of the Brillouin linewidth is also accounted for, the gain coefficient is actually minimum in the backward direction [32b]. Typical laboratory experiments involve pencil-like geometries in which the interaction length is significant only in the backward or forward directions. In these situations, the total gain is actually maximum in the backward direction, where the interaction length is longest. Although the formulas appear to indicate that the gain goes to infinity in the forward direction, the damping time, which is proportional to Γ_B^{-1}, also goes to infinity and the interaction becomes transient. Under these conditions the gain parameter is proportional to $\sin(\theta/2)$ and the Brillouin gain goes to zero in the forward direction. Under some geometries Brillouin scattering at 90° to the laser can also be significant. It can be a source of damage to large glass components in high-power lasers.

For thermal Brillouin scattering the gain has a dispersive shape centered on the frequency shift $\Omega = \Omega_B$, with loss occurring on the low-frequency side and gain occurring on the high-frequency side, peaking at a frequency $\Omega = \Omega_B + \Gamma_B/2$. The maximum absorptive SBS gain depends on the laser frequency as ω^{-1}.

Table 3 shows representative values of the Brillouin linewidth and gain coefficients for a selection of substances.

Brillouin-enhanced four-wave mixing is a related effect that involves both a downshifted wave and an upshifted wave in which the coherent interaction is enhanced by the resonance associated with the sound wave. Gains of the order of 10^5 can be realized. Systems based on this effect are often used for phase conjugation.

Stimulated Rayleigh Scattering

Stimulated thermal Rayleigh scattering (R) can be observed in liquids while Stimulated Rayleigh wing scattering (SRWS) is observed in liquids with anisotropic molecules. Additionally, stimulated Rayleigh scattering due to fluctuations of concentration in gas mixtures can also occur. For R the internal mode obeys a diffusion equation. The R gain is given by

$$g_R = g_R^e + g_R^a$$

Reproduced from Reintjes J and Bashkansky M (2001) Stimulated Raman and Brillouin scattering. In: Bass M (ed.) *Optical Society of America Handbook of Optics*, Ch. 18, 2nd ed., vol. IV. New York: McGraw-Hill.

where g_R^e and g_R^a are the electrostrictive and absorptive contributions given by

$$g_R^e = \frac{\omega\gamma^2(\delta-1)}{4\rho_0 n_L n_R v^2 c^2}\frac{4\Omega/\Gamma_R}{1+(2\Omega/\Gamma_R)^2} \qquad [33]$$

$$g_R^a = \frac{-\omega\gamma\gamma_a\Omega_B}{2\rho_0 n^2 v^2 c^2 \Gamma_R}\frac{4\Omega/\Gamma_R}{1+(2\Omega/\Gamma_R)^2} \qquad [34]$$

Both contributions to the STRS gain have dispersive forms. The electrostrictive contribution is maximum for a down-shifted wave with $\Omega = \frac{1}{2}\Gamma_R$. Its maximum value scales linearly with laser frequency. For the absorptive process the gain depends inversely on the laser frequency, and is maximum for an upshifted wave with $\Omega = -\frac{1}{2}\Gamma_R$. Table 4 shows representative values of the Rayleigh linewidth and gain coefficients for a selection of substances.

Parametric Fluorescence

Some types of stimulated interactions do not involve exchange of energy with the material. These include parametric down-conversion and self-focusing. In parametric down-conversion an incident wave at frequency ω_L scatters into two longer-frequency light waves at signal and idler frequencies ω_s and ω_i. They satisfy the frequency and wavevector relations

$$\omega_L = \omega_s + \omega_i$$
$$k_L = k_s + k_i$$

The equations for the waves are:

$$\frac{\partial}{\partial z}A_s = -i\left(\frac{\omega_s}{2n_s c}\right)\chi^{(2)}A_L A_i^*$$

$$\frac{\partial}{\partial z}A_i = -i\frac{\omega_i}{2n_i c}\chi^{(2)}A_L A_s^*$$

where A_s and A_i are called the signal and idler fields. The solution for the signal field takes the

following form:

$$A_s(z) = A_s(0)\cosh\left(\sqrt{|\kappa|^2|A_L|^2}z\right) - i\sqrt{\frac{\omega_s n_i}{\omega_i n_s}}A_i^*(0)\sinh\left(\sqrt{|\kappa|^2|A_L|^2}z\right) \quad [35]$$

where

$$|\kappa|^2 = (\omega_s\omega_i/4n_s n_i c^2)|\chi^{(2)}|^2$$

The stimulated parametric interaction provides gain for input signal and idler waves. For large values of $\sqrt{|\kappa|^2|A_L|^2}\,z$ the gain becomes exponential in character, similar to the gain in SRS and SBS. When no incident signals are supplied, the source terms in [35] are the vacuum fluctuations at the signal and idler frequencies. Stimulated parametric fluorescence is the basis for parametric oscillators that provide tunable coherent radiation over a wide wavelength range in the visible and infrared.

Stimulated Photorefractive Scattering

Stimulated light scattering also takes place in photorefractive materials. These materials include crystals such as $LiNbO_3$, $BaTiO_3$, $Bi_{12}SiO_{20}$, and others. They possess a unique property of photo-induced index change with very low light intensities. Some of the potential applications include real-time holography, information recording, phase conjugation, parallel signal processing, and ultrafast optical gating. The nonlinearities leading to stimulated scattering are very large and can produce a significant gain in millimeter thick crystals. In order for amplification of scattered light to take place the nonlinearities have to have a nonlocal character due to diffusion or drift fields. Figure 4 shows a two-beam interaction effect in a photorefractive medium leading to stimulated scattering. Solid lines represent intensity maxima of interfering light beams while dashed lines represent diffused index change maxima. The fact that the two do not overlap allows amplification of the signal beam, with the maximum gain occurring at $\pi/2$ phase shift.

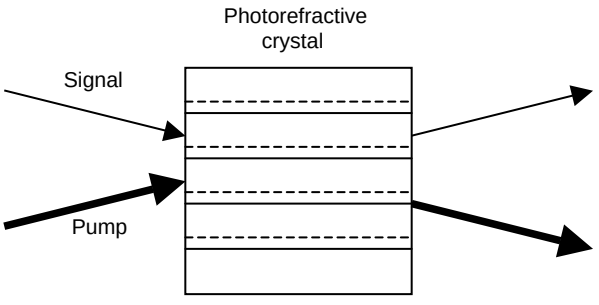

Figure 4 Stimulated photorefractive scattering diagram showing incident pump and signal beams, amplified signal beam, and an index grating formed in the photorefractive crystal.

Stimulated Compton and Thomson Scattering

Light scattering from free electrons is described by Thomson scattering in the low-energy limit, with a cross-section of $(8\pi)/(3)((e^2)/(4\pi\varepsilon_0 mc^2)^2)$, and by Compton scattering in the relativistic limit. Stimulated Thomson or Compton scattering is the source of light emitted from free electron lasers. In these interactions, the electron scatters incoming radiation in its rest frame to a backscattered wave. The ponderomotive force resulting from the interaction with the scattered waves increases the periodic electron bunching, which in turn increases the efficiency of scattering. In some cases, the incoming electromagnetic wave is provided by a microwave source, while in others it arises from a static magnetic wiggler, which appears as an incident electromagnetic wave in the electron rest frame because of a relativistic Lorentz transformation. Free electron lasers are a source of tunable coherent radiation from the microwave region to the ultraviolet.

Self-focusing

In the presence of a strong laser field with intensity I, the refractive index of many materials changes according to the relation

$$n = n_0 + n_2 I$$

where n_2 is termed the nonlinear index. This change in refractive index gives rise to several effects, depending on the temporal and spatial properties of the light. In one type of interaction, a strong forward beam couples to two weaker beams that propagate at small forward angles, providing gain for the weaker beams. One of the weak beams interferes with the strong forward beam to form a phase grating through the nonlinear index, providing gain for the second weak beam. The interference of the second weak beam with the forward beam forms a second phase grating, providing gain for the first weak beam, thereby completing the coupling

for the stimulated process. This effect is similar to Stoke/anti-Stokes Raman scattering, except that the coupling is between waves propagating in different directions rather than between waves with different frequencies.

For interactions with an instantaneous relaxation time, the gain for waves propagating at a small angle to the forward direction is given by

$$g = \frac{K_\perp}{2k}\sqrt{K_{\max}^2 - K_\perp^2}$$

where $K_\perp = \sqrt{k_x^2 + k_x^2}$ is the transverse wavevector, corresponding to the angle

$$\theta = \frac{K_\perp}{k}$$

and

$$K_{\max} = 4k^2 n^{\mathrm{L}} n_2 I$$

is the largest transverse k-vector for which gain is observed. The maximum gain is given by

$$g_{\max} = \frac{K_{\max}^2}{4k}$$

and occurs for an angle corresponding to

$$K_\perp = \frac{K_{\max}}{\sqrt{2}}$$

When the physical interaction that causes the refractive index to change with light intensity has a nonzero relaxation time, gain can be observed at angles larger than that given by $K_{\max}$.

This stimulated four-photon effect can be interpreted as the initiating stage of self-focusing. In the self-focusing effect, a laser beam with a normal mode profile (more intense in the center than at the edges) creates a positive lens in the material, focusing the beam. As the beam intensifies, the power of the lens increases, causing the beam to focus more tightly and eventually coming to a catastrophic focus if other nonlinear effects do not limit the intensity. The four-photon stimulated effect described above results in the spread of k-vectors of the forward beam, corresponding to a reduction in its diameter.

Self-focusing is responsible for breakdown and damage in many solids. Self-focusing in high-power lasers is commonly suppressed by restricting transverse k-vectors to values well below those of maximum gain.

Amorphous Semiconductors

Introduction

Amorphous semiconductors comprise several classes of materials having a range of useful properties that have made many of them commercially important. Their special characteristics are derived from the particular techniques used in their synthesis, and include the ability of some to change their structure under the influence of heat or illumination. Many are photoconductive, making them valuable for photodetectors when large area devices are required (e.g., xerography), or photovoltaic, hydrogenated amorphous silicon being widely used in thin-film solar cells.

'Amorphous' means noncrystalline, thus encompassing glassy materials and disordered covalent-bonded materials. Glasses, such as the amorphous chalcogenides (glassy sulfides, selenides, and tellurides), melt to viscous liquids when heated, whereas disordered semiconductors like amorphous silicon are metastable thin films that vaporize or crystallize when heated. Two other groups of glassy semiconductors, the covalent-bonded II–IV–V_2 compounds and ionic-bonded oxides (e.g., $V_2O_5P_2O_5$) will not be discussed here. Amorphous organic semiconductors are receiving much interest now, because of their potential use in low-cost display devices, but are more logically treated as polymer materials.

The following sections explain the main preparation methods and the structures that result, the importance of defects and the influence these have on optical and electrical behavior, and some of the most important applications.

Amorphous Structure

The common property that distinguishes all amorphous materials from crystalline ones is the absence of long-range order in their atomic structure. These disordered solids have no periodic or translational symmetry. The term is sometimes loosely applied, and it should be noted that elements and compounds that are able to form several structures might contain different phases. An example is 'hard carbon' which in thin-film form may contain tetrahedral amorphous carbon and hydrogenated amorphous carbon, as well as microcrystallites of graphite and diamond. Interestingly, the prediction in 1989 by A.Y. Liu and M.L. Cohen, that crystalline cubic-C_3N_4 would be even harder than diamond, has not been confirmed by experiment. Only a hard amorphous C_xN_y has been produced, even by nitrogen ion beam assisted sputtering of graphite, which it was thought would

have provided sufficient energy to form the close C–N bonds.

When the common crystalline semiconductors, Si and Ge, melt they become liquid metallic conductors. This is because the solid is formed by directional covalent bonds that produce tetrahedral packing of the atoms. In the liquid the bonds are weakened and a closer packed structure found in metals results. However a less ordered atomic arrangement results from condensing vaporized Si or Ge on to a cold substrate. In this case the atoms cannot move into their preferred positions for either tetrahedral or close packing arrays and instead are frozen almost wherever they land. Nonetheless, the arrangement of atoms is closer to that of the tetrahedral crystalline semiconductor than that of the metallic liquid. The radial distribution function of an amorphous semiconductor provides the numbers of atoms versus distance from an arbitrary atom. It shows that the nearest-neighbor distance is the same as in the equivalent crystalline material, although with some spread of values, but that the separation of atoms further away has a less well-defined value. Thus pure amorphous Si and Ge retain the directional covalent bonds between nearest neighbors but have distorted bond angles that make next nearest neighbors lie in different positions from the equivalent crystalline solid. Consequently there is only short-range order and the atoms form a continuous random network, a concept introduced by W.H. Zachariasen in 1932 for glasses. The deposition conditions generally lead to further disruptive effects that will incorporate small voids where the distortion is too large to allow a bond between atoms. These voids together with broken bonds give a defective network that is far from the ideal random tetrahedral 'lattice'.

Amorphous Semiconductor Energy Bands

A frequently asked question is 'Why can amorphous materials show semiconducting behavior?' since they do not have the periodic structure that leads to the allowed energy band scheme in crystalline semiconductors. However, note that metals do not become insulators when they melt, demonstrating that electrical conductivity does not require a periodic atomic structure. In fact, electron energy levels in solids may also be derived by considering chemical bonds when discrete atoms are brought closer together. The valence band in a semiconductor arises from the electron bonding orbitals and the conduction band from the antibonding electron orbitals. The forbidden energy gap (bandgap) is the separation between these two bands, which are only partially filled in semiconductors at room temperature. Thus amorphous semiconductors will have bonding and antibonding energy bands, and a more or less well-defined bandgap according to the defect content.

In fact, pure amorphous Si and Ge are extremely poor semiconductors due to an ill-defined bandgap and the large concentration of defects. Distorted bonds produce allowed electron energy levels that lie adjacent to the well-defined bands in crystals, producing tails of energy levels extending into the bandgap. Electrons that take up these 'tail state' energies are not entirely free to move through the solid but can only hop from one defective site to another. Additional defects arise from unsatisfied covalent bonds that 'dangle' in the spaces between the atoms. These produce electron energy levels within the forbidden gap (Figure 1). Indeed, their concentration is so high in amorphous silicon produced from a condensed silicon vapor, that they fix the position of the Fermi level at approximately the middle of the bandgap and the semiconductor has a high resistivity. The usual option of reducing a semiconductor's resistivity by adding small amounts of dopants from adjacent columns of the periodic table has little effect in this case. A donor atom from group V (e.g., phosphorus) may have all five valence electrons satisfied by a locally distorted arrangement of silicon atoms, instead of having only four bonded electrons and a loosely bound electron as in crystalline silicon. A similar picture exists for an acceptor atom from group III (e.g., boron).

Semiconductors containing group VI elements, S, Se, or Te, have two-fold coordination instead of the tetrahedral arrangement of the group IV elements, Si and Ge. The bonding between atoms in the solid is formed from four of the six p-electrons, which give

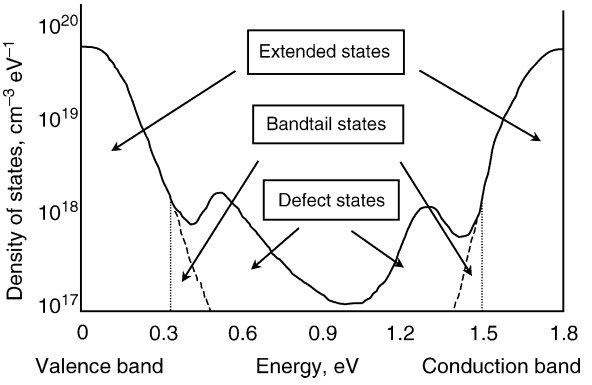

Figure 1 Schematic density of states for hydrogenated amorphous silicon.

rise to the bonding and antibonding energy bands of the solid, and the two remaining p-electrons from each atom form a non-bonding 'lone pair'. The lone pair energy band lies between the bonding and antibonding bands, and is the highest filled band in the solid, thus being the valence band.

Just as in amorphous Si or Ge, dangling bond defects will have energies between the valence and conduction bands, but in lone-pair semiconductors such disturbed energy states will now produce energy levels that fall within the lone pair band instead of within the bandgap. This makes it difficult to dope chalcogenide semiconductors, especially by donors, since the additional energy levels often lie within an existing energy band. Similar considerations apply to ternary chalcogenide alloys: these will have lone-pair bands arising from the group VI element, with additional energy levels from the other components (e.g., from group IV or V). However, amorphous chalcogenides will also contain three-fold coordinated chalcogenide atoms and these defects can associate in pairs or may interact with an adjacent two-fold coordinated atom. Defect centers with two oppositely charged chalcogens may form a 'valence alternation pair' (VAP).

So it may be seen that the semiconducting behavior of solids arises from the nearest-neighbor interactions of the atoms giving rise to allowed electron energy bands, and that long-range order is not necessary to produce the semiconductor's forbidden energy gap. Defects then produce localized energy levels that usually lie within the forbidden gap.

Preparation of Amorphous Silicon

Despite the early use of selenium as a photoconductive semiconductor in xerography, most amorphous semiconductors might have stayed as curious but technologically impractical materials, if an alternative preparation method to physical vapor deposition had not been discovered.

In the 1950s the preparation of high-purity single-crystal silicon was not yet established, and work at Standard Telecommunication Laboratories, UK, was attempting to use radio-frequency heating to produce silicon from low-pressure silane gas (SiH_4). It was noticed that a side effect was a deposit of resistive, noncrystalline material on cool parts of the container, close to unwanted plasma 'glow discharges'. In following up this observation, the technique was developed to produce a variety of other useful compounds from electrical discharges in appropriate gas mixtures, particularly silicon nitrides and oxides. With new scientific interest in amorphous semiconductors, the silicon coatings from silane were examined in more detail, and were shown to be significantly different from amorphous silicon produced by evaporating and condensing silicon. This new form was very photoconductive and could be doped n-type by adding phosphine to the silane. A more detailed study of doping led to the seminal papers by W.E. Spear and P.G. LeComber of Dundee University, UK, and to an explosive growth in the whole subject, once the potential commercial applications became apparent.

Despite many alternative synthesis methods, plasma chemical vapor deposition (CVD) remains the most widely used, and produces material that has not been surpassed in quality. The key features are a vacuum chamber into which a controlled flow of each of the gaseous sources is fed, and a heated plate on which the substrate is placed for coating. The decomposition of the gases is driven by an electrical discharge between two electrodes, which enables the gas temperature to be much lower than in conventional pyrolysis (thermal CVD). An important aspect of the process is the incorporation of hydrogen into the deposited material, which is thus more accurately known as hydrogenated amorphous silicon, a-Si:H. In the best material, hydrogen is mainly bonded singly as Si–H, but if the preparative conditions are not optimum then there may also be large amounts of $Si–H_2$ (as may be seen from the infrared absorption spectra). Alternative source gases usually contain hydrogen (e.g., Si_2H_6), and hydrogen may be added as a diluting agent for the doping gases (e.g., B_2H_6 or PH_3). Other precursors include fluorinated gases, but these have failed to give the predicted improvements in performance of the semiconductor in such applications as solar cells, and have greater chemical reactivity.

Since silane is spontaneously flammable in air, and the dopant gases are not only flammable but also very toxic, efforts have been made to produce a-Si:H by other means. Sputtering from undoped or doped silicon targets has been a popular choice, but it is still necessary to incorporate hydrogen into the deposited material, for instance by adding it to the usual argon sputter gas. This is because hydrogen serves to passivate unsatisfied 'dangling' Si bonds and to reduce the stresses that would occur in a pure silicon network. Photo-CVD, using ultraviolet light to drive the reaction without raising the temperature, can produce high-quality material but has the problem of unwanted silicon deposits on the illuminated reaction chamber window. Although conventional silane pyrolysis is not

suitable for producing a-Si:H, because the temperatures needed for useful deposition rates also remove much of the hydrogen if the substrate is too hot, it is possible to heat the gas separately from the substrate by means of a hot filament and so produce good-quality films.

Other hydrogenated silicon alloy semiconductors are synthesized by additions to silane of ammonia (giving amorphous silicon nitride, a-Si:N:H), or a hydrocarbon gas such as methane (giving a-Si:C:H), or germane (giving a-Si:Ge:H).

Preparation of Amorphous Chalcogenides

Unlike the tetrahedral group IV elements, useful members of this class of amorphous semiconductors may be produced by vacuum evaporation and condensation on to a relatively cool substrate. Compounds, such as As_2Se_3, do not evaporate congruently and so the deposit will change composition as the evaporation proceeds. More uniform compositions may be obtained by sputtering with argon, and glassy oxides may also be obtained in this way with oxygen added to the inert gas. Chalcogenide glasses may also be prepared by rapid cooling from a melt, or by chemical vapor deposition from heated vapor precursors. Since glasses are thermodynamically unstable, they will tend to transform to a more stable, sometimes crystalline structure. The rate for this process depends on the temperature and may be effectively too slow to observe.

Optical Properties of Amorphous Semiconductors

Optical absorption spectra of amorphous semiconductors clearly show a forbidden energy gap. By plotting a suitable function of the absorption coefficient, α, versus photon energy, $h\nu$, usually that given by J. Tauc, $(\alpha h\nu)^{1/2}$, the 'optical gap' may be determined from the intercept of the linear portion of the plot with the x-axis. Unlike crystalline semiconductors, amorphous ones have no k-selection rules to give indirect and direct transitions across the bandgap, thus a-Si:H behaves as a direct gap material. This 'optical gap' is greater than the bandgap determined from electrical conductivity measurements, since the latter will have contributions from both localized bandtail states (low electrical mobility) and extended states (high electrical mobility) (Figure 2).

The absorption spectra also have a portion at lower photon energies having an exponential dependence on photon energy, known as the Urbach tail. This is related to the structural disorder in the material and the tail states. Transitions involving defect bandgap states lie at even lower photon energy, and the density of defects can be determined from the weak absorption in this region of the spectrum, perhaps by using photothermal deflection spectroscopy to detect the weak optical absorption.

Photoluminescence also provides a probe of the defect content of many materials. Interpretation and identification of the actual defect (e.g., chemical impurity or structural imperfection) is aided by

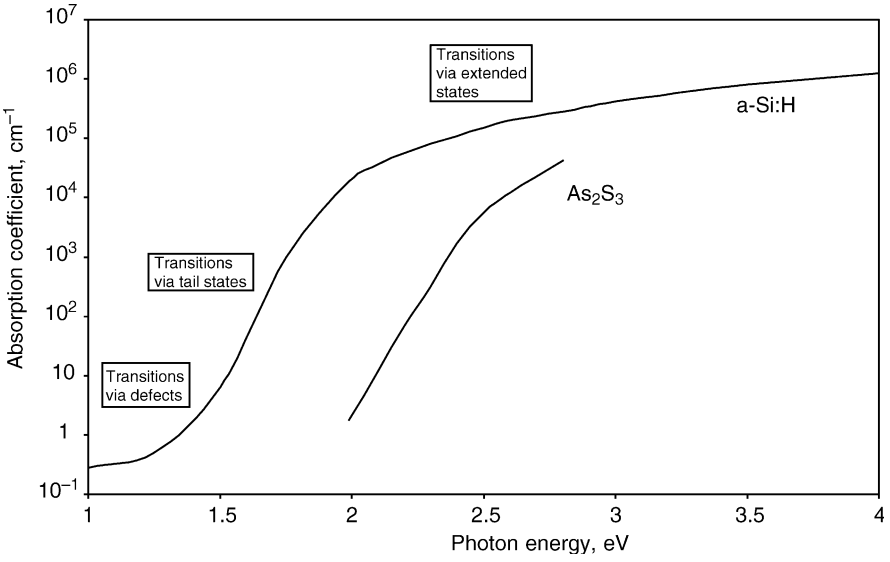

Figure 2 Typical optical absorption spectra of hydrogenated amorphous silicon and arsenic sulfide.

reference to the crystalline form. Both crystalline and amorphous forms of chalcogenide have a wealth of special effects, including reversible photoinduced bleaching and darkening, and laser-induced crystallization and amorphization. In addition the creation and dispersal of defects by appropriate illumination of some amorphous chalcogenides is accompanied by changes in the electron spin resonance (ESR) signal. Some of these effects have been the basis for applications in optical memories. More prosaically, chalcogenide glasses are important infrared transparent materials and amorphous chalcogenide thin films have had historical importance as the photoconductive layer in xerography, although here they are now being supplanted by less toxic amorphous silicon alloys.

Electrical Properties of Amorphous Semiconductors

The electrical conductivity of amorphous semiconductors is often controlled by the defects that are introduced by impurities or by structural flaws. For a-Si:H this provides alternative conduction mechanisms, via extended state electron and hole conduction (as in crystalline silicon), and via hopping of electrons or holes through localized energy levels within the bandtails or within the bandgap. The relative importance of each route depends on the temperature and on the density of states (DOS) in each energy range, as well as on the mobility of the charge carriers.

These different conduction mechanisms are clearly seen in the temperature dependence of the conductivity of a-Si:H and of many amorphous chalcogenides, since a semilog plot of conductivity versus $1000/T$ K will have portions with different slopes as each mechanism dominates a particular temperature range. Near room temperature, good-quality a-Si:H films in the dark exhibit a well-defined Arrhenius relationship with an activation energy that is the energy separation of the Fermi level from the conduction band extended states, electrons dominating the conductivity. The conduction band extended states do not have the high electron mobility found in crystalline silicon, due to the disruption of long-range order and the consequent increased electron scattering. Typical electron mobilities in a-Si:H are $\sim 1\,\mathrm{cm^2\,v^{-1}\,s^{-1}}$, and hole mobilities are even lower.

The band tail states have even worse carrier mobilities, since movement is by hopping to vacant sites that might lie at some distance, and hopping is unlikely between sites that have a large energy difference. (The process has an inverse exponential dependence on the energy difference between the initial and final states.) Hopping of carriers between states that lie within the bandgap is a significant contribution to the conductivity only at low temperatures, unless the density of such defects is high. In materials having weakly localized states, nearest-neighbor hopping is supplanted by variable range hopping, as carriers prefer to hop to a more distant site if it has a smaller energy difference from the starting site than do the neighboring sites. As the temperature is lowered, this hopping distance will increase and the conductivity has N.F. Mott's characteristic $\exp(-B/T^{1/4})$ dependence on temperature, T. Lower-quality films deposited by plasma CVD on to unheated substrates tend to be p-type due to hopping conductivity through the high density of defect states. The link between substrate deposition temperature and material quality is caused by the way in which hydrogen is incorporated into the growing material: high temperatures allow only singly bonded hydrogen, which passivates dangling bonds thus removing bandgap defect energy levels. Low temperatures also allow hydrogen to be incorporated as $Si-H_2$ and this disrupts the Si–Si lattice bonding, producing more defect levels. Confirmation of this effect is obtained from sputtered amorphous silicon, with and without hydrogen added to the argon.

When a-Si:H is illuminated it may show strong photoconductivity, depending on the preparative conditions. Free carriers are generated by the illumination but may fall into defect states (energies within the band gap) where they can be released or can recombine with the oppositely charged carriers. The detailed response to light (wavelength, intensity, duration) and temperature thus depends on the distribution and concentration of defects. Luminescence effects are similarly influenced. Most amorphous chalcogenides are only weakly photoconductive due to their high density of gap states, those near the middle of the gap (e.g., VAPs) being highly effective recombination centers.

The electrical properties of other hydrogenated amorphous tetrahedral semiconductors based on silicon are determined by their defect populations, and in general they are less well behaved. a-Si:Ge:H and a-Si:Sn:H have reduced bandgaps and a-Si:C:H and a-Si:N:H have increased bandgaps, which offer many possibilities for multilayer device design, provided that their normally high defect contents can be reduced or controlled.

The study of glassy semiconductors was stimulated in the 1960s by the discovery of electrical switching in sputtered multicomponent thin films.

These simple devices changed from a nonconducting to a conducting state when the applied electric field exceeded a certain threshold, and returned to their initial state when the current fell below a certain value. A variety of other switching types was discovered, especially under pulsed operation, including those having a memory effect based on the reversible crystallization and vitrification of a narrow filament between the contacts. A theoretical model of these devices comprises both electronic and thermal effects, which are responsible for initiating the switching event and for memory effects. A practical problem has been the variable jitter in the switching time.

Applications

Amorphous silicon alloy films are valuable as the active layers in thin-film photovoltaic cells, two-dimensional optical position detectors, linear image sensors (optical scanners), and thin-film transistors used in liquid crystal display panels. They also have uses as antireflection coatings and planar optical waveguides. Amorphous chalcogenide films have been used as electrical switches and memory devices, for optical data storage, and as dry photoresists and electron beam resists. Both types of amorphous material have been used in xerography and medical X-ray imaging detectors.

Amorphous silicon solar cells have power conversion efficiencies of ~12% for the most complicated structures. These are tandem cells that use different alloys (including a-Si:C:H) for the various layers, in order to enhance effective absorption of the solar spectrum. A serious drawback of using amorphous semiconductors in electronic devices is their short carrier diffusion length. In solar cells this is circumvented by ensuring that there is a built-in field to separate photogenerated electron–hole pairs before they can recombine. Because doped amorphous silicon alloys have high defect densities, it is difficult to make the effective pn junctions that provide such built-in fields in conventional crystalline silicon cells. Instead, amorphous silicon cells use pin structures, where the i-layer is effectively undoped and provides an extended electric field between the p-i and i-n junctions. Long periods of illumination increase the dark current in these devices, as additional defects are generated. This 'Staebler–Wronski effect' is believed to be associated with hydrogen movement at a passivated dangling bond (Si–H) and a nearby weak Si–Si bond. It is a cause of slow degradation in unstabilized solar cells although the change may be reversed by thermal annealing.

In contrast to 'minority carrier' photovoltaic devices, thin-film transistors necessitate the control of majority carriers alone. To address each pixel in a liquid crystal display, a switching element is needed and simple thin-film transistors fulfill this role. Although low carrier mobilities in amorphous semiconductors restrict the current passed and switching speeds, the requirement for coating large area glass panels at low temperatures make a-Si:H with a-Si:N:H gate dielectric almost the only options. Improved performance is possible by using pulsed laser irradiation to change the amorphous semiconductor to polycrystalline material.

Introduction

Direct gap semiconductors have many unique properties which are advantageous for optical and electronic applications, and in particular for detectors and emitters of infrared radiation associated with interband optical transitions. Gallium arsenide, GaAs, based structures have principally been used in the near-infrared, and so-called narrow gap semiconductors in the mid-infrared (MIR) spectral regions. More recently systems based on intersub-band transitions have shown great promise for MIR devices, with the obvious advantage for some applications that they can be constructed from large gap, better controlled materials (mainly InP- and GaAs-based to date) and have a peak operating frequency which is determined simply by the design of the particular quantum structure. Both approaches have been substantially advanced by band structure engineering techniques, reducing Auger losses and phonon losses, respectively, which is the subject of the present work.

The classic examples of narrow gap materials are the III–V semiconductors (InSb, InAs, and their related alloys), II–VI semiconductors (mainly $Hg_{1-x}Cd_xTe$), and the lead salt alloys. As a direct result of the small energy gap, these materials have a very low electron effective mass, very high electron mobility, even at room temperature, and a high saturation velocity. In addition they have a high ratio of stimulated to spontaneous transition probabilities and a large nonlinear susceptibility. However, they have the disadvantage of a high intrinsic carrier density at room temperature and thermal generation rate, so that a fundamental limitation to the performance of devices at elevated temperatures (preferably room temperature) is nonradiative losses resulting from Auger recombination processes. One solution is to cool these systems to 80 K or below which involves expensive and bulky cooling methods such as Stirling-cycle coolers, negating their advantages over other, otherwise inferior, devices. In the past 10 years there has been an intensive effort to circumvent this limitation by quantum structure and so-called 'band structure engineering' techniques made possible by epitaxial growth techniques, whereby the Auger processes are suppressed. Since the emphasis of the band structure engineering work has been mainly towards the optimization of III–V semiconductor lasers rather than detectors, we reflect that emphasis here. Although developed more recently than the bipolar diode lasers, the unipolar quantum cascade (QC) lasers provide perhaps the best example of systems that can be conveniently optimized by band structure engineering techniques. In this case, phonon processes dominate so that the design is to do with phonon suppression. Thus, we are concerned principally with suppression of Auger processes for interband devices, and phonon processes for intraband devices.

Nonradiative Processes and Band Structure Engineering

Suppression of Auger Recombination

Electron recombination processes are dealt with in detail elsewhere in the Encyclopedia (*see* **Semiconductor Physics:** Recombination Processes) but we briefly summarize the main points here. It is well known that there are three principal interband recombination mechanisms by which thermodynamic equilibrium is established in semiconductors: Shockley–Read recombination, radiative recombination, and Auger recombination. These are shown schematically in Figure 1. The Shockley–Read recombination occurs via extrinsic energy levels produced by lattice defects and impurities, Figure 1a, and can in principle be controlled by the procedure used to grow the material; hence it does not provide a fundamental limit to the

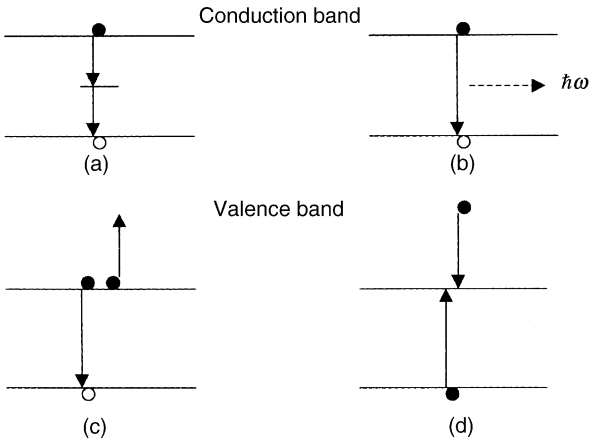

Figure 1 Electronic processes in semiconductors: (a) Shockley–Read recombination; (b) radiative recombination; (c) Auger recombination; (d) impact ionization.

carrier lifetime. The radiative and Auger mechanisms (Figure 1b,c, respectively) are, however, fundamental and are determined by the electronic structure of the material. The former is central to the operation of light-emitting diodes and is approximately inversely proportional to the electron and hole concentration. Optimum detector operation is achieved in materials that are limited by the radiative lifetime mechanism. Thus, in both cases it is desirable to minimize Auger processes.

By contrast with the two-particle radiative recombination process, Auger recombination is a three-particle interaction. For example in one so-called CHCC (or Auger-1) process an electron collides with a second electron; the first electron recombines with a hole in the valence band and the energy produced by the electron–electron collision excites the second electron higher up into the conduction band. This second electron eventually de-excites by phonon emission, and can cause observable heating of carriers by an Auger type of up-conversion. However, for the present article we are only interested in the first part of the process, so we do not consider the heating further here. The Auger process is the inverse of impact ionization where an energetic conduction electron collides with a valence electron, thereby creating an electron–hole pair as shown in Figure 1d. The final state consists of two low-energy electrons and one hole. Analogously, in Auger recombination the initial state has three particles (e.g., two electrons and one hole) and the final state one (e.g., one electron). Due to this three-body nature, the collision probability (or transition rate) per unit volume, R, varies with the cube of the carrier concentration and (if $n = p$) may be written $R = Cn^3$, where n is the electron density and C is referred to as the Auger coefficient. Note that the Auger rate is sometimes defined per carrier as $R' = Cn^2 = 1/\tau_A$, where τ_A is the Auger lifetime.

Narrow gap III–V semiconductors have the familiar three-band (so-called Kane energy band structure – (*see* **Semiconductor Physics:** Band Structure and Optical Properties) consisting of an s-like conduction band separated by a small energy gap from a triply degenerate p-like valence band, part of whose degeneracy is raised by spin–orbit splitting as shown in Figure 2. Thus, a large number of permutations of Auger processes become possible for n- and p-type semiconductors. Those which are initiated by a collision between two electrons are referred to as conduction, or n-n, Auger processes (e.g., the CHCC process), and those by a collision between two holes as valence, or p-p, Auger processes. It can be shown that the n-n process (so-called CHCC or Auger-1) illustrated in Figure 3a is dominant in bulk n-type and the p-p process

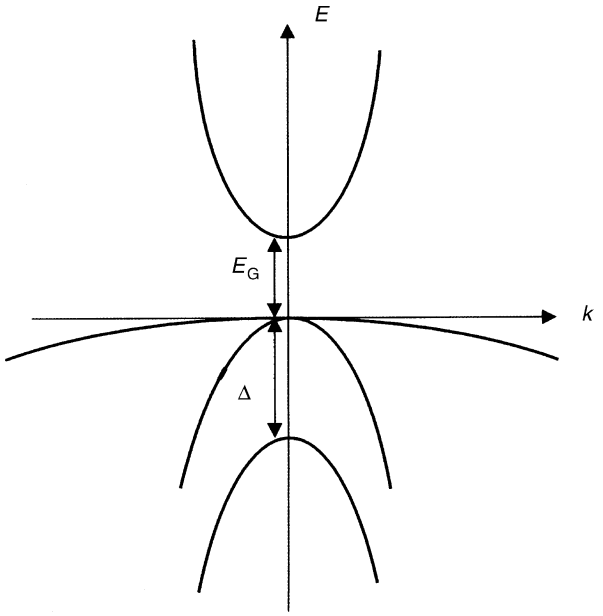

Figure 2 Schematic diagram of the conduction and valence band structure of InSb showing the energy bands around the Γ-point ($k = 0$) that are involved in Auger transitions.

(so-called CHLH or Auger-7) shown in Figure 3c is dominant in bulk p-type semiconductors, and so these have received the most attention. For larger gap (shorter wavelength) semiconductors there is sometimes a significant resonance between the bandgap and the spin–orbit splitting and the p-p process (CHSH) shown in Figure 3b becomes important. Clearly these simple descriptions require extension when the more complex band structure of strained layer superlattice quantum systems is considered.

With certain approximations, some analytic solutions for the Auger recombination rates are possible. This model is, while not appropriate for higher levels of band structure engineering, very important for giving an insight into how Auger effects should be studied, and how they themselves might be engineered. The approximations generally used are parabolic bands and Boltzmann statistics, but some further analytic results may also be obtained when these restrictions are relaxed. Bloch functions and Fermi's golden rule are utilized (*see* **Semiconductor Physics:** Recombination Processes) to describe the particle states, so obtaining the general expression for the Auger rate per unit volume. Energy and momentum conservation provide strong constraints on the resulting integral, and give rise to a considerable reduction in the Auger transition rate. However if, for example, the momentum conservation constraint is relaxed due to occupied levels existing with a broad range of momenta, such as at some band extremum with a

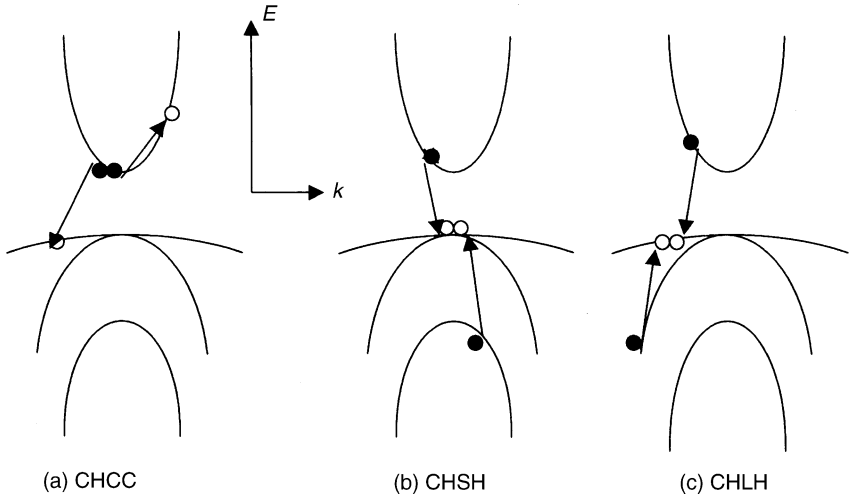

Figure 3 Important Auger recombination mechanisms for mid-infrared (MIR) semiconductor detectors and lasers: (a) CHCC or Auger-1; (b) CHSH; (c) CHLH or Auger-7.

large effective mass, then the Auger rate will be strongly enhanced. Or to put it the other way round, the Auger rate can be reduced by engineering the band structures such that the heavy hole effective mass is reduced (e.g., by stress – see below) to approach that of the conduction band. Furthermore, since we are concerned with nonradiative recombination across the bandgap with energy E_g, any energy levels (again band extrema in particular) separated from the conduction or valence band edges by E_g are particularly susceptible to the excitation part of the Auger process. The Auger rate may therefore be reduced by designing the structure so that there are no band extrema at energies E_g from the conduction and valence band edges.

Interband (Bipolar) Lasers

The technology of band structure engineering, which includes superlattices, quantum confinement, and intentional incorporation of strain, has now become sufficiently advanced that it can be employed in a routine manner. As originally proposed, the modified band structure of strained III–V quantum-well structures can lead to significant benefits for diode laser performance, including reduced threshold current density, improved efficiency, and enhanced dynamic response and speed. Predicted advantages have been demonstrated, although for near-infrared devices these have not been quite as substantial as originally hoped because of the presence of phonon-assisted Auger processes which are not so susceptible to band structure engineering techniques. Strained layer lasers are now commercially available at a variety of MIR wavelengths, where the dominant nonradiative loss is via the direct interband Auger scattering routes.

From the point of view of the present article the main contribution of 'designed' strain splittings and quantum confinement is in the reduction of the Auger coefficient itself, by removing states that easily satisfy the momentum and energy conservation conditions required for the process to take place. However, in addition to this there can be a substantial reduction in the threshold carrier injection level required for population inversion in a laser. In real III–V semiconductors the heavy hole valence band mass, m_h, is so much greater than the electron mass, m_e, that the usual laser picture of degenerate electron and hole distributions does not apply. At normal carrier injection levels the quasi-Fermi level of the holes is above the top of the valence band resulting in a classical heavy hole distribution. Thus, the lower laser levels are almost completely filled with electrons, by contrast with the ideal situation of two mirror bands. This leads to an injection level for the laser threshold of greater than 2:1 required for the actual case compared to the ideal case. Since the Auger recombination rate per unit volume is approximately proportional to the cube of n, this factor of ~ 2 reduction in injection level can produce a factor of almost an order of magnitude reduction in this loss mechanism. Large biaxial strains, either compressive or tensile, can lead to a considerable reduction in the hole mass and hence in the density of states at the top of the valence band, so that the laser characteristics may then approach those of an ideal semiconductor, with $m_e = m_h$.

A further important loss mechanism is free hole absorption of the heavy holes resulting from intervalence band transitions. This can be effectively

eliminated, and other improvements made to laser performance, by the introduction of a strained layer structure which raises the degeneracy of the light and heavy hole at $k = 0$ and reduces the mass of the heavy hole. One example of this comes just from the symmetry of the problem, where clearly the cubic symmetry of the p-like valence band is not matched to the uniaxial symmetry of the laser beam. Application of biaxial or uniaxial strain removes the cubic symmetry, changing the relative energies of the p_x, p_y, and p_z valence states, and making it possible for almost all of the injected holes to be in the states of the correct symmetry to take part in the lasing action. The one parasitic phenomenon in semiconductor lasers which is hardly affected by band structure engineering is spontaneous emission, which will always make some contribution to the current density required at threshold.

The band structure of a bulk unstrained direct gap tetrahedral semiconductor is shown again for comparison in Figure 2. The effect of biaxial tension and compression is shown respectively in Figure 4a,b. In each case the lowest conduction band is approximately parabolic near the zone center, but becomes anisotropic with the electron dispersion at small k. The axial strain breaks the cubic symmetry of the semiconductor, introducing a tetragonal distortion

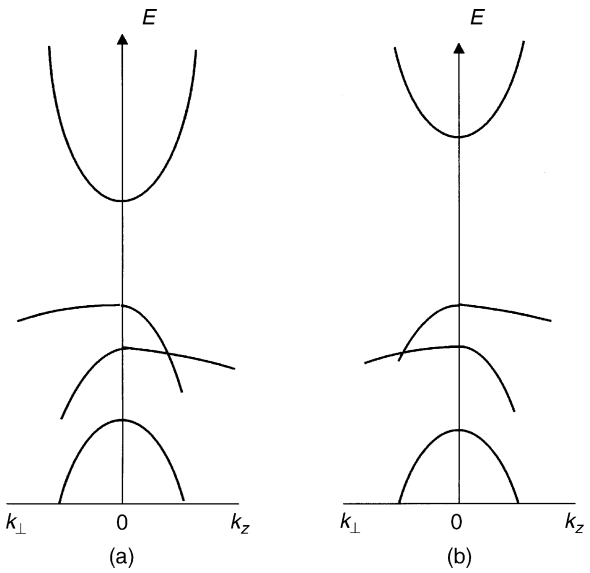

Figure 4 Schematic representation of the band structure of a direct gap tetrahedral semiconductor: (a) under biaxial tension the hydrostatic component of the tension reduces the mean bandgap, while the axial component splits the degeneracy of the valence band maximum and introduces an anisotropic valence band structure (the highest band being light along the strain axis, k_z and comparatively heavy perpendicular to that axis, $k_\perp$); (b) under biaxial compression the mean bandgap increases and the valence splitting is reversed.

which splits the degeneracy of the light and heavy hole states at the valence maximum, Γ, typically by about 60–80 meV for a 1% lattice mismatch. The resulting valence band structure is highly anisotropic (Figure 4a,b), with the band which is heavy along the strain axis, wavevector $k_\perp$, being comparatively light in the plane, along $k_\parallel$, and vice versa. The in-plane mass, $m_\parallel$, determines the density of states, and thus, under compression (Figure 4b), can be reduced according to the principles described above to improve conditions towards those for ideal laser operation: viz, (1) that there is only one band at the valence band maximum; (2) that it has an effective mass as close to that of the electron as possible; and (3) that above the Bernard–Duraffourg transparency condition, the polarization of the gain is anisotropic, with spontaneous emission and gain being suppressed along all directions except along the axis contributing to the laser beam.

Since the Auger recombination involves three carriers, the Auger current J_{NR} in a device with an undoped active region varies approximately as $J_{NR}(T) \propto C(T)n_{th}^3$, where $C(T)$ is the temperature-dependent Auger coefficient per unit volume and nth is the threshold carrier density. The influence of strain on Auger recombination has two aspects, as discussed above. First, J_{NR} is very sensitive to any reduction in n_{th} brought about by strain either through a decrease in h (heavy hole) mass or an increase in the optical transition strength. Secondly, strain may change the magnitude of $C(T)$ for the interband Auger processes described earlier (Figure 3). A simple calculation of Auger recombination in a quantum well heterostructure, assuming parabolic bands and Boltzmann statistics, shows that the coefficient increases exponentially with temperature as $C(T) = C_o\exp(-E_a/kT)$, where the activation energy, E_a, is approximately dependent on $(m_h)^{-1}$. Thus, both of these should be reduced by several orders of magnitude due to a reduction in the heavy hole mass, m_h, resulting from the strain effects discussed above.

Phonon Scattering: QWIPs and QC Lasers

Sub-band transitions are useful for MIR detectors and emitters because they make it possible to cover a broad range of MIR wavelengths using the same combination of large gap, InP-based and GaAs-based state of the art semiconductor alloys that are used for high-speed electronics and optical communications. They are the most advanced of the low-dimensional solids from the point of view of demonstrated detector performance. This superior control of materials results in high uniformity and has thus

allowed the demonstration of large 128×128 arrays with excellent imaging performance. Detectivities $D^* > 10^{10}\,\mathrm{cm\,Hz^{1/2}\,W^{-1}}$, low noise equivalent temperature differences, and excellent infrared video imaging can be achieved at 10 μm for temperatures $T = 10–80$ K.

Although the QWIP (quantum well infrared photodetectors) detectors showed promise for many years as alternatives to HgCdTe systems, the first intersub-band laser was not realized until the demonstration of the quantum cascade (QC) laser. Intersub-band (QC) lasers differ fundamentally from bipolar diode lasers in that they rely on only one type of carrier and on electronic transitions between conduction sub-band states arising from size quantization in semiconductor quantum heterostructures. These in-plane sub-bands have the same curvature (by contrast with the interband devices which have conduction and valence bands of opposite curvature), so that the joint density of states and corresponding gain spectrum (collision limited) is much narrower and approximately symmetric. Thus, the arguments which show that the Kane-type band structure is particularly disadvantageous for the overall Auger loss mechanism in interband diode lasers do not apply; the problems resulting from having $m_e \ll m_h$ are removed and the inversion is much less sensitive to thermal broadening of the electron distribution. In addition, there is no free hole absorption, and, since the component semiconductor materials are of comparatively wide bandgap, there is negligible intrinsic carrier concentration. However, the threshold current density tends to be rather large owing to the rapid nonradiative phonon relaxation of the population inversion.

In the original QC laser structure the electrons streamed down a potential staircase, sequentially emitting photons at the steps, consisting of coupled quantum wells in which the population inversion between discrete conduction band excited states was achieved by control of tunneling. The laser structure was grown with the $Al_{0.48}In_{0.52}As/Ga_{0.47}In_{0.53}As$ heterojunction material system lattice matched to InP. Electrical pumping was achieved by alternating 25 undoped coupled-well active regions with compositionally graded layers. The coupled-well region was essentially a four-level laser system, where a population inversion was achieved between the two excited states, $n = 3$ and $n = 2$. While the nonradiative phonon emission lifetime is short ($\tau_{32} \sim 4.3$ ps at the electric fields used in the tunneling process), strong coupling to an adjacent GaInAs well gives an even shorter lower state lifetime ($\tau_{21} \sim 0.6$ ps) from optical phonons with nearly zero momentum transfer between the strongly overlapped and closely spaced $n = 2$ and $n = 1$ states. This enables the achievement of a population inversion between these states. (Note that the separation between the $n = 2$ and $n = 1$ states, E_{21}, is designed to be approximately equal to the optical phonon energy.)

The radiative efficiency of these QC devices is unavoidably low ($<10^{-3}$) because most of the electrons in the upper sub-band relax within ~1 ps through nonradiative optical phonon emission before radiative transitions with a lifetime in the nanosecond range have a chance to occur. An alternative configuration has been proposed, the type II interband cascade laser (T2ICL), which retains the advantages of cascaded tunneling injection and wavelength tuneability but eliminates the nonradiative phonon path between valence and conduction bands of opposite curvature. In addition, band structure engineering ideas discussed above are incorporated to suppress the unwanted Auger processes; the design results in a light in-plane hole mass and the removal of resonances between the energy gap and intervalence transitions.

Dilute Magnetic Semiconductors

R R Gałązka, Polish Academy of Sciences, Warsaw, Poland

Introduction, General Remarks

Semimagnetic semiconductors (SMSs) are a group of solids at the interface between semiconductors and magnetic materials. Semimagnetic semiconductors, also referred to as dilute magnetic semiconductors, are semiconductor-based solid solutions where some of the cations are replaced by transition metals or rare earth elements. The crystallographic structure of the semiconductor is conserved; the lattice constant is a function of composition. From a magnetic point of view SMSs are disordered magnetic materials, since magnetic atoms are randomly distributed in the cation sublattice of the semiconductor compound. Table 1 presents the most complete list of bulk ternary SMSs. Quaternary SMSs are also investigated (e.g., PbSnMnTe or CdMnSeTe).

Generally speaking, in SMSs there coexist two interrelated and interacting subsystems: mobile delocalized charge carriers and localized magnetic moments connected with paramagnetic ions. Electronic (mainly optical) properties of SMSs have been the subject of intensive studies since early in 1970. Due to the strong spin exchange interaction between mobile carriers and localized magnetic moments (the exchange constant of the sp-d interaction is of the order of 1 eV for II–VI SMSs) significant changes of the band structure and behavior of the carriers were observed. A number of new physical phenomena were discovered, such as giant Faraday rotation (now important in magnetic field sensors and other applications in, for example, the automobile industry based on this strong magneto-optical effect), the magnetic field induced metal–insulator transition, the bound magnetic polaron and quantum thermomagnetic oscillations. Investigations of the influence of the electron subsystem on the magnetic properties of SMSs are connected with the observation of a ferromagnetic phase in PbSnMnTe induced by carrier concentration.

Molecular beam epitaxy (MBE) grown GaAs with Mn opened a new chapter of III–V SMSs showing ferromagnetic behavior with the highest transition temperature $T_c = 110\,\mathrm{K}$. In 1987 the first paper devoted to layered structure and magnetic properties of low-dimensional (LD) SMSs was published starting intensive studies of superlattices and other LD structures made of SMSs.

Energy Band Structure, Optical and Magneto-optical Properties of SMSs

Replacing cations such as Cd or Hg with a paramagnetic ion such as Mn in the same crystallographic structure does not markedly disturb the semiconductor properties of the material. The energy gap changes (increases) but the conduction and valence bands conserve their symmetry and character as in nonmagnetic semiconductor mixed crystals. The spin momentum of paramagnetic ions is connected with the 3d or 4f shell, for transition metals or rare earth elements, respectively. The energy level of 3d or 4f electrons lies below the top of the valence band and thus has negligible influence on its shape or that of the bottom of the conduction band. Thus all basic semiconductor optical properties connected with the band symmetry and topology are the same as for a typical semiconductor. These are described, for example, in articles on the lead salts (MS641) involving direct optical transitions at the L-point of the Brillouin zone, and on mercury cadmium telluride (MS639) with direct optical transitions at the Γ-point. The only influence of the magnetic subsystems on electrons comes from the spin exchange interaction between mobile carriers and localized magnetic ions. This interaction can be represented by a Heisenberg term

$$H_{\mathrm{ex}} = \bar{\sigma} \sum_i \bar{S}_i J(\mathbf{r} - \mathbf{R}_i) \qquad [1]$$

where $\bar{\sigma}$ and $\bar{S}$ are spin operators of the band electron and magnetic ion, respectively, the summation is over all lattice sites occupied by the magnetic ions, and J is the exchange constant.

Assuming mean field and virtual crystal approximations this term can be rewritten in the form which is periodic with a lattice constant:

$$H_{\mathrm{ex}} = x\langle \bar{S} \rangle_{\mathrm{av}} \bar{\sigma} \sum_R J(\mathbf{r} - \mathbf{R}) \qquad [2]$$

where x is the molar fraction of magnetic ions, $\langle \bar{S} \rangle_{\mathrm{av}}$ is the average over all magnetic ions and is directly

related to the magnetization of the sample:

$$M = N_0 g \mu \langle \bar{S} \rangle_{\mathrm{av}} \qquad [3]$$

N_0 is the number of unit cells per unit volume, g is the Lande factor for magnetic ions, and μ is the Bohr magneton.

The Heisenberg term must be added to the effective-mass Hamiltonian to solve the energy eigenvalue problem for SMSs. Realizing this was the turning point in understanding their properties and provided a basis for this group of alloys to be distinguished from other semiconductor mixed crystals. Since that time SMSs have become the subject of intensive studies in Europe and elsewhere.

The exchange interaction depends on the ion spin and the exchange constant. The spin of Mn is the highest for transition metals and equals five Bohr magnetons, and whilst a typical value for the exchange coupling between magnetic ions $J_{\mathrm{d-d}}$ is 10^{-3} eV, the exchange constant for electrons and holes with magnetic ions $J_{\mathrm{sp-d}}$ is about 1 eV in SMSs.

The exchange interaction is also strongly temperature and magnetic field dependent. As the macroscopic magnetization of a sample is proportional to the thermodynamic average value of the magnetic ion spin, to a good approximation we can replace the ion spin operators in the Hamiltonian by their average value, calculated or taken from measurements of the magnetization. From typical magnetic functions we can thus obtain information on the electron behavior.

In semiconductors, an external magnetic field acts on both the orbital motion and the spin of electrons producing Landau quantization and spin splitting, to an extent dependent on the effective mass of the carriers. The exchange interaction acts on their spin only and is, in effect, mass independent. Because of this, and also the large value of $J_{\mathrm{sp-d}}$, the band structure in turn changes drastically under the influence of an external magnetic field and depends strongly on temperature. From **Figure 1** we can see that the very typical structure of the degeneracy of the light and heavy hole valence bands disappears in SMS when a magnetic field is applied. The change is accompanied by a drastic increase of hole mobility like that observed in low-dimensional structures. In SMS such as $Hg_{1-x}Mn_xTe$ or $Hg_{1-x}Mn_xSe$ (for $x \leq 0.07$) (**Figure 2**), the magnetic field produces an overlap of the valence and conduction bands, an effect never observed in nonmagnetic semiconductors.

Impurity levels are also influenced by exchange interactions: the ionization energy of an acceptor

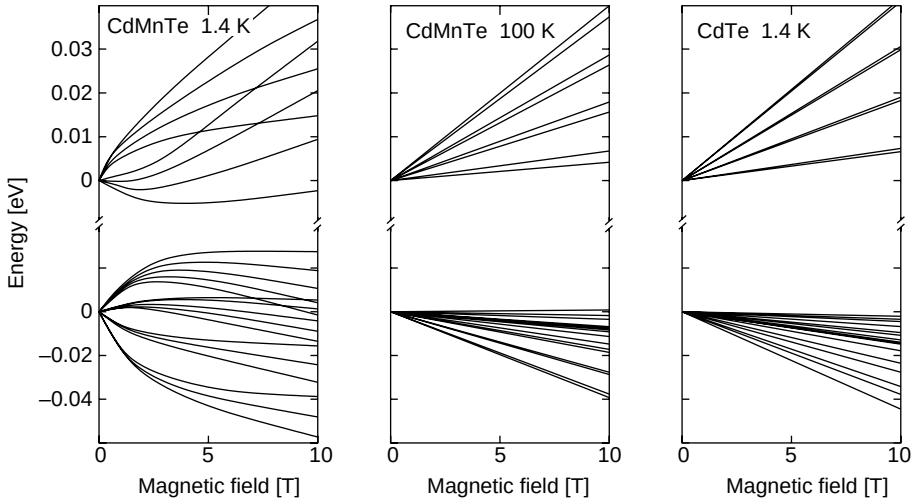

Figure 1 Conduction and valence band quantization in an external magnetic field for $Cd_{0.95}Mn_{0.05}Te$ and CdTe. Spin splitting, which is very weak in CdTe, is the main effect in CdMnTe. Notice the almost equal splitting of the heavy- and light-hole bands in CdMnTe. The influence of exchange interaction is visible even at 100 K. The picture of CdTe over this range of temperature is practically unchanged. Reproduced from Gałązka RR (1987) Semimagnetic semiconductors. *Europhysics News* 18(6): 90–92.

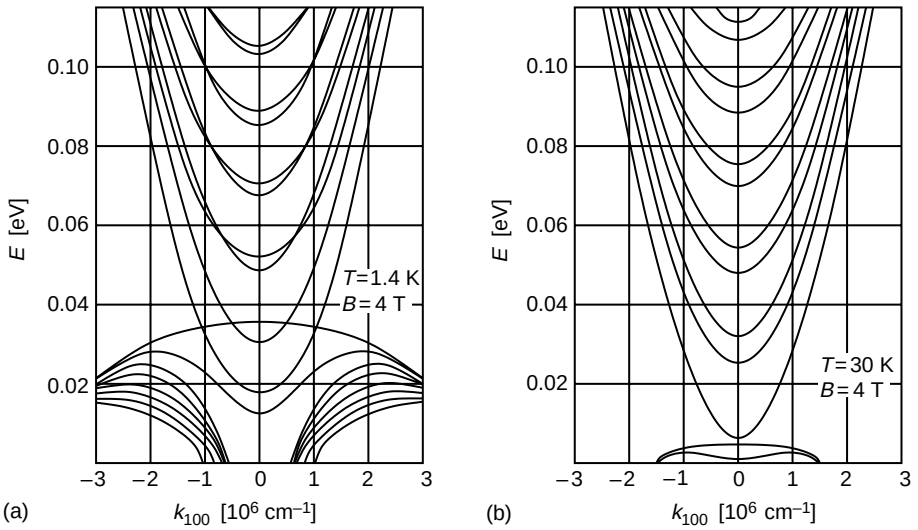

Figure 2 Energy band structure of $Hg_{1-x}Mn_xTe$, $x = 0.02$, calculated at 14 K (a) and 30 K (b) in a magnetic field of 4 T. After Gałązka RR (1978) Semimagnetic semiconductors based on HgMnTe and CdMnTe. Reproduced from Wilson BLM (ed) ICPS 14th, Edinburgh Institute of Physics, Conference series no. 43, 1978, p.133–140.

decreases and its wavefunction becomes anisotropic under the influence of a magnetic field. Both effects produce a giant negative magnetoresistance and a field-induced insulator–metal transition. Indeed all (particularly optical) properties susceptible to being changed by a magnetic field are very different in SMSs from those of standard semiconductors: the Faraday effect., Shubnikov–de Haas oscillations, interband magnetoabsorption, luminescence and spin flip Raman scattering (see below) become strongly dependent on temperature and magnetic field.

In the absence of a magnetic field, the average value of the ion spins is zero, the magnetization is zero too, and SMSs should behave as typical non-magnetic semiconductors. Whereas this is true for delocalized band electrons, when an electron is localized around an impurity, a bound magnetic

polaron can be observed. This concept was first introduced to explain the behavior of magnetic semiconductors (Eu chalcogenides) and then later was applied also to SMSs. A localized electron can produce a spontaneous magnetization within the range of its wavefunction via the exchange interaction. Local ferromagnetic ordering in this range produces a Stokes shift in spin-flip Raman scattering even in the absence of an external magnetic field and other related phenomena. Local fluctuations of magnetization and a detailed knowledge of electronic states are essential for a theoretical description of this effect. The bound magnetic polaron is a subtle example of the feedback between electronic and magnetic subsystems present in SMS.

Magnetic Properties

Magnetic properties of SMS connected with the exchange interaction between paramagnetic ions are similar to those of other dilute magnetic materials. The broad range of possible magnetic ion concentrations (up to $x = 0.80$ in $Zn_{1-x}Mn_xTe$ and $x = 0.70$ for $Cd_{1-x}Mn_xTe$) allows us to observe the evolution of magnetic interactions in the same crystallographic structure as a function of magnetic ion concentration. A continuous transition from diamagnetic behavior (for $x \leq 0.005$) of the host semiconductor, to paramagnetism, spin-glass (for $x \geq 0.02$) and finally antiferromagnetic order has been observed. Type III antiferromagnetic ordering is observed for $x > 0.6$ indicating that the magnetic elementary cell contains two elementary cells of the cation sublattice. From a crystallographic point of view the magnetic subsystem is disordered; the distribution of magnetic atoms on the cation sublattice is random.

A spin-glass-like state is observed in SMSs in the broadest range of paramagnetic ion concentrations ($0.02 \leq x \leq 0.60$) below and above the percolation threshold (Figure 3). Indeed the temperature dependence of the magnetic susceptibility below and above the transition temperature and their dynamic properties at low and high magnetic fields suggest rather the existence of two spin-glass phases arising from the competition between spin-glass and clustering behavior. Below the percolation threshold ($x \leq 0.17$ for fcc lattice) the mechanism responsible for a spin-glass phase is even less clear, although, for such a dilute system it must be long-range to produce freezing of the spins.

The antiferromagnetic order has been inferred from specific heat and magnetic susceptibility measurements, and additional information concerning this phase has come from neutron diffraction studies: only a certain fraction of the total number of magnetic ions (e.g., about 50% for CdMnTe, $x = 0.65$) is well ordered; the rest remain in a disordered spin-glass phase. Thus a mixed phase (antiferromagnetic and spin-glass coexisting together) rather than a truly antiferromagnetic phase is observed.

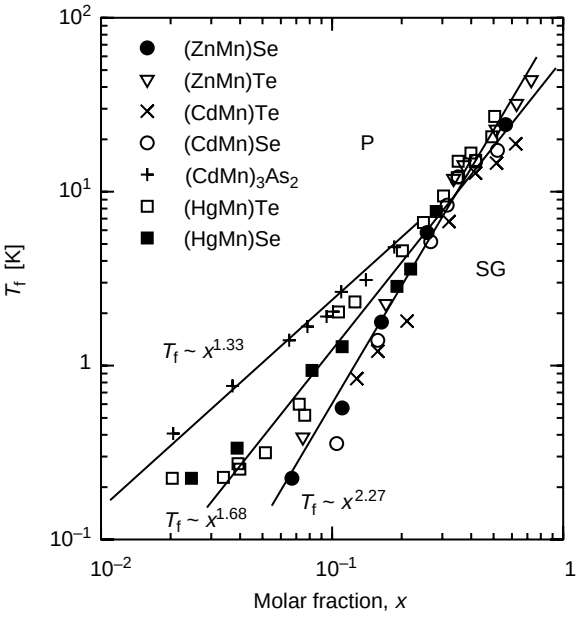

Figure 3 Magnetic phase diagram for the listed SMSs. P indicates the paramagnetic region, SG indicates the spin-glass region. Reprinted in part from Gałązka RR (1995) Influence of electron subsystem on magnetic properties of semimagnetic semiconductors. Copyright Elsevier Science.

The influence of carrier concentration on magnetic properties has been extensively investigated in metallic alloys. Several IV–VI semiconductors like SnTe can exhibit quite high metallic-like carrier concentrations. In the quarternary alloy PbSnMnTe, the concentration of holes can be varied by annealing in the range 10^{20} to 5×10^{21} cm^{-3}. In $Pb_{0.25}Sn_{0.72}Mn_{0.03}Te$ an abrupt transition from the paramagnetic to ferromagnetic phase has been found for $p > 3 \times 10^{20}\,cm^{-3}$. The Curie temperature is a function of hole concentration, but the Mn ions conserve their magnetic moment of five Bohr magnetons. The magnetic phase diagram for this first ferromagnetic SMS (Figure 4) is thus three dimensional (T,x,n) in contrast to the

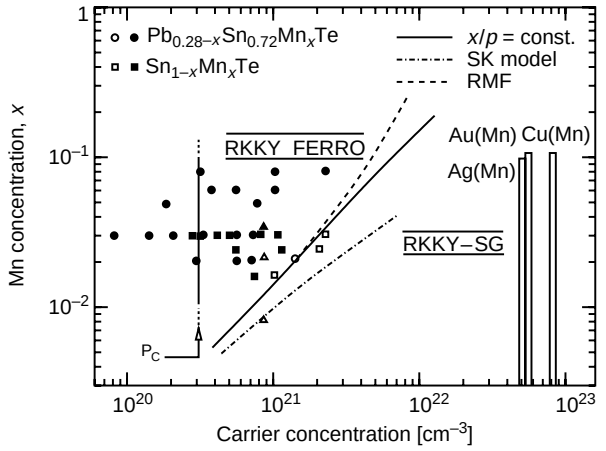

Figure 4 Magnetic phase diagram for PbSnMnTe (•) and SnMnTe (▪). The ferromagnetic phase is observed in the region above the critical carrier concentration p_c and the straight line defined by the equation $x/p = \text{const}$. Away from this region a spin-glass state is observed. Calculated phase boundaries between the ferromagnetic and spin-glass state are also shown for two theoretical models: SK: Sherrington–Kirkpatrick model and RMF: random mean field model. Canonical metallic spin-glasses are also shown. Reproduced from de Jonge WJM, Story T, Swagten HJM and Eggerkamp PJT (1992) Carrier-induced breakdown of ferromagnetism. *Europhysics Letters* 17: 631–636.

two-dimensional diagram (T,x) usually presented for magnetic alloys. Even a low concentration of spin polarized carriers when optically pumped can change the magnetization of HgMnTe owing to the strong exchange interaction of carriers with magnetic ions.

Low-Dimensional (LD) SMSs: Magneto-optical and Spintronic Effects

Modern technology such as MBE makes it possible to obtain quasi-3D SMSs in the whole range of x from 0 to 1. It also gives broad possibilities to create different combinations of semiconductor, SMS, and magnetic materials. In addition the dimensionality of LD structures influences the properties of both electronic and magnetic subsystems. Further there is almost always some strain in the system which also influences the properties of superlattices and other LD structures. Studies of LD SMSs not only extend the material base but open a new area of dimension-dependent phenomena and interactions in SMS systems.

Among many effects observed in LD SMS structures we will mention only a few phenomena, where exchange interaction is essential and which cannot be observed in nonmagnetic LD semiconductors. In all cases the giant (magneto-optical) Zeeman splitting caused by the exchange interaction plays a key role.

In superlattices made of ZnSe/ZnMnSe with a small amount of Mn, the band offset of conduction and valence bands is negligible at zero external magnetic field. In the presence of an external field the conduction and valence bands of ZnMnSe split creating a spin-superlattice because the spin-split states allow only one spin configuration. The possibility of the existence of such a spin superlattice was earlier suggested for SMSs and later experimentally observed.

If the superlattice, quantum well or heterostructure is made of SMS and non-SMS material (e.g. ZnTe/CdMnSe or CdTe/CdMnTe) one can exploit the drastic differences in the Zeeman splitting occurring in different layers to pinpoint the localization in space of specific electronic states. If one (hole or electron) or both states involved in optical transitions originate from the SMS layer, this state will show a very strong Zeeman splitting in the external magnetic field. Thus the SMS component can be used as a 'marker' in order to bring out the general properties of the wavefunction distribution.

Excitonic Zeeman splitting in non-magnetic quantum wells with SMS barriers can be applied to studies of the shape of interface profile and the influence of the growth conditions on the shape of the interface. If the interface is not completely flat, even a small fraction of magnetic atoms in the well close to the interface can significantly enhance the Zeeman exciton splitting in the quantum well. The sensitivity of this method allows one to detect the sharpness of an interface with one monolayer accuracy.

The MBE technique opens up possibilities of creating hybrid structures with SMSs, useful for spintronic devices such as spin filters, spin transistors and tunneling magnetoresistance sensors. Very importantly, it has been realized that SMSs are highly suitable to form the ferromagnetic spin injecting electrodes in such systems where simple metallic electrodes fail because of the large electrical resistance mismatch between the electrode and the semiconductor in which the spin is being processed. A further possibility is to fabricate hybrid metallic ferromagnetic–SMS structures. In such a case one can make use of the magnetic field exerted by the metallic ferromagnet positioned very close (on an atomic scale) to the SMS layer or quantum structure, thus affecting the spin splitting in the latter. One could use such a fringe field to shape the band edges in such a fashion that an additional localization of the carriers in a two-dimensional quantum well is induced

leading to formation of quantum wires or dots. In other applications a spin-coherence storage effect has been obtained for core electron polarization in Mn-doped ZnSe quantum wells. The optically pumped conduction electron spin polarization generates a nonequilibrium spin polarization of the paramagnetic core electron spins(3d in the case of Mn) through the core–conduction-electron coupling. This core electron spin polarization persists long after the conduction electron spin polarization has decayed away and presents an interesting avenue towards information storage.

The physics of SMSs is currently a well-established part of solid state physics. In the investigations of bulk crystals and LD structures many problems are solved and new problems are waiting further research. Particularly important seems to be investigation of layers and LD structures because of the broad technological possibilities and because of the new important factor (i.e., dimensionality) whereby spin-dependent phenomena can be intentionally regulated.

List of Units and Nomenclature

g	Lande factor for paramagnetic ion
H_{ex}	Heisenberg spin exchange Hamiltonian
J_{d-d}	exchange constant for coupling between paramagnetic ions (transition metals)
$J(\bar{r}-\bar{R})$	exchange constant
J_{sp-d}	exchange constant for electron or hole coupling with paramagnetic ions
LD	low dimensional
M	magnetization
MBE	molecular beam epitaxy
N_0	number of unit cells per unit volume
SMS	semimagnetic (diluted magnetic) semiconductor
$\langle\bar{S}\rangle_{av}$	average value of spin operator
T_c	Curie temperature
V_h	hybridization energy
x	molar fraction of paramagnetic ions
$\boldsymbol{\mu}$	Bohr magneton
$\overline{\boldsymbol{\sigma}}, \bar{S}$	spin operators

Background

Gallium Arsenide (GaAs) is an important semiconductor that has come to dominate the field of optoelectronics by virtue of its favorable electro-optical properties and the ease by which it can be controllably modified by extrinsic means; combining it with its large family of related alloys ($Al_xGa_{1-x}As$, $In_xGa_{1-x}As$, $GaAs_xP_{(1-x)}$, $(In_xGa_{(1-x)})_yAsN_{1-y}$) and via the growth of hetero-structures with reduced dimensionality (Quantum Wells-2D, Wires-1D, and Dots-0D). In such low dimensional semiconductor nanostructures, quantum mechanical effects are directly exploited to customize and dramatically enhance electro-optical properties. Such investigations of the fundamental electro-optical properties of GaAs-based compounds has resulted in the emergence of several new device concepts such as the Quantum Cascade laser, led to the discovery of new physical phenomena like the fractional Quantum Hall effect, and may pave the way for an entirely new class of opto-electronic devices with true quantum functionality.

In the following, we explore the fundamental physical and electro-optical properties of GaAs and its related alloys and illustrate the considerable impact this remarkable family of materials has had on modern semiconductor devices.

Fundamental Physical Properties

The crystal structure of GaAs (Figure 1 – inset) consists of two interpenetrating face centred cubic lattices that accommodate the group III and V atoms respectively. The sub-lattices of Ga and As are shifted from each other by $a/4$ along the [111] body diagonal, where a is the lattice constant, forming the well-known zincblende crystal structure. For stochiometric GaAs, the lattice constant is $a = 0.56536(1)$ nm at room temperature which translates to a Ga–As nearest neighbor separation (bond length) of 0.2308 nm.

Figure 1 summarizes the variation of the lattice constant for a number of GaAs related III–V semiconductor alloys, plotted as a function of their fundamental electronic bandgap. Particularly relevant is AlAs, which also crystallizes in the zincblende form and has a lattice constant (a(AlAs) = 0.5660(2) nm) almost identical to that of GaAs ($\Delta a < 1\%$). The sole fact that the $Al_xGa_{(1-x)}As$ alloy can be almost perfectly lattice matched to GaAs over its entire compositional range, whilst exhibiting near continuously variable electronic and optical properties, is the principal reason for the key role GaAs-related materials play in semiconductor opto-electronic devices. We continue by investigating the electronic and optical properties of the $Al_xGa_{(1-x)}As$ family of materials and discover why they are particularly suited to opto-electronic device applications.

Summary of Electronic Properties of GaAs and $Al_xGa_{1-x}As$

The optical properties of semiconductors are determined principally by inter-band radiative transitions involving electronic states in the vicinity of the conduction (CB) and valence band (VB) extrema. Consequently, in the following we focus on electronic properties of GaAs close to these points and substantiate our discussion using experimental data obtained from optical spectroscopy.

GaAs Bandstructure

GaAs is a direct-gap semiconductor ($E_g = 1.42$ eV at 300 K), both the conduction band minimum and

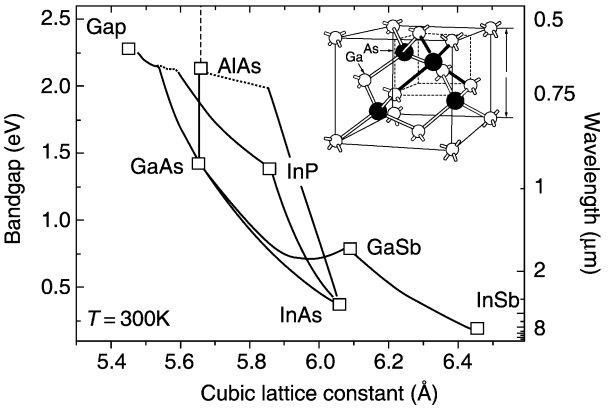

Figure 1 Fundamental bandgap of selected compounds within the III–V semiconductor family plotted as a function of the cubic lattice constant – a. The inset depicts the zincblende crystal structure within the GaAs unit cell. Data obtained from various sources, see for example Brozel MR and Stillman GE (eds) (1996) *Properties of Gallium Arsenide*, INSPEC, emis Datareviews Series No.16 and Loffe Institute, on NSM semiconductor data repository at http://www.ioffe.rssi.ru

valence band maximum occurring at the center of the Brillouin zone (Γ-point). Figure 2 summarizes our discussion of the electronic structure of GaAs, depicting the bandstructure schematically within the first Brillouin zone. The valence electron configurations of Ga and As atoms result in the band edge CB states being two-fold degenerate due to the electron spin and characterized by an almost isotropic effective mass of $m^*_\Gamma = 0.068\, m_o$. For GaAs heterostructures with reduced dimensionality, the very weak anisotropy of the conduction band states can generally be ignored when calculating the lowest energy confined electron states but has a significant impact on higher quantized levels and must, therefore, be included. In addition to the fundamental CB minimum at the zone center or Γ-point of the Brillouin zone, satellite minima occur at the six equivalent X-points ($k = (1/a, 0, 0)$) and eight equivalent L-points ($k = (1/a, 1/a, 1/a)$). The X-point and L-point minima lie $\Delta E_{\Gamma X} = 0.49$ eV and $\Delta E_{\Gamma L} = 0.32$ eV above the Γ-minimum at low temperatures ($T = 4.2$ K) and are characterized by strongly direction dependent effective masses parallel (∥) or perpendicular (⊥) to the principal axes. Electronic states in the vicinity of these minima are termed the X and L-valleys respectively and have a significant impact on high-energy electron transport in devices such as HEMTs and in avalanche carrier multiplication processes, but do not generally play a significant role in the optical properties of the binary – GaAs. However, satellite CB minima can strongly influence the optical properties of GaAs–AlAs superlattices and QWs that can exhibit a type-II band alignment for GaAs layer thicknesses < 6 nm. In this case, the electrons (holes) are localized in the AlAs (GaAs) layer and the nature of the AlAs X-states dominates the optical properties.

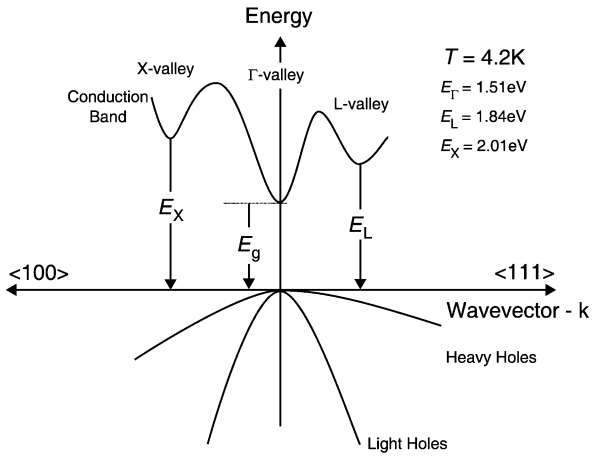

Figure 2 Schematic representation of the bandstructure of GaAs showing just a single conduction band over whole Brillouin zone in Γ-L and Γ-X directions only and neglecting the split off band that does not significantly influence electrical or optical properties.

Table 1 Low temperature GaAs effective masses for electrons (upper panel) and holes (lower panel). Values marked with * are inferred from measurements on GaAs based heterostructures and values marked ** are calculated

	Crystallographic axis	*Effective Mass (m_o)*
CB-Γ minimum	*Isotropic*	0.068(2)
CB-X minimum*	∥ [100]	1.9
	⊥ [100]	0.19
CB-L minimum**	∥ [111]	1.9
	⊥ [111]	0.075
VB-HH	[111]	0.72(3)
	[100]	0.33(6)
VB-LH	[111]	0.08(3)
	[100]	0.09(4)

The valence band (VB) states of GaAs are four-fold degenerate at the bandedge and, characteristic of most zincblende semiconductors the valence bandstructure, is significantly more strongly anisotropic than the CB states discussed above. Away from the Γ-point, the four-fold degeneracy of the valence band states is lifted into 2 doubly degenerate sets of bands termed the heavy (HH) and light hole (LH) bands by virtue of their zone center effective masses (Table 1). The HH band is considerably more strongly anisotropic than the LH band and is characterized by a much larger effective mass along the [100] direction when compared with [001], $m^*_h[111] > m^*_h[001]$. The anisotropy of the LH states is much weaker than for the HH band, with approximately equivalent effective masses along [100] and [111] crystallographic directions. Typical values for the CB and VB effective masses are summarized in Table 1, obtained using a variety of experimental techniques at low temperature.

Temperature Dependence

Quantitative values given above relate specifically to the bandstructure at liquid helium temperatures ($T = 4.2$ K). Increasing temperature results in a narrowing of many of the conduction–valence band gaps discussed above and lowering of the effective masses. This temperature dependence of the fundamental bandstructure arises from the anharmonic dilation of the lattice and from interactions with phonons, the population of which becomes significant at elevated temperature. In the simplest picture, one can visualize the effect of increasing temperature

Table 2 Varshnii coefficients for the Γ, L, and X CB minima in GaAs relative to the top of the VB. For the Γ minimum a number of experimental works are available and the value cited is the average

	$\alpha(10^{-4}$ eV/K)	β (K)
Γ point	5.45	210
X point	7.20	205
L point	6.05	204

as a shrinking of the first Brillouin zone as the lattice constant increases, and with a subsequent increase of the band curvature leading to ~5–10% lighter effective masses at room temperature than at 4.2 K. In addition, the dramatic increase of the phonon population at elevated temperatures results in a narrowing of the fundamental bandgaps. Phenomenologically, the temperature dependence of the fundamental bandgaps can be well described by the well-known Varshnii relation

$$E_g(T) = E_g^{T=0\ \mathrm{K}} - \frac{\alpha T^2}{(T+\beta)} \qquad [1]$$

where α and β are experimentally determined constants which are sensitive to the bandgap of interest (e.g. Γ, X, or L, etc.) as summarized in Table 2.

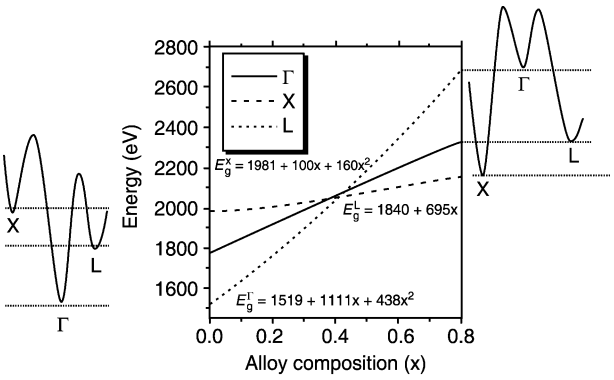

Figure 3 The absolute energy (at 4.2 K) of the Γ, X and L CB minima for $Al_xGa_{(1-x)}As$ as a function of aluminum composition up to $x \sim 0.8$. Higher compositions are not given due to the well-known unreliability of experimental data due to instability of high Al content $Al_xGa_{(1-x)}As$ due to oxidation. Polynominals describing each curve are also plotted. Data taken from the following sources: Γ-minimum, Bosio C, Staehli JL, Guzzi M, Burri G and Logan RA (1988) Direct-energy-gap dependence on Al concentration in $Al_xGa_{1-x}As$. *Physical Review* 38: 3263–3268, X-minimum, Guzzi M, Grilli E, Oggioni S, Staehli JL, Bosio C and Pavesi L (1992) Indirect-energy-gap dependence on Al concentration in $Al_xGa_{1-x}As$ alloys. *Physical Review* B45: 10951, and L-minimum, Henning JCM, Ansens JPM and Roksnoer PJ (1986) Spectroscopic determination of L6 conduction-band minima in $Al_xGa_{1-x}As$. *Journal of Physical Chemistry*, L335.

GaAs/$Al_xGa_{(1-x)}As$ – The Most Significant Alloy

Incorporation of aluminum into the GaAs crystal to form $Al_xGa_{(1-x)}As$ results in a number of profound and important modifications of the electronic properties compared with pure GaAs. Aluminum is more strongly electronegative than Gallium and consequently the electron charge distribution along the Al–As bonds are more strongly localized towards the group-III site than for Ga–As bonds which qualitatively results in a widening of the fundamental bandgap with increasing aluminum composition (x).

The variation of the $Al_xGa_{(1-x)}As$ energy gaps for the Γ, X, and L conduction band minima at low temperature are summarized in Figure 3 as a function of the alloy composition up to $x \sim 0.8$. The data of Figure 3 reflect the results of optical emission and absorption measurements and are most reliable for more dilute compositions since crystalline AlAs and high Al content $Al_xGa_{(1-x)}As$ oxidize rapidly under atmospheric conditions.[1] With increasing Al content, the Γ-minimum shifts rapidly to higher energy whilst the shift of the L and X-minima is significantly less pronounced. At $x \sim 0.4$ the Γ and X minima intersect and for $x > 0.4$, the lowest energy conduction band minimum shifts to the X-point and the fundamental bandgap becomes indirect. This effect is responsible for the short wavelength cutoff of $Al_xGa_{(1-x)}As$/GaAs based multi-quantum well LEDs at $\lambda \sim 630$ nm since the transition to an indirect bandgap is accompanied by a drastic reduction of the radiative efficiency. Shorter wavelength LED operation region of the spectrum is possible by moving to other related alloys in the III–V family such as $(Al_xGa_{1-x})_{0.5}In_{0.5}P$ (520–630 nm) and $(GaAs)_{0.6}P_{0.4}$ (~600 nm). We return to discuss the optical properties of $Al_xGa_{(1-x)}As$ below in Section 4.

As expected, the pronounced modifications of the bandgap induced by Al incorporation are accompanied by modifications of the carrier effective masses and temperature dependence of the bandgap. These compositional dependence of the Γ, X, and L conduction band and HH and LH valence band effective masses are summarized in Table 3.

It should be stressed that the relationships given in Table 3 should be considered to be accurate at the

[1] The ease by which high Al content $Al_xGa_{(1-x)}As$ can be oxidized is of great technological benefit for device fabrication. Examples include the formation of current apertures in injection lasers, $Al_xGa_{(1-x)}As$ etch stops etc. For a summary Brozel MR and Stillman GE (eds) (1996) *Properties of Gallium Arsenide*, INSPEC, emis Datareviews Series No.16.

Table 3 Compositional variation of the electron and hole effective masses for $Al_xGa_{(1-x)}As$ taken from various sources: Data drawn from the following sources: Lautenschlager Γ-P, Garriga M, Logothetidis S and Cardona M (1997) *Physical Review* B35: 9174 and Grilli E , Guzzi M and Zamboni R (1992) *Physical Review* B45: 1638. Thurmond CD (1975) L-minimum. *Journal Electrochemical Society,* 122: 1133 and Aspines DE (1976) L-Minimum. *Physical Review* B14: 5331

	Crystallographic Axis	*$Al_xGa_{(1-x)}As$ Effective Mass (m^0)*
CB-Γ minimum	*Isotropic*	$0.0682 + 0.0835x$
CB-X minimum	∥ [100]	$1.9 - 1.02x$
	⊥ [100]	$0.19 + 0.06x$
CB-L minimum	∥ [111]	$1.9 - 0.58x$
	⊥ [111]	$0.075 + 0.075x$

VB-LH	DOS	$0.087 + 0.09x$

$\sim 5-10\%$ level, since reliable experimental data only exists for the GaAs binary endpoint and more dilute alloy compositions ($x < 0.3$).

The Varshnii coefficients of the temperature dependence of the bandgap vary with $x(0 < x < 0.5)$ according to $\alpha(x) = 5.5 + 3.35x(10^{-4}\,\text{eV/K})$ and $\beta(x) = 225 + 88x(\text{K})$ respectively. Recent photoreflectance measurements have indicated that these simple linear relationships do not hold well over the entire compositional range with evidence for some bowing of $\alpha(x)$ and $\beta(x)$ closer to the AlAs binary endpoint.

GaAs/$Al_xGa_{(1-x)}As$ Hetero-interfaces

Modern epitaxial growth techniques now enable the routine fabrication of semiconductor heterostructures consisting of a well-defined sequence of atomically precise layers of different materials, which together manipulate the opto-electronic properties to suit a particular device or application. Of particular technological relevance is the GaAs/$Al_xGa_{(1-x)}As$ hetero-interface since both materials are lattice matched for $0 < x < 1$ (Figure 1), and multiple layers of GaAs and $Al_xGa_{(1-x)}As$ can be readily deposited without introducing defects into the crystal which seriously degrade optical performance. In this section, we summarize the most salient features of the GaAs/$Al_xGa_{(1-x)}As$ hetero-interface, with particular emphasis on the electronic properties before continuing to discuss the optical properties of $Al_xGa_{(1-x)}As$ in Section 4.

The most important parameters that characterize a semiconductor hetero-interface are the magnitude and sign of the conduction (ΔE_c) and valence band (ΔE_v) offsets. These parameters determine how effectively electrons and hole are localized within specific epilayers and are related to the total difference in the bandgap ($\Delta E_g = E_g^{AlGaAs} - E_g^{GaAs}$) via $\Delta E_g = |\Delta E_c + \Delta E_v|$. Taking the mean of 21 separate optical and electrical investigations between 1985 and 1995, the currently accepted value for the band-offset ratio is $\Delta E_c/\Delta E_v \approx 64/36$, with an associated variance over the body of the data of approximately $\pm 8\%$. It should be stressed that the majority of the experimental investigations of the band offsets at the GaAs–$Al_xGa_{(1-x)}As$ hetero-interface have been performed for alloy compositions $x < 0.4$ and much less experimental data exists regarding the variation of $\Delta E_c : \Delta E_v$ with higher Al composition. A rather old review (*c.* 1992), collating data available, at the time has indicated that the absolute energies of the conduction and valence band offsets vary with composition as $\Delta E_c = (800 \pm 30)x$ meV for $(x < 0.4)$ and $\Delta E_c = (510 \pm 40)x\,(0 < x < 1)$. It is widely assumed that the band offsets do not change appreciably with temperature.

Optical Properties of GaAs and Significant Alloys

Optical Absorption

Monochromatic light of energy $E_p = \hbar\omega$ incident on the surface of GaAs may stimulate interband optical transitions in which a photon is absorbed and an electron from the valence band is promoted into the conduction band. In processes involving a single photon, the photon momentum is entirely negligible compared with the electron and optical transitions are vertical in k-space.

Following excitation, the electron–hole (e–h) pairs relax extremely rapidly ($\tau_{LO} \sim 150$ fs) by sequential emission of multiple longitudinal optical (LO) phonons until their energy becomes close to the bandedge and further LO-phonon emission is forbidden by energy conservation requirements. This initial phase of the carrier relaxation can be extremely rapid, the LO-phonon scattering time in GaAs being due to the semi-polar nature of the crystal. After this initial

rapid relaxation phase, the electron and hole populations relax principally via acoustic phonon emission ($\Delta E < 2$ meV) over much longer timescales ($\sim 10-300$ ps), which depend upon the lattice temperature, carrier type and density. Finally, the electron and hole populations form thermal distributions via carrier–carrier and Auger scattering over longer timescales up ~ 500 ps. During these final relaxation and thermalization phases, e–h pairs are depleted from the conduction and valence bands by interband radiative recombination.

For energies less than the bandgap, the semiconductor normally appears transparent, although the presence of impurities and defect levels can result in a weak absorption 'tail' below the gap. Optical absorption by impurities results in only electrons in the conduction band or holes in the valence band. The wavelength of light that just causes the creation of an electron–hole pair is given by $\lambda = hc/E_g$, where h is Planck's constant, c the speed of light and E_g the fundamental bandgap. As described in Section 3.1, this corresponds to approximately $\lambda = 870$ nm at room temperature, depending on the type and level of the doping. Light with wavelength much shorter than this, corresponding to energies much larger than E_g, will create electron–hole pairs higher up the band structure with higher energy and be strongly absorbed. These carriers, however, will rapidly lose this excess energy by interacting with the lattice and relax to the minima of the conduction and valence bands.

The optical absorption is usually quantified by the absorption coefficient, α, which is a function of the photon energy or wavelength and is shown for GaAs in Figure 4. The fraction of the light intensity that is absorbed in the semiconductor after passing through a thickness x is given by $f = (1 - \exp(-\alpha x))$ and the fraction of light intensity that is transmitted is then simply $\exp(-\alpha x)$. α is usually expressed in units of cm^{-1} and at energies above the bandgap has values typically between $10^4-10^5\,\mathrm{cm}^{-1}$. Light with wavelength corresponding to energies above the bandgap is usually absorbed very efficiently (>90%) within a few microns. Increasing the bandgap, say by adding aluminum, would have the effect of making the material more transparent at a given wavelength.

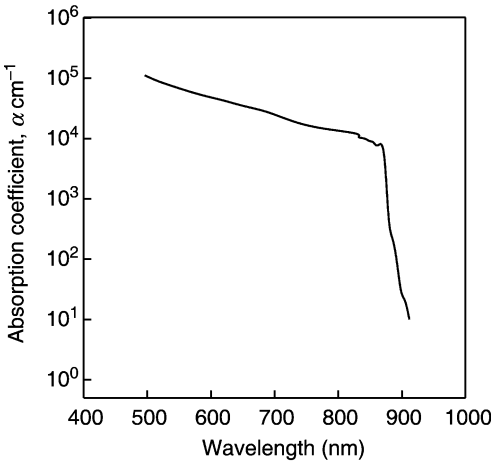

Figure 4 Variation of the absorption coefficient, α, as a function of wavelength in GaAs at room temperature.

Optical absorption is an important process as it allows light to be converted to free carriers, and hence a current in the semiconductor. This forms the basis of optical detection by most types of semiconductor photodetectors.

Refractive Index

The speed (more precisely the phase velocity) of light, of all wavelengths, in a vacuum is constant at $\sim 3.10^8\ \mathrm{m\,s}^{-1}$. The speed of light in a medium such as a semiconductor is slower due to the microscopic interaction of the electromagnetic wave with the crystal. The refractive index, R_I, is defined as the ratio of the speed in a vacuum to the speed in the semiconductor. Increasing the density of the medium decreases the speed. Changing the semiconductor, for example by adding aluminum, not only increases the bandgap as discussed above, but also decreases R_I for a given wavelength.

At wavelengths corresponding to an energy just below the bandgap of the semiconductor, the material is essentially transparent, i.e., the absorption coefficient is low.

Light can be made to travel in a waveguide comprising this semiconductor, provided that it was surrounded by semiconductor material of a lower R_I. Light is totally internally refracted at the interface between the GaAs and $Al_xGa_{1-x}As$ and so cannot escape. The semiconductors with a smaller R_I usually have a larger bandgap, so are even more transparent at the operating wavelength and help to physically confine the electrons and holes within the GaAs.

The R_I can be changed by injecting charge (electrons or holes) into the semiconductor, by changing the temperature (which changes the bandgap), and by applying an electric field. This forms the basis of operation of devices such as optical modulators. Unfortunately it also can cause 'chirping', i.e., the unwanted change in light

intensity or wavelength as the charge or temperature changes.

The R_I which is a function of the wavelength, is sometimes expressed as a complex number:

$$R_I = n + ik \quad [2]$$

where n is the real part and k is the imaginary part called the extinction coefficient, which is related to the absorption coefficient. Typical room temperature values of n for GaAs vary from about 3.37 at $\sim$1.55 μm to 3.87 at 620 nm.

Common GaAs Based Alloys for Novel Technological Applications

GaInP/AlGaInP – 'Red, Orange and Green Emission'
The alloy $(Al_xGa_{1-x})_{0.52}In_{0.48}P$ is becoming technologically important as it has the same lattice parameter as GaAs for all values of x, so can grow lattice matched on GaAs. This alloy system offers the largest direct bandgap of virtually any III–V (excluding the Nitride family), so has attracted considerable interest for visible lasers and LEDs in the wavelength range 530 nm–670 nm. At room temperature the direct Γ bandgap increases almost linearly from $\sim$1.85 eV for $Ga_{0.52}In_{0.48}P$ to $\sim$2.3 for $(Al_{0.5}Ga_{0.5})_{0.52}In_{0.48}P$. For values of $x > 0.5$, the bandgap becomes indirect as in $Al_xGa_{1-x}As$ ($x > 0.4$) when the X-level indirect bandgap becomes lower than the Γ-level direct bandgap. Earlier work in this alloy suggested that the point at which it became indirect was at $x = 0.66$. The X-level bandgap appears to be relatively insensitive to the aluminum composition and has a value of $\sim$2.3 eV at room temperature.

GaAs/GaInAsN – '1.3 μm and 1.55 μm for telecommunication applications'
One limitation of GaAs is that most of the compounds that are lattice matched to it, such as $Al_xGa_{1-x}As$ or $(Al_xGa_{1-x})_{0.52}In_{0.48}P$, have bandgap energies that are large, making them unsuitable for telecommunication applications which require narrow bandgap materials capable of operating in the range 1.3 μm to 1.55 μm. Adding indium (In) to GaAs can decrease the bandgap but also causes strain as the lattice parameter increases, which limits the amount of indium and total thickness of the structure.

Recently, it has been shown that while adding In to GaAs increases the lattice parameter, adding N to GaAs decreases it. Consequently GaInAsN can be made to be lattice matched to GaAs by controlling the In and N content. Unlike conventional alloy semiconductors, adding In or N both result in a reduction of the bandgap energy. Furthermore, GaInAsN is found to be a direct bandgap material with a type I band lineup when combined with $Al_xGa_{1-x}As$, which is a wide bandgap material also lattice matched to GaAs. These properties make GaInAsN ideally suited for lasers and there have been several reports of devices operating at 1.3 μm in the literature.

Introduction

SiGe is now a mature materials system with electronic circuits on the market place. While no optical devices are available yet, there is a substantial amount of research in the field. In this article, the fundamental materials properties will be reviewed. As SiGe is a strained system, we shall start with the basic material properties as this determines the Ge content and layer thicknesses which are available for use. The band structure and electronic behavior will then be reviewed before the optical properties of the material.

The main drive for SiGe research in optical systems is the ability to use the extensive Si processing knowledge and to integrate a number of components onto a Si chip. Conventional Si transistors may also be used as driver circuits for the optical components, reducing chip counts in systems and therefore reducing costs. As Si processing is substantially cheaper than other semiconductor materials, if SiGe devices can be made on Si processing lines, they have the potential to be substantially cheaper than comparable III–V or II–VI devices. The SiGe material properties that will be reviewed in this article should be considered as an expansion of bulk silicon.

Material Properties and Strain

Ge has a 4.2% larger lattice constant that Si (Table 1). When growing epitaxial films of germanium or the alloy $Si_{1-x}Ge_x$ $(0 < x < 1)$ on a silicon substrate, there exists a maximum thickness called the critical thickness above which it costs too much energy to strain additional layers of material into coherence with the substrate. Instead defects appear, in this case misfit dislocations, which act to relieve the strain in the epitaxial film. Relaxed Si, Ge or SiGe films form diamond, diamond and zincblende lattices respectively while strained heterolayers below the critical thickness form a tetragonal symmetry arrangement. The strain therefore will substantially modify the electronic and optical properties of the material as will be discussed later.

Most SiGe films are produced by either chemical vapor deposition or molecular beam epitaxy. Both these techniques allow the deposition of films at low temperatures (typically 670–970 K) which is essential to prevent strained layers relaxing and forming defects. Chemical vapor deposition uses a number of different gases such as silane, disilane, dichlorosilane, and germane (occasionally with a hydrogen carrier gas) as the main species, while phosphine or arsine are used as n-type dopants and diborane is the typical p-type dopant. With the high melting point of both silicon and germanium, molecular beam epitaxy requires electron beam evaporators for the host materials silicon and germanium while effusion cells of antimony (occasionally phosphorus) and boron are used for n- and p-type dopants, respectively.

There are a number of models used to calculate the equilibrium critical thickness. The most often quoted is the Matthews and Blakeslee model (Figure 1). Experimentally it has been shown that defect-free films with thicknesses above the critical thickness may be grown (Figure 1) although these layers are metastable and will relax if temperatures above the

Table 1 Materials properties of Si, Ge and relaxed $Si_{1-x}Ge_x$

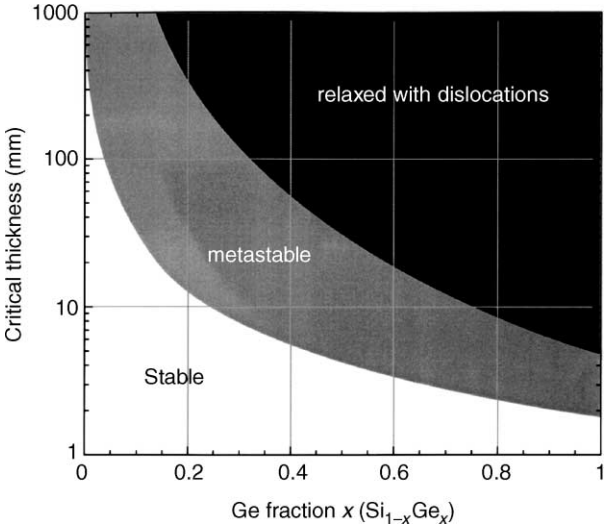

Figure 1 The critical thicknesses for growing a strained $Si_{1-x}Ge_x$ epitaxial layer on a bulk silicon substrate. The white area corresponds to the region below the equilibrium critical thickness as calculated with the Matthews and Blakeslee model while the gray region corresponds to a metastable layer which may relax after thermal treatments. The black area will have dislocations and strain relaxation using any growth technique or temperature.

growth temperature are applied to the heterolayers. For any manufacture, the layers cannot be metastable as high-temperature processes are normally employed in processing. The Matthews and Blakeslee equilibrium critical thickness, h_c for strained-$Si_{1-x}Ge_x$ on bulk Si is given by

$$h_c = \frac{0.55}{x}\ln[10h_c] \qquad [1]$$

while an approximate value can be obtained from

$$h_c \approx 1.7793x^{-1.2371}(\text{nm}) \qquad [2]$$

Figure 1 clearly demonstrates that for thick SiGe films, low Ge contents must be used.

There is also a substantial interest in producing low-defect relaxed $Si_{1-y}Ge_y$ films or strained-Si on a relaxed $Si_{1-y}Ge_y$ substrate which can provide bandgaps and band discontinuities not available to pseudomorphically grown alloy layers. Ideally the relaxed $Si_{1-y}Ge_y$ substrate is grown on a Si substrate as this allows integration with conventional complementary metal oxide semiconductor (CMOS) electronics. To date no high-quality bulk single-crystal $Si_{1-y}Ge_y$ substrates are available due to the strong segregation of Si and Ge phases as liquid SiGe crystallizes. Growing a thick $Si_{1-x}Ge_x$ layer on Si well above the critical thickness so that it relaxes produces a threading dislocation density of about $10^{12}\,\text{cm}^{-2}$ which is far too large to produce device-quality material for electronics or optics. By growing a linearly graded $Si_{1-y}Ge_y$ with the grading rate sufficiently low (typically 10% per μm), the strain relaxation mechanism changes from a nucleation relaxation mechanism to a glide relaxation mechanism resulting in dislocations with comparatively long misfit segments. The defect densities are typically 10^5–$10^6\,\text{cm}^{-2}$ (Figure 2) although recent thermal processes and other techniques have now reduced this to $100\,\text{cm}^{-2}$.

Substantial work has appeared in the literature on self-organized growth of islands. Such islands are of interest in many materials systems as the quantum confinement they may offer can potentially enhance luminescence properties in numerous opto-electronic devices. The dots are formed by the Stranski–Kranstanow growth mode in a strained system. Planar epitaxial layers grown under stress conditions can lower their elastic energy by morphological changes. For the growth of strained-Ge or $Si_{1-x}Ge_x$ on bulk Si, this corresponds to the formation of islands when the growth parameters in the system are correctly set. While the islands may have well-defined shapes, the formation of the dots relies on random nucleation followed by ripening and coalescence. These mechanisms have produced large distribution of sizes (up to 30% of the mean size), densities and positions. It is quite common to have distributions of two or more sizes of islands and the densities are typically of order of 10^8–10^9 islands per cm^2. While the heights of these islands may be as low as 3 nm, the

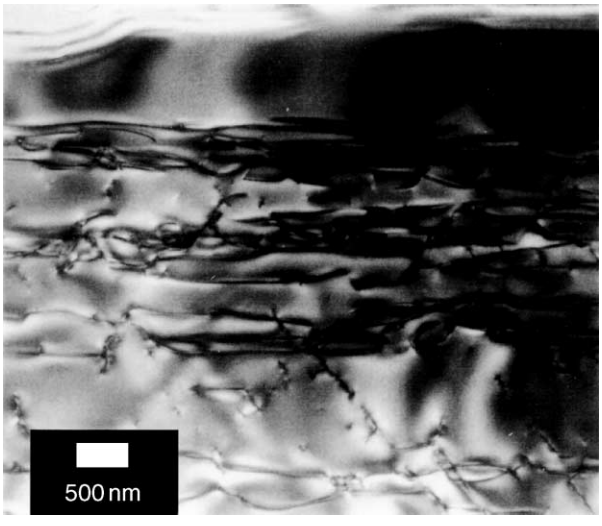

Figure 2 A transmission electron micrograph of a strain relaxation buffer grown by DERA, Malvern. The dense region of dislocations corresponds to an approximately 4 μm thick $Si_{1-y}Ge_y$ layer which is graded from $y = 0$ to $y = 0.23$. Above this is a 1 μm thick $Si_{0.77}Ge_{0.23}$ buffer which has no dislocation segments threading to the surface.

widths of the islands are typically 20 nm or greater, which is not yet small enough to produce the quantum confinement properties useful for significant improvements in opto-electronic devices.

Electronic Properties and Band Structure

As many of the optical properties and responses are derived or result from the band structure of materials, this section will concentrate on the band structure and electronic properties of SiGe layers. The bandgap of SiGe whether strained or unstrained is always below that of bulk Si. This potentially allows applications at longer wavelengths than comparable Si devices. Figure 3 shows the appropriate bandgaps for both the unstrained and strained $Si_{1-x}Ge_x$ grown on relaxed Si. For the unstrained case with a Ge fraction $x < 0.85$, the band structure is Si-like with six Δ-valleys forming the conduction band (Figure 4a). For $x > 0.85$ the band structure is Ge-like with four L-valleys. When strain is applied, both the conduction band and the valence band are split. Figure 4b shows the splitting of the conduction band with the Δ_4 valleys lower in energy and the Δ_2 valleys higher. In addition the valence band is split with the heavy-hole band being higher in energy than the light-hole band (Figure 3). The split-off band is also moved further away from the light and heavy hole bands as the strain in the system is increased. The indirect energy gap for the strained $Si_{1-x}Ge_x$ at 4.2 K as measured by photoluminescence is given by

$$E_g = 1.155 - 0.43x + 0.0206x^2 \text{ [eV] for } x < 0.85 \quad [3]$$

$$E_g = 2.010 - 1.27x \text{ [eV] for } x > 0.85 \quad [4]$$

while the direct bandgap is given by

$$E_g = 3.395 - 1.287x + 0.153x(1-x) \text{ [eV] (300 K)} \quad [5]$$

Due to the critical thickness, measurements of the bandgap of strained $Si_{1-x}Ge_x$ grown pseudomorphically on bulk Si substrates has been limited to low Ge concentrations. Using photoluminescence measurements at 4.2 K, Robbins has obtained a value for the exciton bandgap for strained $Si_{1-x}Ge_x$ layers for $x < 0.25$ to be

$$E_g = 1.155 - 0.874x + 0.376x^2 \text{ [eV]} \quad [6]$$

The bandgap for any strained $Si_{1-x}Ge_x$ layer grown on a relaxed $Si_{1-y}Ge_y$ substrate is shown in Figure 5. If the active strained $Si_{1-x}Ge_x$ layer is compressively strained then the conduction band is split into Δ_4 valleys being lower in energy and the Δ_2 valleys being higher (Figure 4b). For tensile strain (such as strained Si on a relaxed $Si_{1-y}Ge_y$ substrate), the Δ_2 valleys are lower in energy and the Δ_4 valleys are higher (Figure 4b).

The band alignments for typical heterolayer structures are shown in Figure 6. Pseudomorphically grown strained $Si_{1-x}Ge_x$ layers are only useful for forming quantum wells in the valence band (Figure 6a). Photoluminescence measurements do suggest a type I band alignment for these structures (quantum wells in both the conduction and valence bands) although it was later shown that the material is type II but due to charges producing band bending, the photoluminescence wrongly suggests a type I transition. For a quantum well for electrons, strained Si layers are grown on a relaxed $Si_{1-y}Ge_y$ substrate. In addition, quantum wells in the valence band can be produced for strained $Si_{1-x}Ge_x$ layers with high Ge content grown on relaxed $Si_{1-y}Ge_y$ substrates for $x > y$. In almost all cases the band alignments are type II although a small region exists where theory suggests type I is possible but this has not been demonstrated experimentally at present.

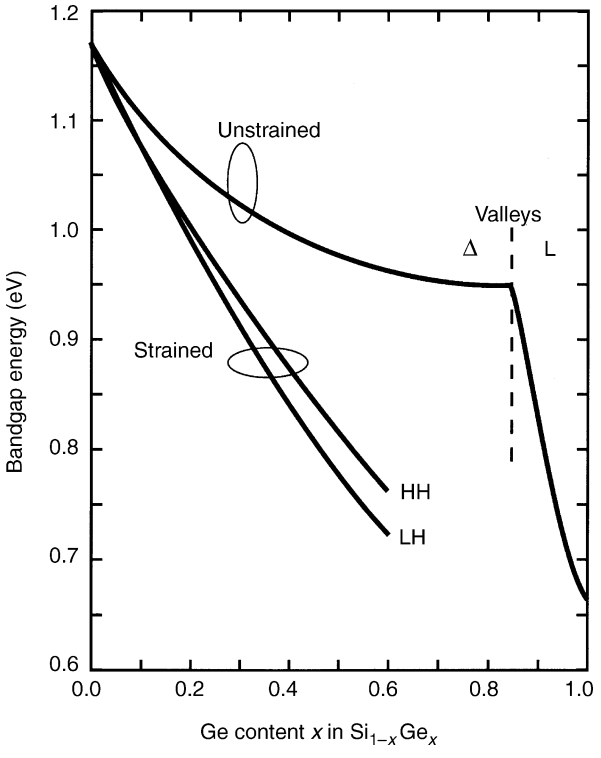

Figure 3 The bandgap energy for strained $Si_{1-x}Ge_x$ on a relaxed Si substrate and unstrained $Si_{1-x}Ge_x$. For the unstrained there is a discontinuity at $x \sim 0.85$ where the band structure changes from Si-like with Δ-valleys to Ge-like with L valleys (see Figure 4).

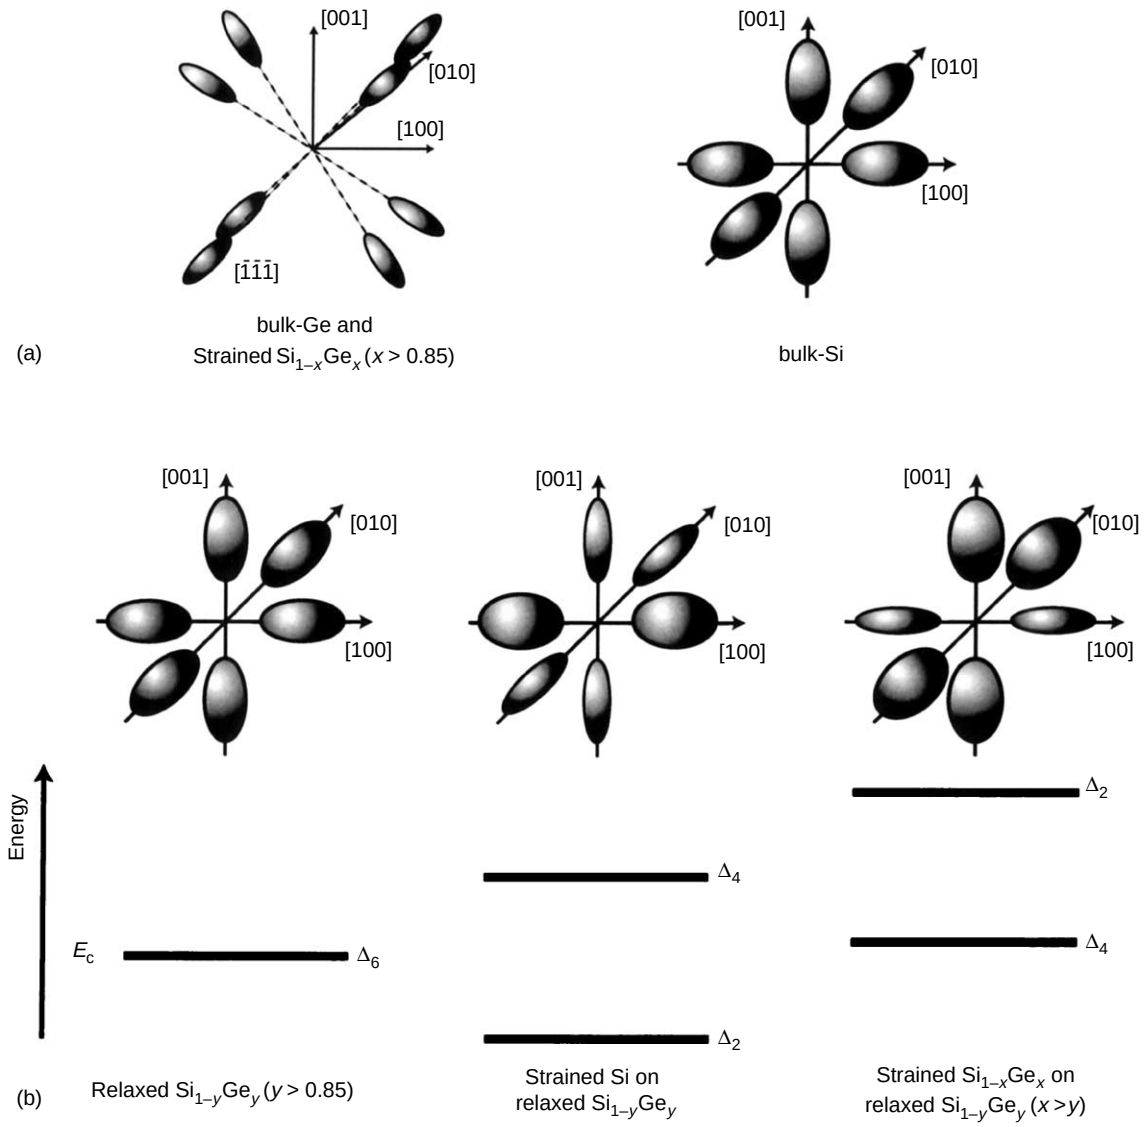

Figure 4 (a) A schematic diagram of the valleys for Ge-like and Si-like material. (b) A schematic diagram of the valley structures and energy levels of the conduction bands for relaxed, tensile strained (strained Si on relaxed $Si_{1-y}Ge_y$) and compressively strained (strained $Si_{1-x}Ge_x$ on relaxed $Si_{1-y}Ge_y$ ($x > y$)) material.

The valence band discontinuity is given by

$$\Delta E_v = (0.74 - 0.06y)(x - y)\,[\text{eV}] \qquad [7]$$

while the conduction band discontinuity for strained Si on a relaxed $Si_{1-y}Ge_y$ substrate is

$$\Delta E_c = 0.6y\,[\text{eV}] \qquad \text{for } x < 0.6 \qquad [8]$$

The complete set of ΔE_c and ΔE_v values for all x and y are shown in Figures 7 and 8 respectively. Table 2 gives some of the electronic data on Si, Ge, and relaxed $Si_{1-x}Ge_x$ including mobilities, bandgaps, and effective masses.

The mobilities for electrons and holes in relaxed $Si_{1-x}Ge_x$ layers are below the bulk Si and Ge layers due to alloy scattering (Table 2). For strained layers, mobility enhancements have been demonstrated in a number of different systems. Electron mobility enhancements result from the splitting of the valleys reducing intervalley scattering. Hole mobility enhancements result from the splitting of the valence band and reduction of effective masses. The hole mobilities for pseudomorphically grown strained $Si_{1-x}Ge_x$ quantum wells have shown values as high as $17\,000\,\text{cm}^2\,\text{V}^{-1}\,\text{s}^{-1}$ at a carrier density of $2 \times 10^{11}\,\text{cm}^{-2}$ for $Si_{0.87}Ge_{0.13}$ layers. Higher Ge contents reduce the mobility due to alloy scattering. At room temperature, only modest mobility improvements of about 20% have been observed giving $220\,\text{cm}^2\,\text{V}^{-1}\,\text{s}^{-1}$ at the high carrier

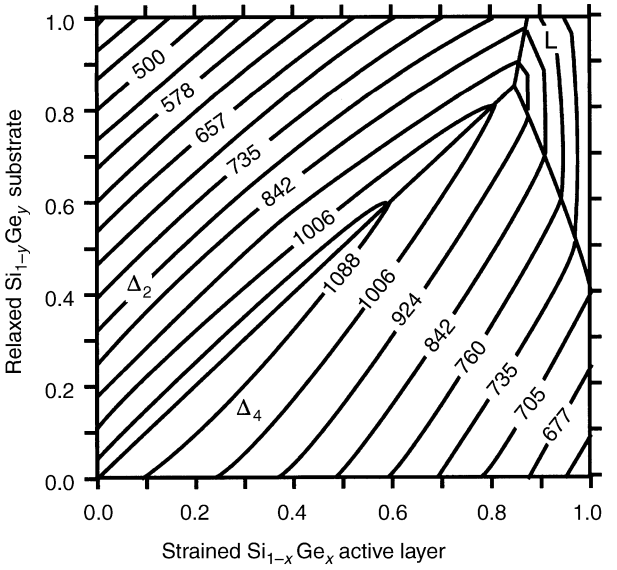

Figure 5 The bandgap energy (in meV) for strained $Si_{1-x}Ge_x$ grown on a relaxed $Si_{1-y}Ge_y$ substrate. Theoretical curves from Riger and Vogl have been calibrated to the experimental data from pseudomorphic layers.

densities required for electronic devices of about 2×10^{12} cm^{-2}. To remove alloy scattering, pure strained Ge channels grown on relaxed $Si_{1-y}Ge_y$ substrates have shown low-temperature mobilities of 55 000 cm^2 V^{-1} s^{-1} for densities of 5×10^{11} cm^{-2} with the room-temperature values reaching 1665 cm^2 V^{-1} s^{-1}. For electrons, a strained Si layer on relaxed $Si_{1-y}Ge_y$ substrates ($0.2 < y < 0.3$) also reduces the alloy scattering in the channel and produces much higher low-temperature mobilities of 390 000 cm^2 V^{-1} s^{-1} for densities of 4×10^{11} cm^{-2} while room-temperature values have peaked at 2830 cm^2 V^{-1} s^{-1}. All these values correspond to electrons or holes at heterointerfaces. Enhanced mobilities have also been observed for strained Si metal oxide semiconductor field effect transistors (MOSFET) where electron mobility enhancements of 75% compared to the bulk Si devices has been reported on relaxed $Si_{0.8}Ge_{0.2}$ although intrinsic transconductances are only increased by 60%. For holes, a strained Si layer on a $Si_{0.8}Ge_{0.2}$ relaxed substrate has demonstrated a 50% mobility enhancement over a bulk Si MOSFET.

The effective mass for electrons in strained Si layers on relaxed $Si_{1-y}Ge_y$ substrates for $0.1 < y < 0.4$ has produced a very small spread of effective masses with values of 0.19 m_0 (where m_0 is the free electron mass) for the longitudinal mass as measured by cyclotron resonance and the temperature dependence of Shubnikov–de Haas oscillations. The electron effective masses are very similar to the bulk values for

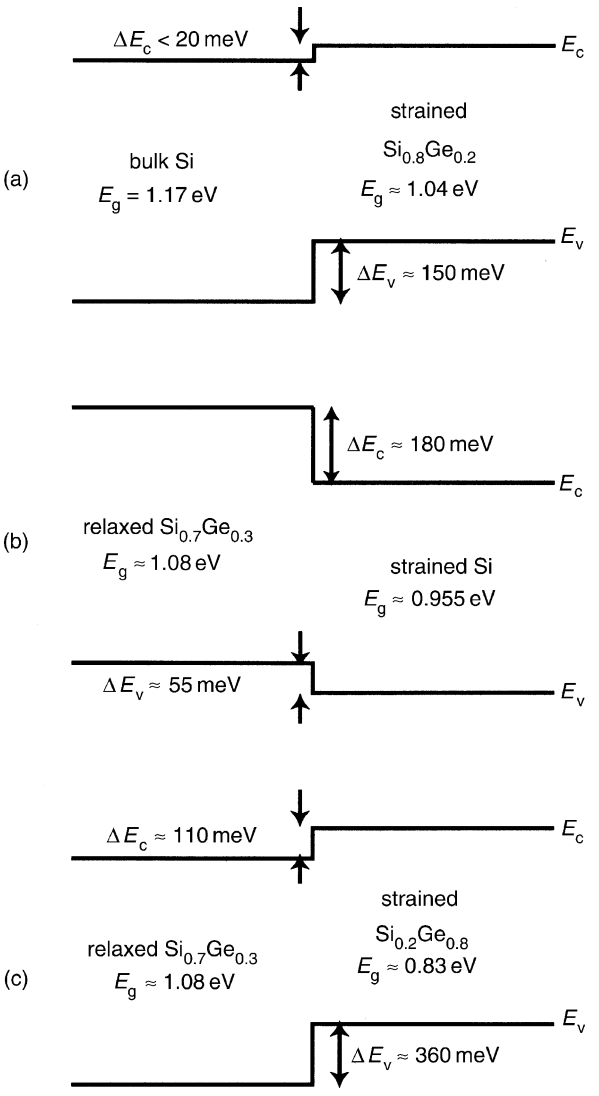

Figure 6 A schematic diagram of some typical SiGe heterolayer structures showing the bandgap, conduction band discontinuity, ΔE_c, and the valence band discontinuity, ΔE_v. (a) shows a quantum well in the valence band using a pseudomorphic strained $Si_{0.8}Ge_{0.2}$ layer; (b) shows a quantum well in the conduction band using a strained Si layer on a relaxed $Si_{0.7}Ge_{0.3}$ substrate; and (c) shows a quantum well in the valence band using a high Ge content layer on a relaxed substrate with lower Ge content.

strained Si quantum wells. Hole effective masses in pseudomorphically strained $Si_{1-x}Ge_x$ layers have produced a large spread of data even for similar alloy and strain values mainly due to the large nonparabolicity of the valence band (Table 3) and many of the measured samples having metastable $Si_{1-x}Ge_x$ quantum wells. The in-plane hole mass is theoretically expected to decrease as the strain in the system is increased but to date the experimental values have been much lower than theoretically calculated values. Experimental data (Table 3)

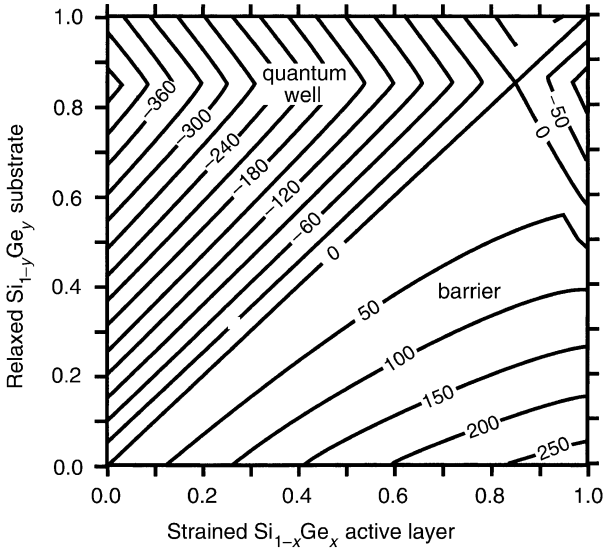

Figure 7 The conduction band discontinuity (in meV) for strained $Si_{1-x}Ge_x$ grown on a relaxed $Si_{1-y}Ge_y$ substrate. Positive numbers correspond to potential barriers to electrons while negative values represent quantum wells. The general trends and unknown experimental regimes are from the theoretical work of Rieger and Vogl while the quantum well data for $0.1 < y < 0.4$ and $x = 0$ has been recalibrated from experimental work. No experimental data are known to allow calibration of the barrier regime.

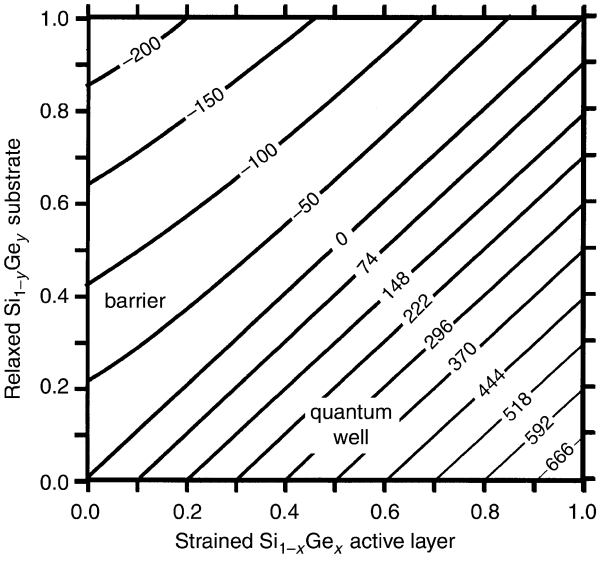

Figure 8 The valence band discontinuity (in meV) for strained $Si_{1-x}Ge_x$ grown on a relaxed $Si_{1-y}Ge_y$ substrate. Positive numbers correspond to quantum wells for holes while negative values represent potential barriers. The values from theory in the quantum well region agree well with experimental values but little experimental data exist to compare the barrier data from the theorertical values (plot from Rieger and Vogl) with experiment.

suggests that strained $Si_{0.88}Ge_{0.12}$ layers have a heavy effective mass of about $0.3\,m_0$ compared to the bulk value of $0.55\,m_0$.

Optical Properties

Due to the problems of producing high-quality single crystals of $Si_{1-x}Ge_x$, there are relatively little data on the optical properties of relaxed $Si_{1-x}Ge_x$ in the literature. The situation is even worse for strained $Si_{1-x}Ge_x$ as the layer thicknesses are limited to below 30 nm for Ge contents above 0.1, a value much smaller than the penetration depths in the system at most optical frequencies. There is, however, substantial interest in the optical properties, particularly the refractive index, as they suggest that SiGe can be used as a waveguide on Si substrates.

For the relaxed $Si_{1-x}Ge_x$ layers, most of the published work in the field has been from crystals grown by liquid phase epitaxy using melts of indium or tin. The samples had free hole concentrations of $10^{17}\,cm^{-3}$ along with indium or tin impurities and details can be found in the reviews by Humlícek. Some of the data are also from thick epitaxial layers grown well above the critical thickness where the threading dislocation density is likely to be about $10^{12}\,cm^{-2}$. The data below 2 eV were obtained by absorption measurements, those between 2 and 5.6 eV have been obtained using ellipsometry and the values between 6 and 12 eV were obtained by reflectance measurements.

Figures 9 and 10 show the real and imaginary parts of the complex dielectric function defined as $\varepsilon = \varepsilon_1 + i\varepsilon_2$ where $i = \sqrt{-1}$ for a number of different Ge contents. Figures 11 and 12 show the real and imaginary parts of the complex refractive index defined by $N = n + ik = \sqrt{\varepsilon}$. The peak starting at 3.395 eV and decreasing as the Ge content is increased corresponds to the E_1 transition across the direct gap and may be used to find the Ge content using the expression

$$x = 4.707 - \sqrt{6.538E_1 - 0.0397} \qquad [9]$$

The refractive index is high owing to the strong electronic interband absorption in the visible and ultraviolet regions of the spectrum.

The other important optical property of the material is the absorption. The absorption coefficient is defined as $K = 4\pi k/\lambda$ where k is the extinction coefficient for a wavelength λ. The intensity of a wave traversing a distance d in a homogeneous medium of extinction coefficient, k, is attenuated by a factor $\exp(-Kd)$. Therefore $1/K$ is the penetration depth. The absorption coefficient is shown in Figure 13.

Table 2 Electronic properties of Si, Ge and relaxed $Si_{1-x}Ge_x$

Element		*Si*	*Ge*	*Bulk unstrained $Si_{1-x}Ge_x$*
Direct bandgap	(eV) at 300 K	3.4	0.80	$3.395 - 1.287x + 0.153x\,(1 - x)$
Indirect bandgap	(eV) at 300 K	1.11 (D)	0.664 (L)	$1.155 - 0.43x + 0.0206x^2$ $(x < 0.85)$ $2.010 - 1.27x$ $(x > 0.85)$
Spin-orbit splitting	Δ_{so} (meV)	44	290	Discontinuity at $x \sim 0.85$
Electron mobility	μ_e ($cm^2\,V^{-1}\,s^{-1}$) at 300 K	1450	3900	$\mu_e = 1466.2 - 6425.9x + 6601.8x^2$ $+7716.5x^3 - 10944x^4 (x < 0.6)$ $\mu_e = 2.9235 \times 10^{-28} e^{71.105x} + 4790.1$ $-14246x + 11117x^2 (x > 0.6)$
Hole mobility	μ_h ($cm^2\,V^{-1}\,s^1$) at 300 K	505	1800	$\mu_h = 188.42 - 935.7x + 5455.5x^2 - 8553.7x^3$ $+ 5751.7x^4$ (all x) ($N_A = 1 - 50 \times 10^{16}$ cm^{-3})

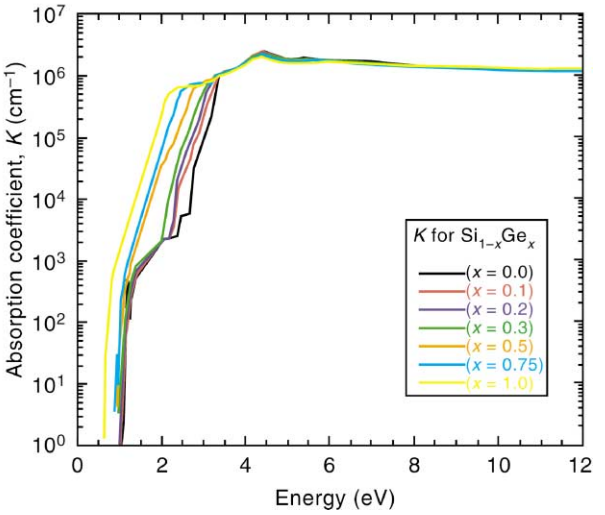

Figure 13 The absorption coefficient K.

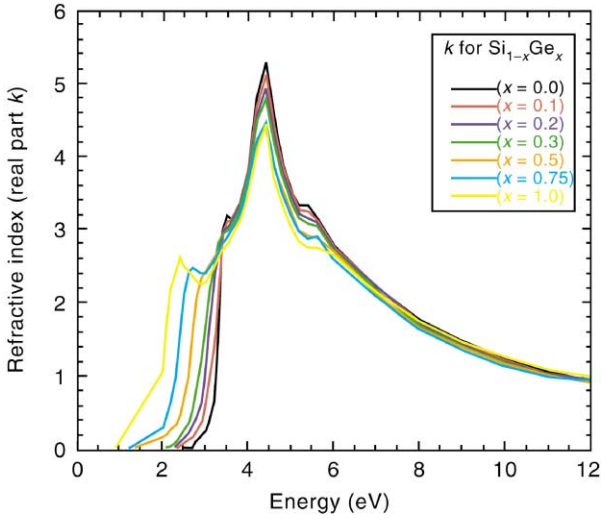

Figure 12 The imaginary part (k) of the complex refractive index $N = n + ik$.

Determining the optical properties of strained $Si_{1-x}Ge_x$ layers has been substantially more difficult. The major problem is that the absorption coefficient is about $10-20\,cm^{-1}$ around the fundamental bandgap (Figure 6) and therefore any shift due to strain effects becomes very difficult to observe using absorption techniques in thin SiGe layers. Additional complexity results as the substrate material has a fundamental bandgap close to the strained layer. Therefore photoluminescence is one of the few methods for extracting experimentally the optical changes due to strain.

The splitting of the conduction (Figure 8) and valence bands (Figure 9) has already been discussed. The photoluminescence signals will also shift with strain for the lowest lying bandgap energy. Almost all the experimental data for strained layers have been obtained for pseudomorphically grown strained $Si_{1-x}Ge_x$ alloys on bulk Si substrates and the data agree well with the bandgaps shown in Figures 3 and 5. The quantum well photoluminescence signal is found to shift by -1.4 meV per kbar of pressure. After removal of nonhydrostatic components, a value of -1.52 meV per kbar for the pure hydrostatic shift has been reported.

Conclusions

A review has been presented of the fundamental properties of relaxed and strained $Si_{1-x}Ge_x$ alloys. The materials properties were first reviewed and demonstrate the limitations imposed by the critical thickness. The electronic properties including the bandstructure were then discussed and demonstrate the lowered bandgap for $Si_{1-x}Ge_x$ alloy compositions compared to bulk Si. This property has been used in $Si_{1-x}Ge_x$ p-i-n photodetectors to move the absorption to longer wavelengths in an attempt to compete with III–V photodetectors for the important 1.3 μm and 1.55 μm fiber optic frequencies. In the final section the optical properties of relaxed and strained $Si_{1-x}Ge_x$ material were reviewed. The difference in refractive indices has opened research into SiGe on Si waveguides.

Introduction to InGaN

The optical properties of wurtzite GaN are of interest mainly to band-structure theorists. Luminescence from pure InN has probably never been detected. It is therefore surprising that the combination of these binary III–N compounds produces a solid solution, InGaN, which has revolutionized blue–green optoelectronics in the last 10 years, and may form the basis of a new lighting technology to replace the tungsten lamp in the first half of the twenty-first century.

InGaN is also the material basis of the blue laser diode, which will be used for future generations of optical data storage and for many other applications that require a compact source of short-wavelength coherent light. The market for nitride light emitters has been growing at a rate of ~20% a year since the introduction of the first blue nitride light-emitting diode (LED) by Nichia Chemical in 1993. The first commercial lasers, with lifetimes in excess of 10 000 hours, were released in 1998.

So what is InGaN? The naïve response–that it is a semiconductor alloy–ignores the theoretical demonstration, based on simple equilibrium thermodynamics, that InN is insoluble in GaN at the temperatures usual for growth (using metalorganic vapor phase epitaxy, MOVPE). If we imagine a cation lattice, on which we distribute Ga and In atoms, in a fixed numerical proportion, in order to form a solid solution of given composition, it is thermodynamically probable that the In atoms will associate to form agglomerations in certain regions of the lattice. The size, shape, and properties of the resulting concentration fluctuations have been a topic of intense speculation.

Practically speaking, InGaN layers are grown either as rather thin (<3 nm) quantum wells (QWs) immersed in GaN or AlGaN or as thicker epilayers (10–500 nm) on top of thick GaN templates. Only the QWs are of use in devices, whereas the composition and structure of the thick epilayers are easier to measure in research applications. It is dangerous to suppose that the material retains

the same properties when grown in thicker layers. Recently, a third class of sample has emerged, in the form of self-organized 'quantum boxes' (originally French *bôites*), which we shall call QBs. These samples, grown at low temperatures by molecular beam epitaxy (MBE) comprise pancake-shaped disks of uncertain composition, about 50 nm across and 3–5 nm high.

Optical Spectra of Devices

There have been several 'generations' of nitride LED. We refer here to the Nichia Blue, Extrablue (actually turquoise) and Green diodes which set the scene in 1996, and the Amber diode which first appeared in 1998, although not yet available commercially. The spectral properties of these devices have been stable while their efficiencies have improved in the intervening years. The basic design appears to incorporate a single quantum well. Up to a point, the wavelength tuning depends upon the incorporation of different amounts of indium in the well. (Green and amber devices may have the same amount.)

In what follows, we prefer to specify composition by quoting the indium nitride content, x, according to the formula unit

$$\mathrm{In}_x\mathrm{Ga}_{1-x}\mathrm{N} = x\mathrm{InN} + (1-x)\mathrm{GaN} \qquad [1]$$

Electroluminescence (EL) spectra of blue and green diodes are shown in Figure 1. Spectra are broad (compared to $k_\mathrm{B}T$ at room temperature) with exponential tails to high and low photon energies. The linewidth tends to increase as the device peak wavelength shifts further to the red.

Whereas it is difficult to measure directly the optical absorption spectrum of an ultrathin layer of material, an equivalent measurement can be made on an LED by monitoring the photocurrent (PC) generated by incident monochromatic light. PC spectra of the blue and green diode are shown in Figure 1, together with the absorption and photoluminescence (PL) spectra of a thick violet-light-emitting epilayer.

The spectra of Figure 1 transform into each other by 'stretching' the x-axis, using the bandgap energy of GaN as an anchor point. Comparison of many pairs of spectra produces evidence of a *universal scaling behavior*, which relates the details of each spectrum to a single controlling parameter. In the case of epilayers, this is undoubtedly the InN fraction, as we shall see later.

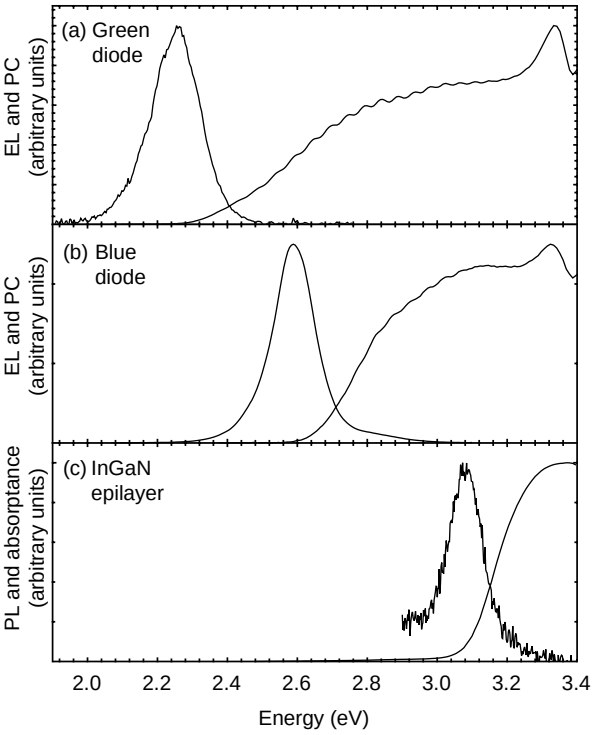

Figure 1 EL and PC (quasi-absorption) spectra of nitride LEDs, compared to PL and absorption spectra of a thick InGaN epilayer.

In order to describe the form of the absorption/excitation curve, we introduce the formal expression

$$\alpha = \frac{\alpha_0}{1 + \exp\left(\dfrac{E_\mathrm{g} - E}{\Delta E}\right)} \qquad [2]$$

where α_0 is the plateau absorption, observed experimentally, but not yet theoretically explained, E_g is the (effective) bandgap energy of the sample, E is the photon energy, and ΔE is an energy broadening term, similar to the well-known Urbach parameter.

Optical Energy Relationships

The spectral universality pointed out in the previous section requires the existence of certain relationships between the optical energies. We list the defining energies as the bandgap, E_g, the peak energy of EL or PL, E_p, and the difference between these energies, measured for a particular sample, which we call the Stokes shift:

$$\mathrm{SS} = E_\mathrm{g} - E_\mathrm{p} \qquad [3]$$

(While the energy broadening tends to increase in a regular fashion with the Stokes shift, there are irregularities in both ΔE and the PL linewidths of samples from different sources. Hence ΔE and PL

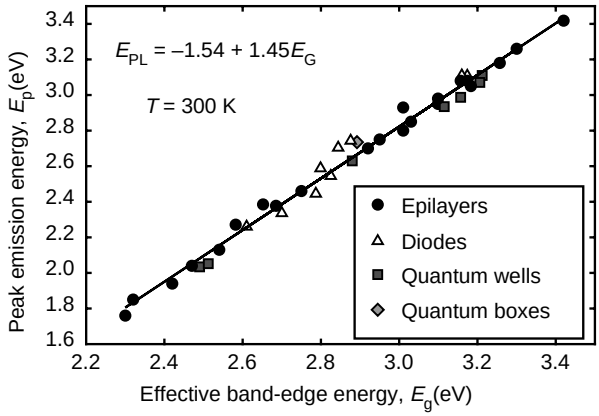

Figure 2 Linear dependence of luminescence peak energy on effective bandgap.

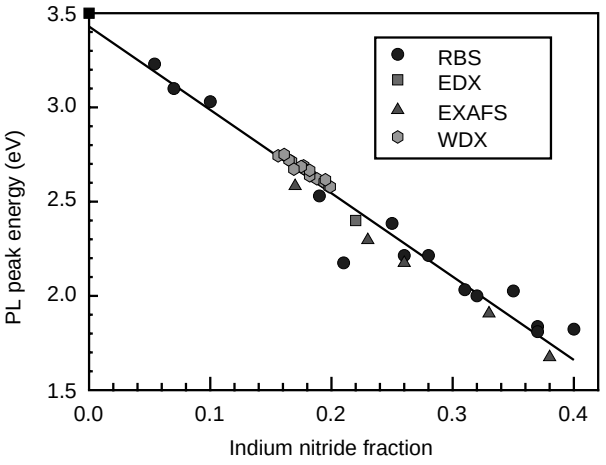

Figure 3 Linear dependence of the PL peak energy on the InN content of InGaN epilayers.

linewidth appear to be local rather than universal parameters.)

The relationship between E_g and E_p for a wide range of emitters is found to be linear (Figure 2):

$$E_p = 1.45E_g - 1.54 \qquad [4]$$

The bandgap energy and luminescence peak energy coincide at $1.54/(1.45 - 1) = 3.42$ eV, which corresponds to the energy bandgap of pure GaN. The simple linear dependence of E_p upon E_g implies a linear increase of the Stokes shift energy with increasing detuning from the GaN band edge.

Dependence of Optical Energies on *x*, the InN Fraction, for Thick Epilayers

As stated above, it is usual to measure the composition of thick layers, rather than quantum wells, for reasons of experimental convenience. Several techniques can be used to this end, including measurement of the lattice constants by X-ray diffraction (XRD) (one asymmetric and one symmetric reflections are required to take into account the strain state of the layer), Rutherford backscattering spectrometry (RBS), wavelength-dispersive (preferable) or energy-dispersive X-ray fluorescence (XRF), sputtered ion mass spectroscopy (SIMS), and extended X-ray absorption fine structure (EXAFS).

All usable techniques provide comparable results if carried out with sufficient care. We plot the peak energy of PL emission against the measured indium nitride fraction for a range of epilayer samples in Figure 3. Once more, the dependence appears to be linear in a restricted composition range. The best-fit line to a linear function $E_p(x)$ has an x-intercept which is close to the bandgap of GaN. The dependence of the optical energies on the indium nitride fraction can now be summarized by three interdependent linear relations, which are valid in the composition range $0 < x < 0.4$:

$$E_p = 3.4 - 4.4x$$

$$E_g = 3.4 - 3.0x \qquad [5]$$

$$SS = 1.4x$$

The measurements described above rely on separate determinations of composition and an optical energy for each sample. Since all samples are to some extent inhomogeneous, it would be preferable to make such measurements at one and the same time. This can be done by using an electron probe microanalyzer, modified to allow simultaneous cathodoluminescence (CL) spectroscopy. CL is analogous to PL. A recent study of samples with $0.05 < x < 0.25$ has yielded the result:

$$E_c = 3.40(1) - 3.91(5)x \qquad [6]$$

with error bars (shown) that are about ten times smaller than those of the previous work.

Bandgap of InN

It is dangerous to extrapolate experimentally determined relationships beyond the range of measurements used to derive them.

The bandgap of an alloy is best represented by a quadratic function of x, with the deviation from linearity described by a bowing parameter. The above measurements suggest a small bowing parameter for the InGaN alloy system. If we ignore bowing and equate E_p with E_c, the InN bandgap obtained by setting $x = 1$ is calculated to be 0.71 eV. This is certainly an underestimate, but is similar to recent values obtained experimentally for layers of

pure InN grown by Molecular Beam Epitaxy. Before the year 2000, the generally accepted value of the InN bandgap was close to 2 eV.

Origin of the Stokes Shift

Stokes shifts originate in systematic energy loss during the excitation–luminescence cycle. While the bandgap, as defined above, is the mean energy of electron–hole pairs across the bandgap, the PL peak is the modal energy of electron–hole recombination. The large Stokes shift in the InGaN system is probably due to the influence of giant internal electric fields that separate the carriers prior to recombination.

In the absence of a microscopic model, it is difficult to provide a quantitative description of energy loss in the excitation–emission cycle. Experiment shows that the shift can be as large as ~ 0.6 eV in an epilayer with $x = 0.4$. If such a layer were 100 nm thick and uniform in composition, it would be strained by about 4% when pseudomorphic to a GaN template, with an estimated vertical electric field of 6×10^6 V m^{-1}. Unit strain would correspond to a 15-eV shift (equivalent to a piezoelectric deformation potential). While these numbers are large, they seem reasonable in the light of sophisticated theoretical calculations of the magnitude of the piezoelectric effect in InGaN. But it is an unfortunate experimental fact that layers grown with different thicknesses, and presumably under different states of strain, may show the same value of the Stokes shift.

If the material has composition fluctuations, accompanied by strain variations, the recombination energy will be much more sensitive to the local environment. One can imagine a situation in which recombination always takes place at the lowest available energy, as carriers diffuse under the action of local strain/electric fields. This situation would be rather similar to that which pertains in quantum wells with spatial energy disorder, caused by well width fluctuations. A theoretical treatment of localization in three dimensions would be very difficult.

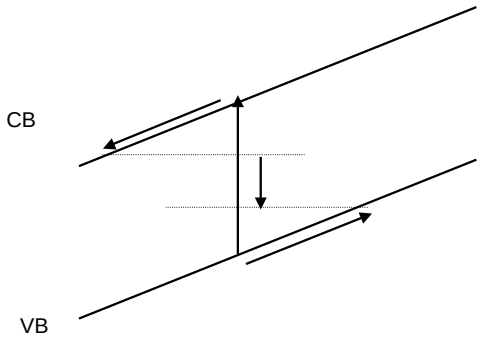

Figure 4 Excitation–emission cycle in the presence of an electric field. CB and VB are conduction band and valence band, respectively.

In any case, the physical situation of excitation and recombination in the presence of an electric field is that sketched in Figure 4.

Quantum Wells and Quantum Boxes

The incorporation of quantum wells has several advantages for light-emitting devices. In nitrides, the expected increase of oscillator strength for radiative transitions, due to the reduced dimensionality, is mitigated to some extent by the opposing effect of the internal electric fields, but the quantum well still acts as an energy sink for mobile excitations and as a site for carrier localization.

Quantum confinement can also act as a wavelength tuning mechanism in QW devices. The effect in blue-emitting nitride devices is rather small until the QW width falls below 3 nm. It should be clear that a reduction in the photon energy of recombination with increasing well width will accompany vertical separation of carriers in a piezoelectric model. Usually, as mentioned above, wavelength tuning in nitride devices is accomplished by changing the composition. What should we make of the fact that amber and green diodes apparently have the same composition? It would appear that the well widths are different. On the other hand, the amber emitters have anomalously narrow linewidths, which may imply that some other mechanism is in force. Here, we must let the matter rest, in the absence of detailed structural information.

Quantum boxes should be distinguished from quantum dots (QDs). The former are mesoscopic objects that form spontaneously under certain growth conditions, which usually involve the influence of strain. The best-characterized example in semiconductor physics is the Stranski–Krastanow growth of InGaAs structures on GaAs. While GaN in AlGaN forms recognizable nanocrystals, InGaN forms less well-defined structures of indeterminate shape, some 30–50 nm in lateral extent and 3–10 nm high. QDs, on the other hand, are truly zero-dimensional objects, in the sense that carrier motion is quantized simultaneously in three spatial dimensions. The utilization of reduced dimensionality to enhance recombination probabilities in active devices is only valid when QB structures meet the criteria of low dimensionality: the carrier motion must be restricted to a distance smaller than the appropriate Bohr radius.

Structure of InGaN Epilayers

The state of strain of InGaN epilayers is usually determined by XRD. Both symmetric and asymmetric

reflections are required to calculate the actual values of the out-of-plane and in-plane lattice constants, c and a, respectively. These can then be compared with those predicted for a relaxed alloy by Vegard's law, for example:

$$c(\mathrm{In}_x\mathrm{Ga}_{1-x}\mathrm{N}) = xc_{\mathrm{InGaN}} + (1-x)c_{\mathrm{GaN}} \qquad [7]$$

The composition itself, as well as the state of strain, can be determined from measurements of c and a with one additional assumption: that the Poisson ratio of the alloy also obeys Vegard's law. If the composition is known from an independent chemical measurement, this assumption can be tested.

InGaN epilayers are usually grown on thick GaN formers. In pseudomorphic growth, the constraint, $a(\text{layer}) = a_{\mathrm{GaN}}$ applies. This is sometimes assumed to be the case when layers are thinner than about 50 nm, but nothing should be taken for granted when dealing with this material. Each layer is different. A similar warning applies to the assumption that thick InGaN layers will be relaxed. It has recently been shown that partially relaxed and pseudomorphic regions may actually coexist within the same InGaN film, which nevertheless has a composition that is uniform throughout. Other films may show a concentration gradient due to compositional pulling during growth.

The local structure of InGaN films has been measured using In-edge EXAFS. Using a tetrahedral two-shell model that does not distinguish the wurtzite and cubic crystal structures, we find that the In–N1 bond length is more or less independent of the alloy composition in the range $0.17 < x < 0.38$ of samples measured, having a value of 2.11(1) Å (compared to 2.16 Å in pure InN). The M1 shell of mixed In and Ga atoms is located on average at about 3.28 Å, as shown in Figure 5.

The straight line on the figure connects the values of the a lattice parameters (of GaN at $x = 0$ and InN at $x = 1$) and hence represents the predictions of Vegard's law for a relaxed or bulk alloy. The measured In–M1 separations are less dependent on x than Vegard predicts.

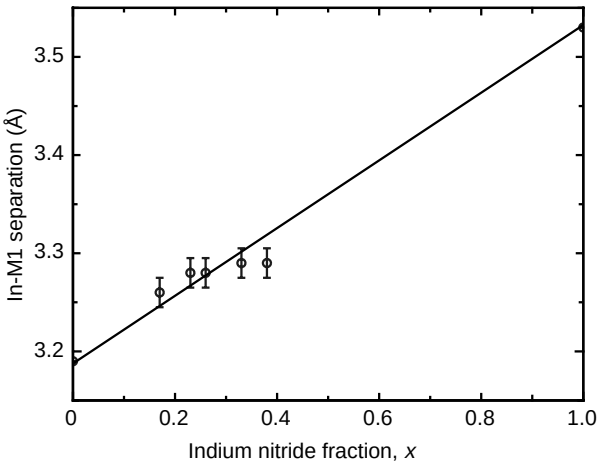

Figure 5 EXAFS-determined local structure parameters of thick InGan films.

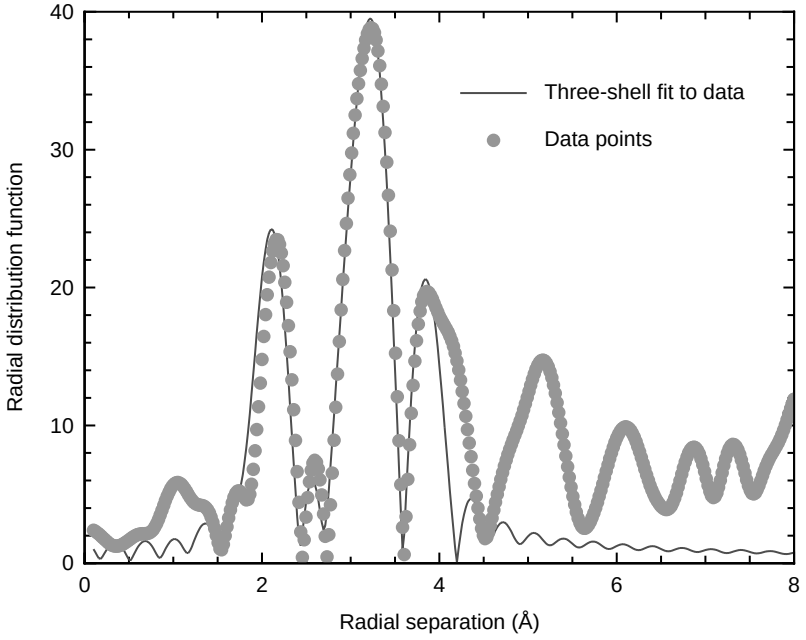

Figure 6 Fourier transform of the EXAFS spectrum yields the radial distribution function of an InGaN QB sample.

Local Structure of InGaN QW and QB

There has been a great deal of speculation in the literature concerning the local structure of InGaN alloys in the active layers of light-emitting devices. Much of this discussion paddles in the shallows of invalid comparison, as researchers extrapolate their findings from the results of measurements and calculations that can be made to those that cannot. One example is the large theoretical effort devoted to the defect physics of GaN, which is supposed somehow to 'explain' the optical properties of InGaN. ('Let us first suppose that all the horses in the race are spherical.')

We will try to avoid invalid comparisons in the brief discussion that follows. Recently, a Strathclyde University/Daresbury Laboratories/CHEA-CNRS Valbonne collaboration has succeeded in measuring the local structure of an InGaN QB sample, grown on a thick GaN template by MBE. The radial distribution function (RDF) around the target In probe atom is shown in Figure 6, together with a three-shell fit to the data.

The first shell of neighbors comprises four N atoms at 2.10(2) Å, the second shell is pure Ga at 3.22(3) Å, and the third shell pure In at 3.56(3) Å. These results suggest that there are two distinct In environments in such samples. One resembles the InGaN alloy, encountered in the epilayer samples, while the other is an environment of pure InN.

On the basis of these results, it is extremely likely that InGaN phase-separates in QB growth to form a two-component mixture comprising an In-poor and an In-rich phase. The manner in which these phases interpenetrate is a matter for speculation.

Large Gap II–VI Semiconductors

J F Donegan, Trinity College Dublin, Dublin, Ireland

© 2005, Elsevier Ltd. All Rights Reserved.

Background

The chemical reaction of group IIA (Be, Mg), IIB(Zn, Cd) and group VI (O, S, Se, Te) atoms produces solid crystalline materials which are classified as semiconductors. The archetypal compound is ZnSe and this material will be used as the main example in this article. These are termed II–VI binary (involving two elements) compounds. It is also possible to grow alloy materials where more than one atom from each group is used; an example is $Zn_xCd_{1-x}Se$ where x is the proportion of Zn in the material. In general, there is a random arrangement of the Zn and Cd atoms within the crystal structure. Both binary and alloy semiconductor materials are single crystals so that the atoms are arranged in a periodic three-dimensional system called a lattice. The lattice may be represented by a unit cell; simply by repeating the pattern of the unit cell, we can generate the entire crystal lattice.

At the atomic level, the zinc (selenium) atom is bonded to 4 selenium (zinc) atoms which are arranged at the corners of a tetrahedron. The unit cell formed by this tetrahedral arrangement is termed the zincblende structure and is illustrated in Figure 1a. The dimension shown is called the lattice constant a and is characteristic of a particular II–VI semiconductor material. Some II–VI materials crystallize with a different unit cell which is termed the wurtzite structure, though again the atoms are bonded to four others in a tetrahedral arrangement as shown in Figure 1b. In this case, two lattice constants denoted a and c are required to characterize the unit cell. Some of the II–VI materials can occur in either of these two structures depending on how they were grown. The lattice constants of several II–VI compounds are given in Table 1.

II–VI Materials Growth

All of the II–VI family of semiconductors have high melting points due to the strong bonding that exists between the atomic species; values are given in

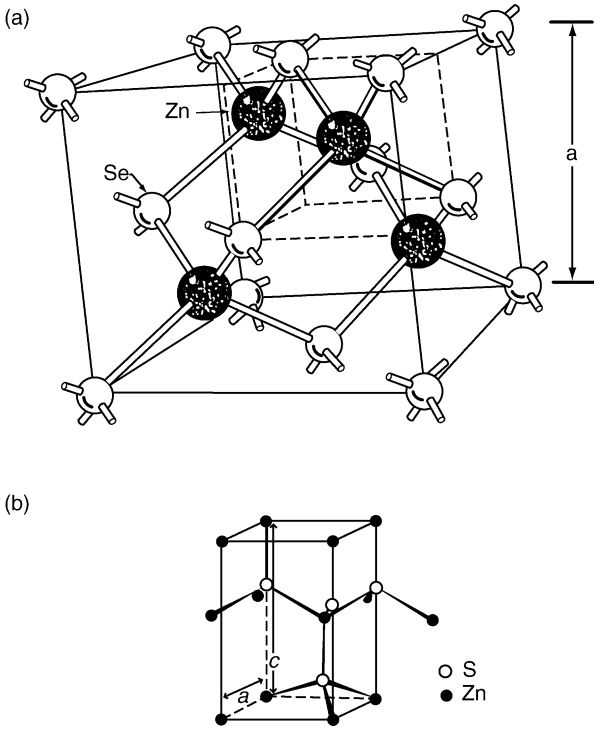

Figure 1 (a) Zincblende lattice; (b) wurtzite lattice. *a* and *c* are the lattice constants as given in Table 1.

Table 1. The crystals can be grown either by cooling a liquid (often called a melt) or by condensation from a gas (vapor). Crystal growth is a very precise and difficult process requiring the control of a large number of variables most notably temperature and pressure. As many of the II–VI materials can exist in either the zincblende or wurtzite structures, producing single crystals with only one structure is often quite difficult. Many of the crystals are 'twinned'; in a zincblende structure, a twin produces a wurtzite structure in one plane. The photograph in Figure 2 shows a ZnSe single crystal. This crystal took several days to grow indicating that very stable growth conditions must be maintained over long periods of time. The vapor phase technique takes advantage of the high vapor pressure of the II–VI compounds that allows for the growth of large single crystals at temperatures much below the melting point of these materials. Vapor growth is helped also by the congruent evaporation of the two constituents into the vapor state in a dissociated form. These two vapor constituents also recombine stoichiometrically into the solid crystal. The melting points and vapor pressures at the melting points of some II–VI semiconductors are given in Table 1.

It is also possible to grow materials in a layer-by-layer fashion onto an existing substrate; this is termed epitaxial growth. Recent developments have allowed the growth to proceed one atomic layer after the other. As a result, materials can be grown that are less than 100 Å in size. At these small sizes, the fundamental electronic and optical behavior of these materials is altered due to quantum mechanical effects. These materials are termed quantum wells. Growth temperatures in these cases are much below the melting point of these materials and allow for uniform single crystals without any 'twin' formation. In molecular beam epitaxy (MBE), atomic beams of the constituents impinge onto a heated substrate where they combine to form the crystalline material. Growth of ZnSe onto III–V substrates such as GaAs is well developed. The quality or purity of the single crystals can often be deduced from their optical properties as we will see later.

The addition of small amounts of other atoms into the crystal during the growth procedure is called doping. Semiconductors are materials whose electrical conductivity can be drastically altered by the addition of small amounts of dopants. This ability to control the electrical conductivity is the key to their use in the high-speed devices used in modern optical communications systems (*see* **Semiconductor Physics:** Impurities and Defects). In ZnSe, doping with Cl produces n-type material while doping with N produces p-type material. The ability to form a pn junction (a thin region between n and p type material) is the precursor for the production of optical devices such as light-emitting diodes (LEDs) or laser diodes (LDs) based on II–VI semiconductors. Doping also changes the optical properties of II–VI materials.

All materials are defective to some degree, and these II–VI materials are no exception. The number and type of defects are determined by thermodynamic and purity considerations during the growth process. There are native defects such as vacancies (missing atoms) and dislocations (extra or missing layers of atoms). There are also impurities present; foreign atoms due to the impurities in the starting growth materials. These impurities have an important effect on the ability of the material to emit light. Dopants and impurities may help to increase the amount of light emitted while dislocations usually reduce the emission efficiency in II–VI materials.

Optical Properties of II–VI Semiconductors: Basic Concepts

Introduction

When light is incident on a solid material, its electric field interacts with the electric field within the atoms comprising the solid. This interaction leads to a

number of effects that we can observe. The light will be reflected or scattered from the surface of the solid, depending on whether the surface is smooth or rough on a length-scale similar to the wavelength of light. The materials of interest here are high-quality crystals with a smooth reflective surface. When light enters a material, it is refracted, i.e., it changes direction within the material. The simplest example of this is when a stick is placed in a jug of water, it appears to be bent. It is of course the light that is bent due to its different interaction with the air and with water. Snell's law states that:

$$\frac{\sin \alpha_i}{\sin \alpha_{tr}} = n \qquad [1]$$

where α_i is the angle of incidence of the light and α_{tr} is the angle of refraction. n is known as the refractive index of the material and is characteristic of it. As well as being refracted, any light that enters the crystal is either absorbed within the material or transmitted through the material to emerge on the other side. If the light is absorbed the material will look colored if the absorption takes place in the visible region where our eyes are sensitive. The ZnSe crystal in Figure 2 is such a material; the orange color is due to the absorption of blue light from the white light shining on the material. Other materials look transparent; ZnO is such an example. Following absorption, some materials produce light of their own; the color of the light is characteristic of the material and this process is termed luminescence. Light may also be scattered within a crystal by imperfections and by vibrations of the atoms in the crystal.

When light enters a solid material, the electric field polarizes the atoms within the structure. The positive and negative charges within the atoms move slightly from the equilibrium positions. All of the optical effects mentioned above are related to the induced polarization. As the constituent atoms in the structure are unique, the induced polarization and the resulting optical properties are specific to particular materials, and this makes optical

characterization a very important tool for the investigation of semiconductor materials.

Reflection at the Air-to-Material Interface

Our experience of looking at reflection from glass tells us that these are weakly reflecting materials; the same is true of single crystal II–VI materials such as that in Figure 2. The interface between air and an optical material is a fundamental aspect of optical physics. The amount of light reflected can be determined from Maxwell's equations. The simplest equation is found where light is incident perpendicular to the surface of the material:

$$R = \frac{(n-1)^2}{(n+1)^2} \qquad [2]$$

where R is the reflection coefficient and n is the refractive index of the material. The value of n is characteristic of the particular material. Values of n for several II–VI materials are given in Table 1. The refractive index n for all these II–VI materials is not constant but varies slowly with the wavelength of the light impinging on the material. In Figure 3, we show the wavelength dependence of the refractive index of ZnSe.

Transmission and Absorption of Light within II–VI Materials

Once the light has passed through the interface with the air, it can either be transmitted through the material to emerge on the other side at a second material–air interface or be gradually absorbed within the body of the material. The ZnSe sample in Figure 2 is illuminated with white light, but it appears orange in color to our eyes, i.e., the orange component within the white light is transmitted through the material to our eye. The other components in the light, mostly green and blue, are absorbed within the material. To obtain more quantitative information, we take a spectrum of the absorption within the material. We illuminate the sample with light of different wavelengths and determine how much is transmitted or absorbed at each wavelength. The transmission spectrum of ZnSe is shown in Figure 4.

The visible spectral region extends from 0.4 to 0.7 microns and we see that there is a large change in transmission around 0.5 microns that is responsible for the color of the ZnSe crystal as seen in Figure 2. This spectral region around the onset of a large reduction in transmission at 0.5 microns is termed the bandgap of the material. As in the case of the refractive index, the value is unique to the material. II–VI materials are termed wide bandgap materials as they possess larger values of the bandgap energy than for Si, Ge and the III–V semiconductor materials. If we shine light of wavelength 0.5 microns onto ZnSe material, the transmission is very low. Under these conditions, the material would look black to our eyes. Once the light has been

absorbed by the II–VI semiconductor, it can in turn produce light of its own. This light, known as luminescence, is again characteristic of the particular material and is the basis for the use of such materials in light-emitting diodes (LEDs) and laser diodes (LDs). In Figure 5 we show the luminescence from a II–VI LED. We see also from Figure 4 that at very long wavelengths, the ZnSe material also exhibits a large reduction in light transmission. This spectral region is termed the far infrared and the light absorbed at this spectral region produces vibrations of the atoms within the material, referred to as lattice absorption.

Light Scattering

Within the bulk of the material, small areas may have a different arrangement of atoms or may contain a substantial number of foreign atoms known as impurities. A large grouping of these impurities is known as an inclusion. In these regions, the optical properties will be different from the bulk of the material. Differences in both absorption coefficients and refractive indices can be found. These different refractive indices cause the light passing through the material to be scattered. Poor-quality material will often contain many inclusions. Even to the eye, these crystals will not look highly transparent. Changes in the refractive indices can also occur in highly pure materials due to vibrations of the atoms in the crystals. The lattice vibrations change the distance between the atoms in the material which alters the electric fields within the material and thereby changes the optical properties. Light can also be scattered due to these vibrations; experimental measurements of light scattering can provide useful information on the vibrations in these materials.

Optical Properties of II–VI Semiconductors: More Advanced Concepts

Light–Semiconductor Interactions

Light is an oscillating electromagnetic field whose interaction with semiconductor materials is in terms of the complex dielectric constant $\varepsilon_c = n_c^2$ where n_c is the complex refractive index defined as $n_c = n - ik$. k is known as the extinction coefficient and the value of k determines the amount of absorption in a material. The optical processes of reflection and absorption in semiconductors are governed by this complex dielectric constant. It turns out that there is a strong relationship between these processes. If the absorption spectrum is determined at all frequencies, then we can determine the refractive index spectrum at all frequencies by what is known as the Kramers–Kronig relations. From this description, we can now refine eqn [2] presented above:

$$R = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2} \qquad [3]$$

If the material is transparent at a particular wavelength, then $k = 0$ and we can determine the refractive index n. This is the case for values given in the table. The technique of spectroscopic ellipsometry can be used to determine the optical response of materials over a large wavelength range. This technique relies upon the change from linear polarization to elliptical polarization for light reflected from a material. From these measurements, the dielectric response can be determined.

If we look again at Figure 3, we see that there is a strong change in sample transmission around 0.5 μm. This corresponds to an energy of 2.18 eV

and is the bandgap energy of ZnSe. According to the details presented above, transitions are now being made from the full valence to the empty conduction bands of the semiconductor material. Once we have exceeded the bandgap energy, we can make further transitions between the bands. The spectrum shown in the figure is a broad band, reflecting the change from sharp atomic transitions to broad transitions in the solid state. Light with a wavelength greater than 0.5 μm does not have sufficient energy to effect the transitions between the bands. These wavelengths are not absorbed in the material. The material is transparent and the value of the extinction coefficient k is zero. The orange color of the crystal in Figure 2 corresponds to this transparent spectral region.

Cooling samples to low temperatures close to absolute zero has a profound effect on the optical properties of materials, particularly the absorption spectrum. In Figure 6, we show the absorption spectrum of a ZnSe sample at a temperature of 2 K. The absorption spectrum is determined from the measured transmission by the following equation

$$\alpha = \frac{1}{L} \ln \frac{I_0}{I_t} \qquad [4]$$

where α is the absorption coefficient, L the length of the sample, I_0 the light intensity incident on the sample and I_t the light intensity transmitted through the sample. In addition to the broad band spectrum there are now a number of sharp spectral lines near the bandgap energy.

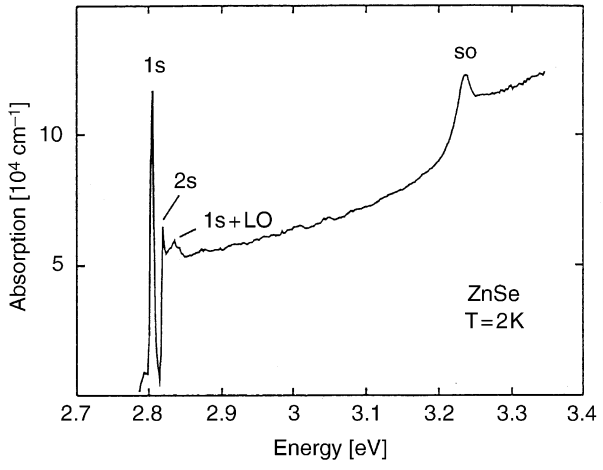

Figure 6 Low-temperature optical absorption spectrum of a ZnSe layer showing the 1S and 2S exciton features, the 1S + 1LO-phonon transition and the split-off (SO) exciton. Reproduced with permission from Bhargava R (ed.) (1997) *Wide Bandgap II–VI Semiconductors*, The Institute of Electrical Engineers: London, Figure 2 of Chapter 4.1.

These lines are due to exciton formation. An exciton is an electron–hole pair bound together by their mutual Coulomb interaction. It is the solid state equivalent of the Hydrogen atom (*see* **Semiconductor Physics:** Excitons). The bandgap energy at 2 K has increased from its value at 300 K. This is due to the thermal changes in the interatomic distance and the vibrational properties of the materials. Values of the bandgap energies determined from the position of the exciton lines in absorption spectra at low and at room temperatures are given in Table 1. At low temperatures, the luminescence is dominated by excitons, and we observe sharp line transitions. The width of the exciton transition is an excellent indicator of the quality of the material, and is often used by crystal growers to determine the quantity of defects in their materials.

It is possible for excitons and for free carriers (those that are not bound together) to recombine without giving out light. This nonradiative process usually involves the creation of local vibrations of the crystal lattice in the vicinity of defects in the material. We can define the radiative efficiency η_r as follows

$$\eta_r = \frac{R_r}{R_r + R_{nr}} \qquad [5]$$

where R_r is the radiative transition rate and R_{nr} is the nonradiative transition rate. In order to develop new optical devices based on II–VI semiconductors, it is essential that the value of R_{nr} be as small as possible. As R_{nr} is directly related to the concentration of defects in these materials, one can see why it is essential to make semiconductors with as few defects as possible. We can study these effects using a pulsed light source. Carriers are created during the pulse of light and recombine after the pulse has stopped. If we measure the luminescence intensity versus time, we can deduce the lifetime, which is given as

$$\frac{1}{\tau} = \frac{1}{\tau_r} + \frac{1}{\tau_{nr}} \qquad [6]$$

where τ_r is the radiative and τ_{nr} the nonradiative lifetime, respectively. By varying the carrier density we can separately determine the contribution to the lifetime from radiative and nonradiative effects. In II–VI materials at room temperature, lifetimes are of the order of 1 ns.

Quantum Wells, High Carrier Density Effects, and Lasers

Recent developments in the growth of semiconductor materials has allowed the production of samples with monolayer accuracy (3–5 Å). If we grow a layered structure with materials of high bandgap on either side of a material of lower bandgap, we can observe quantum mechanical effects. These materials are called quantum wells (*see* **Semiconductor Physics:** Quantum Wells and GaAs-Based Structures). As an example, a 75 Å ZnSe quantum well can be grown between layers of ZnSSe. Due to the small size of the active material, quantum mechanical effects come into play, most notably an increase in the bandgap energy as the width of the quantum well decreases. The effect of placing this material between ZnSSe layers that have a larger bandgap is to confine the electrons and holes to the small region of the well. In this small region, they are less likely to encounter defects and so quantum well materials usually have a higher radiative efficiency than bulk II–VI materials which are grown by standard techniques. In Figure 7, we show the exciton absorption and luminescence from a ZnSe quantum well at low temperature.

If we increase the excitation level in these materials, we can eventually cause them to operate as lasers. At high carrier densities, nonradiative transitions become saturated and radiative efficiency increases. As the refractive indices in II–VI materials are quite large, the reflectivity of the two ends of the sample are usually sufficient to act as the mirrors for the laser cavity. All the II–VI semiconductor materials have exhibited laser action due to their direct bandgap. Most of the early studies of lasing were carried out at low temperature. In recent times, lasing action has been observed at room temperature in CdZnSe quantum well materials and there are attempts at present to develop commercial II–VI lasers for use in optical storage devices and flat panel displays. In Figure 8 we show the transition from luminescence through gain and into lasing action for a CdZnSe quantum well material.

Dopants and Impurities

The key to the large-scale use of semiconductor materials is the large change in the electrical conductivity of the materials with the incorporation of small amounts of other elements. This process is known as doping and the foreign elements are known as dopants. The recent development of II–VI laser diodes in ZnSe materials is based on the p-n diode junction. Electrons injected into the n-type material recombine with holes injected into the p-type material at the junction between these two materials. A particular type of luminescence transition unique to semiconductor materials is the donor–acceptor pair (DAP) recombination. As donor and acceptor atoms are located in specific crystalline sites with respect to one another, we observe that the recombination energy is dependent on separation. Pairs that are close together often exhibit sharp lines while those far apart merge into a broad band. In Figure 9 we show the DAP recombination in ZnSe at 1.6 K.

It is also possible to incorporate foreign atoms in II–VI materials that have a small effect on the electrical properties but significantly change the optical properties. Such foreign atoms are termed impurities to distinguish them from dopants. An example is Mn^{2+} in ZnS. The Mn ions take the place of a small number of Zn atoms in the lattice. The luminescence from such a material is a broad emission in the visible region due to optical transitions on the Mn ions. ZnS:Mn materials are used as phosphors in flat-panel displays.

Effects of Temperature, Pressure, Electric, and Magnetic Fields

The optical properties of II–VI materials are subject to variation due to temperature changes, external pressure and fields. Increasing temperature is found to lead to a decrease in the bandgap of II–VI materials. This decrease is due to the combined effects of an increase in the lattice spacing with temperature and the electron–phonon interaction. As the population of phonons is temperature dependent, this effect increases strongly as temperature increases and is the major contributor to the change in bandgap with temperature. A second effect of increasing the temperature is the change in the luminescence properties. In particular, it is found that the luminescence efficiency decreases and this is reflected in a reduced luminescence lifetime at room temperature compared with low-temperature values. Looking again at eqn [6], it is the nonradiative lifetime that changes rapidly with temperature and results in the decrease in the luminescence efficiency.

Pressure changes may be hydrostatic or uniaxial. In the hydrostatic case, the atoms are all brought closer together, and for the II–VI materials, this results in an increase in the bandgap energy. On the other hand, a uniaxial stress results in a decrease in the bandgap in the direction of the stress and an increase in the transverse directions. In II–VI materials with a wurtzite structure, the situation is more complex with two longitudinal and four transverse deformations possible.

External electric and magnetic fields can also be applied to II–VI semiconductors and thereby the optical properties can be changed. Electric fields polarize the materials and can lead to a reduction in the optical strength of transitions due to this polarization-induced carrier separation. Magnetic fields, on the other hand, lead to a splitting of the conduction and valence bands into Landau levels due to the circular motion of the carriers around the direction of the field.

Introduction

The binary IV–VI compounds formed from Pb and group-VI elements like S, Se, and Te are among the oldest known semiconducting materials, and have been used for many years for electronic and opto-electronic device applications. The first ever reported solid state diode was made from single crystalline PbS and its rectifying properties were exploited in early radio receivers. Later on, interest in IV–VI semiconductors shifted to mid-infrared opto-electronic device applications such as photon detectors operating in the 3–14 μm wavelength range, taking advantage of the narrow energy gap between the valence and conduction band of the IV–VI compounds. Soon after the demonstration of lasing in III–V semiconductor diode structures, the first mid-infrared p-n junction laser was reported using $Pb_{1-x}Sn_xTe$, and since then efficient mid- and far-infrared IV–VI compound diode lasers have been fabricated, finding their main applications for remote sensing of gaseous pollutants in trace gas sensing devices, for toxic gas analysis systems, for human breath analysis in medical diagnostics, and for fabrication process control. Recently, IV–VI multiquantum-well structures have also attracted a lot of attention for their potential as efficient thermoelectric devices.

Basic Properties

In lead salt compounds, both the valence band maximum and the conduction band minimum occur at the L-points of the Brillouin zone. Thus these many-valley semiconductors have a direct gap, but not in the center of the Brillouin zone. In addition the small values of the energy gaps ($E_g < 410$ meV at $T = 300$ K) lead to a strong $\mathbf{k}\cdot\mathbf{p}$ interaction which in turn results in a strong nonparabolicity of the $E(k)$ dispersion relations. The small energy gaps also lead to small effective masses of electrons and holes, and the strong spin–orbit interaction (Pb is a very heavy element) leads to large values of the g-factors.

The bandgaps of the lead compounds have a positive temperature coefficient ($dE_g/dT > 0$) and a negative pressure coefficient ($dE_g/dp < 0$), i.e., the gaps increase with temperature and decrease with hydrostatic pressure. These anomalous properties are related to peculiarities of the band structure, among them the fact that in the lead compounds the Pb 6s levels are below the top of the valence band, and thus are occupied, in contrast to the group IV, III–V and II–VI compounds.

Almost all optical device applications of the IV–VI semiconductors are based on the materials subgroup of cubic lead chalcogenides PbTe, PbSe, and PbS, and their quasibinary alloys with other chalcogenide such as compounds, like PbSnTe, PbSnSe, or ternary alloys like PbEuTe, PbSrTe, PbEuSe, PbSrSe, etc. These compounds all crystallize in the rocksalt structure

with sixfold coordination and lattice constants in the 5.9 to 6.5 Å range. Mechanically, the lead salt compounds are much softer than the tetrahedrally bonded semiconductors, which has significant implications for device fabrication processes.

A further unusual property of the lead compounds is their huge static dielectric constant ε_0. In particular PbTe is close to a structural phase transition from the NaCl structure to a rhombohedral modification with ferroelectric properties. GeTe and SnTe are indeed ferroelectric with Curie temperatures of about 700 K and 145 K respectively, and also PbGeTe and PbSnTe become ferroelectric when the Ge or Sn content exceeds 1% or 20%, respectively. PbTe exhibits a softening of the transverse optic phonon mode with decreasing temperature. Although PbTe remains cubic, the temperature dependence of the static dielectric constant $\varepsilon_0 \propto C/(T-\theta)$ can be associated with an extrapolated negative Curie temperature θ of -75 K. As a consequence, the static dielectric constant increases strongly with decreasing temperature, reaching a value of $\varepsilon_0 = 1350$ at 4 K. This is the reason for the strong increase of the static dielectric constant at low temperatures as shown in Table 1, in which important properties of PbTe, PbSe, and PbS are summarized.

Also, the high-frequency dielectric constants ε_∞ of the lead salts are extremely high, which leads to refractive indices of about 4.4 for PbS, to 5.0 for PbSe and to about 6.0 for PbTe at $T = 300$ K, for photon energies just below the respective energy gaps.

As a result of the huge static dielectric constants, the hydrogen-like impurity binding energies are in the range of μeV, and the carrier scattering at ionized impurities is effectively screened. Consequently, the low-temperature carrier mobilities are high, exceeding 10^6 cm^2/Vs in PbTe. For doping of the lead salts two alternative methods are used, namely (1) adjustment of the stoichiometry of the compounds, or (2) doping with various kinds of impurities. Because the electronic states of these vacancies are resonant within the conduction or valence bands, each metal (Pb or Sn) vacancy acts as a doubly charged acceptor, and each chalcogen (Te, Se, or S) vacancy acts as a doubly charged donor. As a result, background doping levels below 10^{17} cm^{-3} are difficult. For doping with impurities, atoms from group IIIa (In, Ga, Tl), group Va (As, Sb, Bi), as well as group Ib elements (Cu, Ag) are used. These dopants are amphoteric p- or n-type, depending on whether they are incorporated substitutionally on metal or chalcogen lattice sites.

Compound	*Expansion coefficient*
PbS	20.3
PbSe	19.4
PbTe	19.8
GaAs	6
Si	2.6
BaF_2	18.8

Other important aspects of the lead salts are their rather large linear thermal expansion coefficients of around 20×10^{-6} K^{-1} which are about a factor of three larger than that of GaAs, and six times larger than that of Si as shown in Table 2. The thermal conductivity is much lower than that of other semiconductors, which is favorable for their use in thermoelectric devices but causes problems in the removal of the dissipated heat in IV–VI compound diode lasers.

Band Structure

A main property of the electronic band structure of the lead salt compounds is the small and direct energy gap of less than 410 meV (see Table 1). Since the maxima of the valence band and the minima of the conduction band are located at the same wavevector in reciprocal space, optical photons can be directly absorbed or emitted at the band edges. This makes the lead salts very well suited for opto-electronic applications such as infrared photon detectors or emitters. The band extrema are located at the edges in the $<111>$ direction of the Brillouin zone (L-points). In contrast to most other semiconductors, the conduction and valence bands are nearly mirror symmetric with almost equal effective masses for the electrons and holes. Because of the narrow energy gaps, the energy bands are strongly nonparabolic and the effective masses of electrons as well as holes are rather small ($0.02-0.08\,m_0$ for the transverse masses,

see Table 3). In addition, the bands are anisotropic, i.e., the Fermi surfaces are elongated ellipsoids of revolution around the $<111>$ axes, characterized by a longitudinal and transverse effective mass m_l and m_t parallel and perpendicular to the four-fold $<111>$ directions.

For PbTe the effective mass anisotropy is very large with a ratio of about 10 between longitudinal and transverse masses, whereas for PbSe and PbS this ratio is only 1.8 and 1.2, respectively (Table 2). Furthermore, in the alloy system $PbSe_{1-x}Te_x$ the energy gap shows a bowing, but not with a minimum value but rather a maximum gap for x at about 0.7. This is in contrast to the behavior found in direct-gap zincblende semiconductors: the bandgap $E_g(x)$ of an $A_{1-x}B_x$ alloy can generally be represented by $E_g(x) = (1-x)E_g(A) + xE_g(B) - bx(1-x)$ where b denotes the bowing coefficient. For III–V and II–VI compounds $b > 0$; whereas, for PbSeTe alloys $b < 0$.

Apart from the above-mentioned negative pressure coefficients of the direct gaps and their positive temperature coefficient which are tabulated in Table 4, there is a further intriguing anomaly in the chemical trends of the fundamental gap at the L-points: it decreases from PbS to PbSe, but increases from PbSe to PbTe, i.e., the direct gaps do not decrease monotonically with increasing atomic number of the anions. This decrease of the energy bandgap with decreasing temperature is substantial: i.e. it decreases from room temperature to 4 K by about 130 meV (see Table 1). This represents a large relative change with respect to the absolute value of the bandgap, and thus the emission of lead salt based diode lasers can be tuned over a broad wavelength range just by changing the operation temperature. This effect is actually utilized for spectroscopic applications of these lasers.

For adjustment of the fundamental absorption edge of infrared detectors as well as the adjustment of the wavelength emission of lead salt diode lasers, alloying of the lead salt compounds with other chalcogenide compounds is used. As illustrated in Figure 1, for this purpose many different ternary and quaternary alloys have been used. Important alloy systems for far-infrared applications are the lead–tin chalcogenide alloys. The tin chalcogenides (SnS, SnSe, SnTe) form single-phase pseudobinary alloy systems with the lead salts for all compositions. They have similar band structures as compared to the lead salt compounds; however, the arrangement of valence and conduction bands is exchanged. As a result, with increasing Sn content the energy bandgap of the ternary lead–tin chalcogenide alloys decreases and a zero bandgap semiconductor is reached for a certain ternary composition. For an operation temperature of 77 K, the bandgap is zero for a Sn content of $x_{Sn} \sim 40\%$ in the case of $Pb_{1-x}Sn_xTe$, and of $x_{Sn} \sim 20\%$ in the $Pb_{1-x}Sn_xSe$ case.

Optical Properties

The strong fundamental absorption in the lead salt compounds reflects the particularly high joint density of states at the direct gap at the L-points of the Brillouin zone. The main advantage of the lead

compounds with respect to other direct narrow-gap semiconductors like InSb, or HgCdTe alloys, with band extremes at the center, i.e., the Γ-point of the Brillouin zone, is related to the differences in the effective masses. Whereas the transverse effective masses of the IV–VI compounds have comparable values to the effective masses of the narrow-gap III–V and II–VI compounds, the longitudinal effective masses of the lead compounds are much larger. Thus the mass anisotropy together with the four-fold valley degeneracy at the L-point of the Brillouin zone leads to the substantially higher joint density of states and corresponding large absorption constants. Due to the rapid change of $\alpha(\omega)$ in the fundamental absorption range, a peak appears in the refractive index, $n(\omega)$, as shown in Figure 2 for PbTe, PbSe and for PbS. The shift of the peak with increasing temperature to higher photon energies reflects the increasing energy gaps.

In two-dimensional structures the changes of the absorption constant with frequency are particularly steep for energies which correspond to the onset of absorption between quantum confined electric subbands in the valence and conduction band. Such step-like features have indeed been observed in the absorption of PbTe/PbEuTe multiquantum-well (MQW) structures by Yuan *et al.* In Figure 3 the absorption constants and refractive indices are shown for a series of three MQW samples with different PbTe well widths. The steps in the absorption coefficients for the interband transitions associated to the longitudinal valleys with their main axis parallel to the [111] growth direction, denoted by 'l' as well as those associated by the oblique valleys, denoted by 'o' are accompanied by corresponding cusp-like enhancements of the refractive index. These cusps are of importance for the proper design of MQW laser structures.

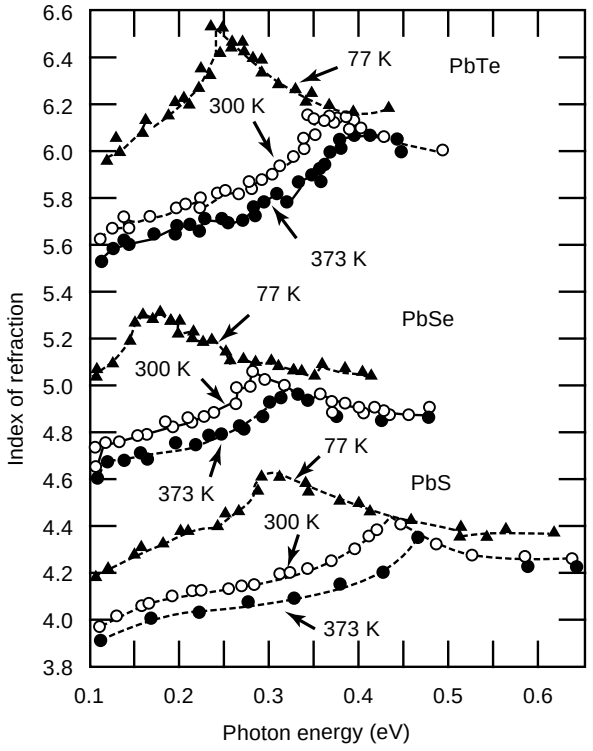

Figure 2 Refractive indices of PbTe, PbSe, and PbS as a function of photon energy at 77, 300, and 373 K. Reproduced with permission from Zemel JN, Jensen JD and Schoolar RB (1965) Electrical and optical properties of epitaxial films of PbS, PbSe, PbTe and SnTe. *Physical Review* 140: A330–A337. Copyright 1965, American Physical Society.

Because of the extremely high values of the refractive indices, the lead salts can easily be combined with materials of much lower refractive indices like EuTe, EuSe, or BaF_2 for efficient multilayer Bragg mirror structures. The high reflectivity of Bragg mirrors is caused by constructive interference of electromagnetic waves reflected at the subsequent interfaces of a multilayer structure. To obtain constructive interference, all interfaces have to be parallel, and, depending on the refractive indices of the media inside the Bragg mirror, the distance between subsequent interfaces should be an even or odd multiple of one quarter of the optical wavelength λ. In practice, stacks of two alternating layers with different refractive indices n_1 and n_2 and with a thickness equal to a quarter optical wavelength are used.

If for these λ/4 layers $Pb_{0.93}Eu_{0.07}Te$ and EuTe are used, a high index contrast of 68% is obtained and therefore very high reflectivities can be achieved already by a very small number of layer pairs. It was shown that a Bragg mirror with 3.5 periods of $EuTe/Pb_{0.93}Eu_{0.07}Te$ layer pairs for a target wavelength of 3.8 μm has only a total thickness as small as 2.55 μm. For comparison with results obtained for other material combinations it is useful to relate the stop bandwidth $\Delta\lambda$ to the center wavelength λ_T of the Bragg mirror. For $EuTe/Pb_{0.93}Eu_{0.07}Te$ this relative stop bandwidth $\Delta\lambda/\lambda_T$ is as large as 50%. An even wider stop bandwidth of 59% was demonstrated for a mirror with PbTe and EuTe λ/4 layers. This value represents, to the best of our knowledge, the highest relative stop bandwidth obtained for molecular beam epitaxy (MBE) grown Bragg reflectors.

Infrared Lasers

Among the infrared diode lasers, those based on IV–VI compounds play a particularly important role. They cover a wavelength range from 2.5 μm to about 30 μm. In fact, up to now most commercially

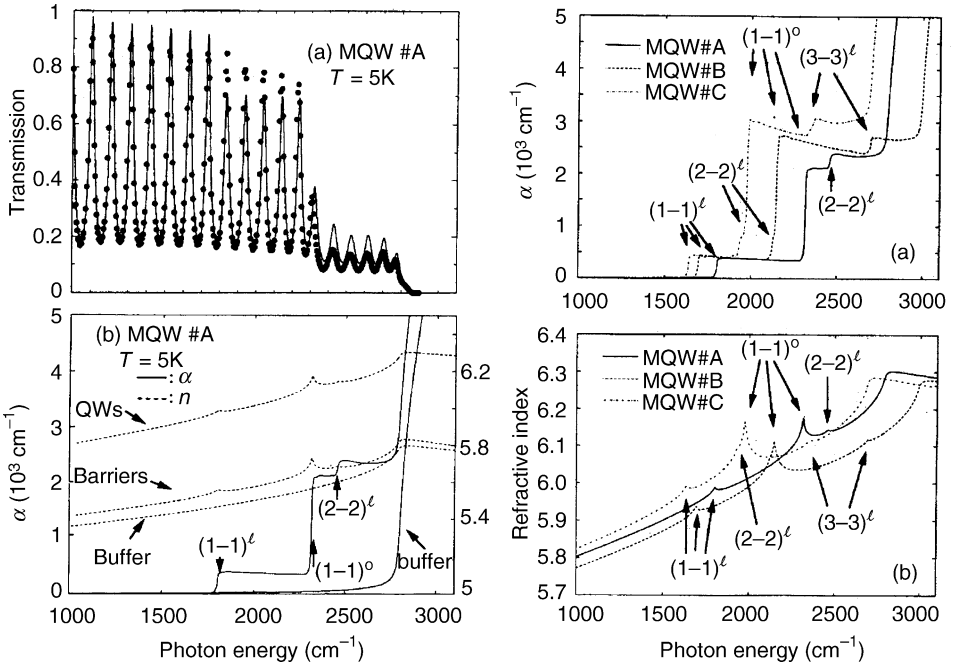

Figure 3 Left panel: (a) transmission versus energy for a PbTe/$Pb_{1-x}Eu_xTe$ multiquantum-well sample A (6.2 nm/62.1 nm, $x = 0.026$, 46 periods). Dots: experimental data; full line: calculation based on an envelope function model. (b) Frequency dependence of the absorption constant (full line) and of the refractive index (dotted lines). The arrows indicate interband transitions between electric sub-bands associated with valleys with main axis parallel to the [111] growth direction (l) and oblique to it (o). Right panel: (a) Comparison of the absorption constant of three PbTe/PbEuTe MQW samples (B: 9.3 nm/55.4 nm, $x = 0.03$, 30 periods; C: 11.8 nm/48.6 nm, $x = 0.024$, 30 periods). (b) Refractive index versus energy. Steps in the absorption constant due to onset of interband transitions are associated with cusps in the refractive index. available mid- and far-infrared laser diodes are made from IV–VI compounds. The main material properties which are advantageous in this respect are (i) the electronic band structure with mirror-like bands at the L-point of the Brillouin zone and the resulting high joint density of states; (ii) the lower nonradiative Auger recombination rate in IV–VI compounds as compared to III–V and II–VI materials, and (iii) the high dielectric constant and the resulting weak detrimental influence of defects on nonradiative recombination losses. At wavelengths longer than 3 μm, IV–VI interband diode lasers are superior to their III–V counterparts for reaching high operating temperatures. So far IV–VI compound lasers hold extreme high cw operating temperature at wavelengths larger than 3 μm. With PbSe/PbSrSe diode lasers pulsed operation up to 60 °C was reported, whereas cw operation up to 223 K was achieved with separate confinement buried PbTe/PbEuSeTe heterostructure laser. Embedding PbTe quantum wells as the active medium in PbEuTe barriers between two dielectric Bragg mirrors optically pumped pulsed lasing was observed up to 65 °C. The recently developed III–V based quantum cascade lasers are rapidly improving and are becoming important competitors for IV–VI lasers. The commercial IV–VI lasers, however, are still based on conventional designs like homojunction, heterojunction, or single and multiple heterojunction lasers.

A unique property of lead salt laser diodes is the ease of tuning of the emission wavelength due to the strong change of bandgap of the IV–VI materials with increasing temperature. This, together with their narrow linewidths, makes these lasers ideally suited for spectroscopic applications, including research in molecular spectroscopy of ions or radicals in heterodyne and acoustic spectroscopy, or Doppler spectroscopy of molecular beams. So far the main applications are in time resolved combustion analysis in the automotive industry, in the monitoring of emissions of power plants, in exact monitoring of gas compositions in chemical plants, and spatially and time resolved *in situ* analysis.

Apart from the significant advances with IV–VI edge emitting diode lasers, vertical cavity surface

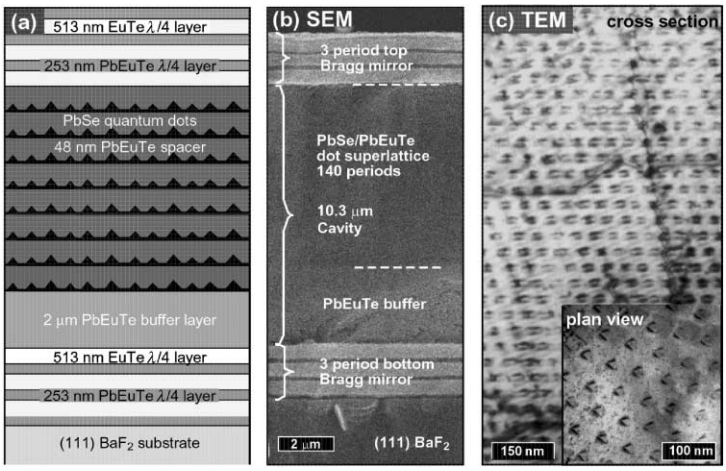

Figure 4 (a) Schematic cross-section of a PbSe quantum-dot VCSEL structure; (b) corresponding cross-sectional scanning electron micrograph; and (c) cross-sectional and plan-view transmission electron micrographs of a PbSe/PbEuTe dot superlattice sample reference sample. emitting lasers (VCSELs) have been successfully produced with optically pumped pulsed mode operation up to 50 °C. These lasers have attractive features like low-divergence circular output beam, low active volumes, and low thresholds.

High-finesse vertical cavity structures have also made it possible to realize mid-infrared surface-emitting PbSe/PbEuTe quantum dot lasers. As shown in Figure 4 in this case a self-organized PbSe/PbEuTe quantum dot superlattice was introduced into the active cavity region between Bragg mirrors consisting of three $\lambda/4$ layer pairs of 513 nm EuTe alternating with 253 nm $Pb_{0.94}Eu_{006}Te$. Optically pumped VCSEL emission at $\lambda = 4.2-3.9\ \mu m$ was achieved up to 150 K. The PbSe dots exhibit a face-centered cubic three-dimensional stacking in the superlattice. Lasing occurs simultaneously at the $m = 28^{th}$ and 29^{th} order cavity modes, which shifts with increasing temperature to the $m = 29^{th}$ and $m = 30^{th}$ mode as shown in Figure 5. This simultaneous stimulated two-mode laser operation is a result of the inhomogeneously broadened quantum-dot gain spectrum, due to PbSe dot size fluctuations.

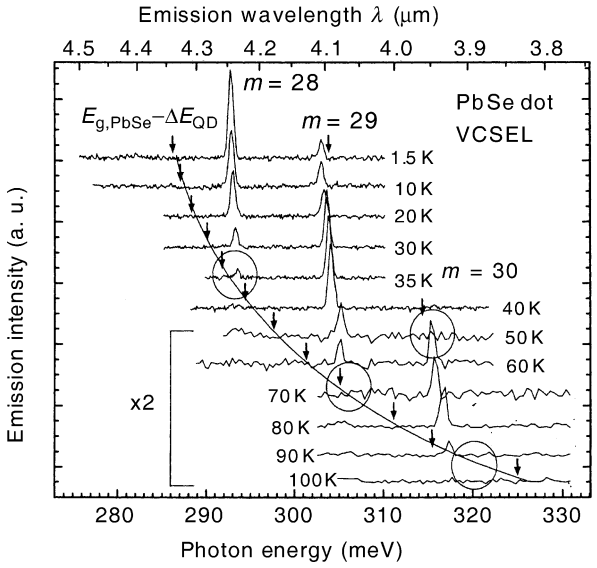

Figure 5 PbSe dot VCSEL emission spectra at various temperatures between 1.5 and 100 K for a pump power twice the threshold, showing the switching of the laser emission to higher cavity modes as the temperature increases. The arrows and the dashed line indicate the low-energy edge of the quantum-dot gain spectrum given by $E_{g,PbSe}(T) + \Delta E_{QD}$, where $\Delta E_{QD} = 141$ meV. Infrared Detectors

The photoconductive properties of PbS and PbSe have been used for the detection of infrared radiation already since about 1930. These detectors are still mass produced either by vacuum deposition or precipitation from aqueous solution in the presence of an oxidizing agent. The polycrystalline films deposited on glass or similar substrates are usually about 1 μm thick with grain sizes of about 1 μm.

Apart from polycrystalline thin-film detectors also single crystalline films have been used for infrared detection. In particular, the photoconductive response

of a sequence of n- and p-doped PbTe multilayers (so-called nipi structures) was shown to come close to that for the theoretical limit for the detectivity D^* of an ideal photodetector at temperatures between 77 and 90 K. Recently, lead selenide detectors have been used in advanced focal plane array (FPA) detectors and are commercially available as linear or bilinear FPAs with up to 526 detector elements. These elements are coupled to CMOS multiplexer readout circuits. The PbSe detector elements are thermoelectrically cooled, with entire power requirement for the FPAs and the cooler of less than 5 W. These structures are a low-cost alternative to the more elaborate FPAs based on HgCdTe technology.

The importance of thermal imaging by using focal plane arrays of many detector elements has recently stimulated further work with IV–VI epitaxial layers. In particular, the possibility of using Si substrates, as first shown by Zogg *et al.*, has brought a new impetus to the field of IV–VI infrared devices. With the use of Si wafers it is possible to integrate the detector of an infrared camera which consists of thousands of pixels to the read-out electronics which is usually based on standard silicon CMOS devices. In this case, the active lead salt infrared detector elements are grown by molecular beam epitaxy on CaF_2/BaF_2 buffer layers deposited on the Si (111) substrates after the fabrication of the electronic circuitry for the read-out. Conventional HgCdTe focal plane technology relies on hybrid structures with In bump bonds between the infrared devices and the Si substrate for each of the pixels. Due to the rather high dielectric constants of the IV–VI compounds as compared to HgCdTe, the high-frequency operation of IV–VI detector structures is limited to about 100 MHz. This upper frequency limit is, however, sufficient for infrared focal plane arrays. With IV–VI active epilayer thicknesses of few μm internal quantum efficiencies close to 100% and external efficiencies of about 60% have been achieved. Using materials like PbS, PbTe, PbEuSe, PbEuTe, or PbSnSe, the cutoff wavelength of the detector array can be varied from 4 to 14 μm at $T = 77$ K. The sensitivity of these detector structures is limited by generation-recombination noise for $T < 100$ K, whereas for higher temperatures these sensors are diffusion limited. The variation of quantum efficiencies between different pixels was shown to be less than about 3% for a 256 pixel device. Since all growth steps for these infrared sensors are performed at temperatures below 450 °C, a processing compatibility exists with standard Si-VLSI technology.

Summary

The peculiar structural, electronic, and optical properties of IV–VI semiconductors as compared to other semiconductor materials are a consequence of the ten valence electrons per atomic pair instead of the eight valence electrons typical for the tetrahedrally bonded group IV, III–V, and II–VI semiconductors. The most important group of IV–VI materials is the so-called lead chalcogenide (lead salt) compounds and their ternary and quaternary alloys. Their electronic band structure with the narrow direct minimum gap not at the center but at the edges of the Brillouin zone (L-points) exhibits a number of unique properties. The minimum energy gap increases with increasing temperature and decreases with hydrostatic pressure. The refractive indices are particularly large. As compared to narrow-gap III–V or II–VI semiconductors the Auger recombination rates are by two orders of magnitude smaller. All these properties provide the lead salts with great advantages for achieving infrared p-n junction lasing operation at comparatively high temperatures. Furthermore, efficient microcavity designs with extremely high reflectivities of 99% were realized with only three layer periods of combination like $PbSrTe/BaF_2$ or PbEuTe/EuTe due to their extremely high refractive index contrast. Further applications of the lead compounds are high sensitive infrared detectors, including focal plane array detectors which can be fabricated with comparatively low cost technologies, as well as thermoelectric devices.

Introduction

Mercury-cadmium telluride (HgCdTe or $Hg_{1-x}Cd_x$Te) is a pseudobinary alloy semiconductor that crystallizes in the zincblende structure. The energy bandgap $E_G(x,T)$ varies continuously, and nearly linearly, with alloy composition parameter x, ranging from 1.6 eV for the wide-gap semiconductor CdTe to −0.3 eV for the semimetal HgTe. The bandgap passes through zero at an alloy composition of $x = 0.16$ (for $T = 0$ K). This broad range of energy bandgap provides a continuum of materials whose absorption edge can be tailored to provide high-performance quantum detectors for wavelengths over the 1–30 μm spectral range. Direct allowed valence-to-conduction band transitions are responsible for large values of the optical absorption coefficient, which enable quantum efficiencies approaching 100% to be achieved in practical device designs. Long minority carrier lifetimes result in low thermal noise, and permit high performance to be achieved at operating temperatures that are the highest reported among infrared detectors of comparable cutoff wavelengths. HgCdTe is well-established today as

the most broadly applicable high-performance infrared detector material.

This article summarizes the fundamental properties of this versatile alloy semiconductor, and relates the material properties to its success as an infrared photoconductive and photovoltaic detector material.

Historical Background

It is noteworthy that HgCdTe is probably the first example of a semiconductor material that was intentionally created to satisfy well-defined theoretical device requirements. The importance of the infrared atmospheric transmission window at 8–12 μm was well known for thermal imaging systems, which enable night vision by imaging emitted infrared radiation from the scene rather than reflected visible radiation. The only available infrared detectors with the required sensitivity at 8–12 μm were extrinsic photoconductors such as copper-doped germanium, in which the photoinduced transitions were between a donor or acceptor level and the adjacent band extremum. However, such extrinsic detectors required cooling to prohibitively low temperatures, such as 10–15 K, which made thermal imaging systems bulky and impractical.

Theory showed that the reasons for such a low operating temperature were fundamental to the extrinsic detector material itself – essentially a short carrier lifetime that resulted in a large thermal generation rate and a correspondingly large thermal noise. Theory also showed that an intrinsic detector, in which the photoinduced transitions were direct (vertical) transitions between the valence band and the conduction band, could have significantly longer carrier lifetimes. This meant that an intrinsic detector, with a bandgap of 0.1 eV that matched the 8–12 μm band, could achieve the required sensitivity at much higher operating temperatures, as high as 77 K, that of liquid nitrogen. These theoretical and practical considerations motivated the search in the late 1950s for a semiconductor with a direct bandgap of 0.1 eV.

The first report of the synthesis of the semimetal HgTe and the wide-bandgap semiconductor CdTe to form the semiconductor alloy HgCdTe was published in 1959 by the Royal Radar Establishment in Malvern, England. This seminal paper reported both photoconductive and photovoltaic response at wavelengths extending to 12 μm, and made the understated observation that this material showed promise for intrinsic infrared detectors.

Soon thereafter, working under a US Air Force contract with the objective of devising an 8–12 μm background-limited semiconductor infrared detector that would operate at temperatures as high as 77 K, the group led by Paul Kruse at the Honeywell Corporate Research Center in Hopkins, Minnesota developed a modified Bridgman crystal growth technique for HgCdTe. In 1962 they reported both photoconductive and photovoltaic detection in rudimentary HgCdTe devices.

Fundamental Material Properties

Three fundamental properties determine the degree to which a semiconductor will make a successful infrared detector. First, the energy bandgap must be approximately equal to the smallest photon energy to be detected. There can be severe cooling penalties if the bandgap is significantly smaller than the smallest photon energy of interest. Second, the optical absorption coefficient must be large enough so that nearly all incident photons of interest are converted to electron–hole pairs for practical values of device thickness. Third, the inherent recombination mechanisms must allow long carrier lifetimes to be realized so that thermal generation rates, and hence thermal noise, can be minimized for practical devices and operating conditions.

The three key features that make HgCdTe the nearly ideal infrared detector material – tailorable energy band gap over the 1–30 μm range, large optical absorption coefficients that enable high quantum efficiency, and favorable inherent recombination mechanisms that lead to high operating temperature – are direct consequences of the energy band structure of this zincblende semiconductor. They apply no matter whether the device embodiment is a photoconductor, a photodiode or a metal–insulator–semiconductor detector. In addition, HgCdTe has many other favorable material properties, summarized in this article, that are technologically important for realizing practical infrared detectors. Tables 1 and 2 summarize various material properties for $Hg_{1-x}Cd_xTe$. **Table 1** summarizes material properties for $Hg_{1-x}Cd_xTe$ that vary with alloy composition x and temperature T: lattice constant a, energy band gap E_G, cutoff wavelength λ_{CO} ($= 1.24/E_G$), intrinsic carrier concentration n_i, conduction band effective mass ratio m_C/m_0, conduction band g-factor g_C, static and high frequency dielectric constants $\varepsilon_S/\varepsilon_0$ and $\varepsilon_\infty/\varepsilon_0$, index of refraction $n_R = (\varepsilon_\infty/\varepsilon_0)^{1/2}$, electron and heavy hole mobilities μ_e and μ_{hh}, mobility ratio b, radiative and Auger-1 lifetimes τ_{RAD} and $\tau_{Auger\text{-}1}$, and typical lifetimes $\tau_{typical}$ observed in n-type HgCdTe of low carrier concentration ($<1 \times 10^{15} cm^{-3}$).

Energy Band Gap and Band Structure

The energy band gap $E_G(x, T)$ of $Hg_{1-x}Cd_xTe$ varies continuously, and nearly linearly, with alloy composition parameter x, ranging from 1.6 eV for the wide-gap semiconductor CdTe to −0.3 eV for the semimetal HgTe, as shown in Figure 1a. Also plotted in Figure 1a is the cutoff wavelength $\lambda_{CO}(x, T)$ ($\approx hc/E_G(x, T)$, where h is Planck's constant and c is the speed of light), defined as that wavelength at which the photoresponse falls to 50% of its peak value. The energy bandgap $E_G(x, T)$, defined at the difference between the Γ_6 and Γ_8 band extrema at $\Gamma = 0$, passes through zero at an alloy composition of $x = 0.16$ (for $T = 0$ K), as illustrated in Figure 1b. This broad range of energy bandgap provides a continuum of materials whose absorption edge can be tailored to provide high-performance quantum detectors for wavelengths over the 1–30 μm spectral range.

Optical Absorption Coefficient

Optical absorption coefficient data for several alloy compositions of $Hg_{1-x}Cd_xTe$ are plotted versus wavelength in Figure 2. Several trends are evident. The absorption strength generally decreases as the gap becomes smaller due both to the decrease in the conduction band effective mass and to the $\lambda^{-1/2}$ dependence of the absorption coefficient on wavelength λ. There is an exponential tail at energies just below the bandgap energy.

Carrier Lifetime Mechanisms

There are two fundamental mechanisms that determine the minority carrier lifetime in defect-free HgCdTe: radiative recombination and Auger recombination (Auger-1 in n-type and Auger-7 in p-type). Because they involve only interactions among electrons and holes in the valence and conduction bands, and do not require the intermediary of defect states, these mechanisms are regarded as inherent to the material itself, depending only on the band structure, the donor or acceptor concentration, and the temperature. The important advantage that HgCdTe enjoys as a high-performance detector material is that these fundamental mechanisms provide, for practically achievable

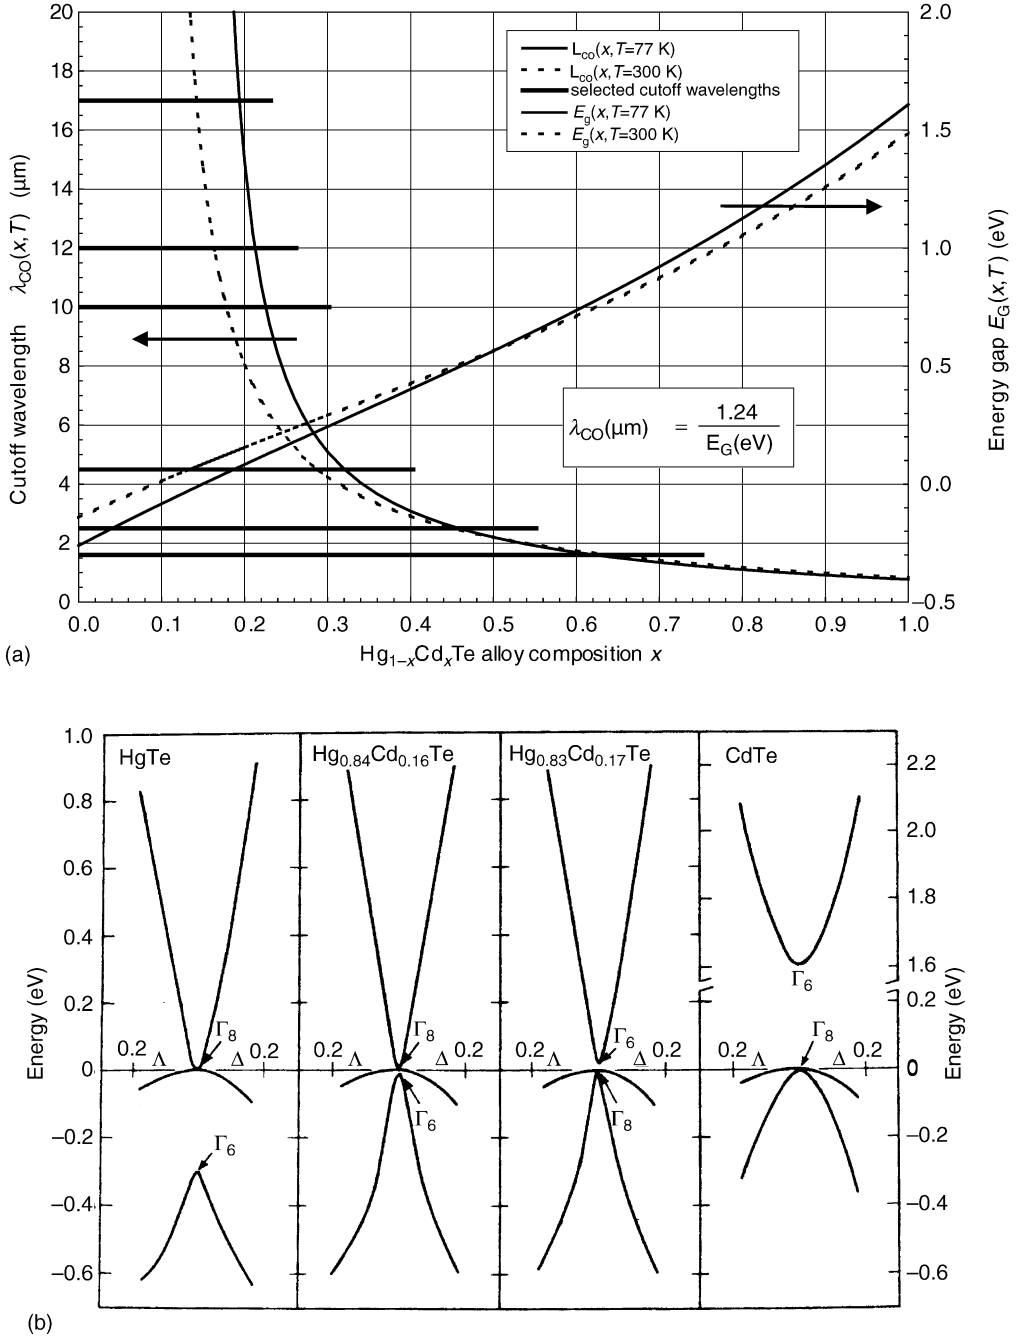

Figure 1 (a) Energy bandgap $E_G(x,T)$ and cutoff wavelength $\lambda_{CO}(x,T)$ for $Hg_{1-x}Cd_xTe$, plotted versus alloy composition parameter x, for temperatures of 77 K (solid curves) and 300 K (dashed curves). Horizontal bars indicate important cutoff wavelengths for HgCdTe detector technology. (b) Band diagrams near the Γ point calculated for HgTe, for two compositions of $Hg_{1-x}Cd_xTe$, and for CdTe, illustrating the transition from negative to positive energy bandgap. The energy bandgap is defined at the difference between the Γ_6 and Γ_8 band extrema at $\Gamma = 0$. Part (b) reproduced with permission from Chadi DJ and Cohen ML (1973) Electronic structure of $Hg_{1-x}Cd_xTe$ alloys and charge-density calculations using representative K points. *Physical Review B* 7: 692–699.

carrier concentrations, lifetimes that are long enough (and hence thermal generation rates that are low enough) that background-limited sensitivity is achieved at temperatures substantially higher than for other classes of infrared detectors, such as extrinsic detectors (As-doped Si, Cu-doped Ge) and quantum-well infrared photodetectors (QWIPs).

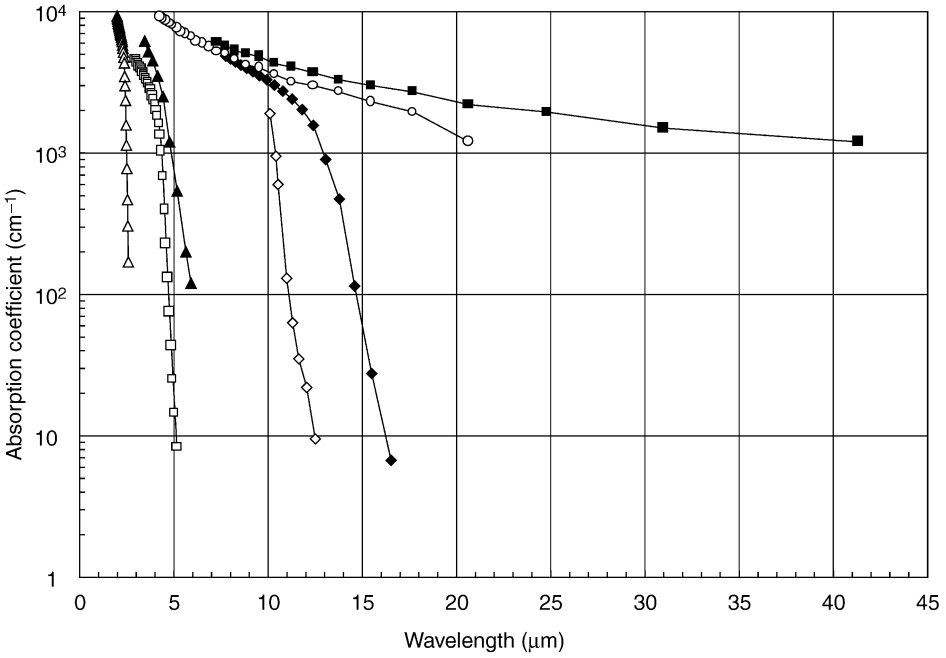

Figure 2 Optical absorption coefficient data for several $Hg_{1-x}Cd_xTe$ alloy compositions, for photon energies near the fundamental absorption edge, plotted versus wavelength.

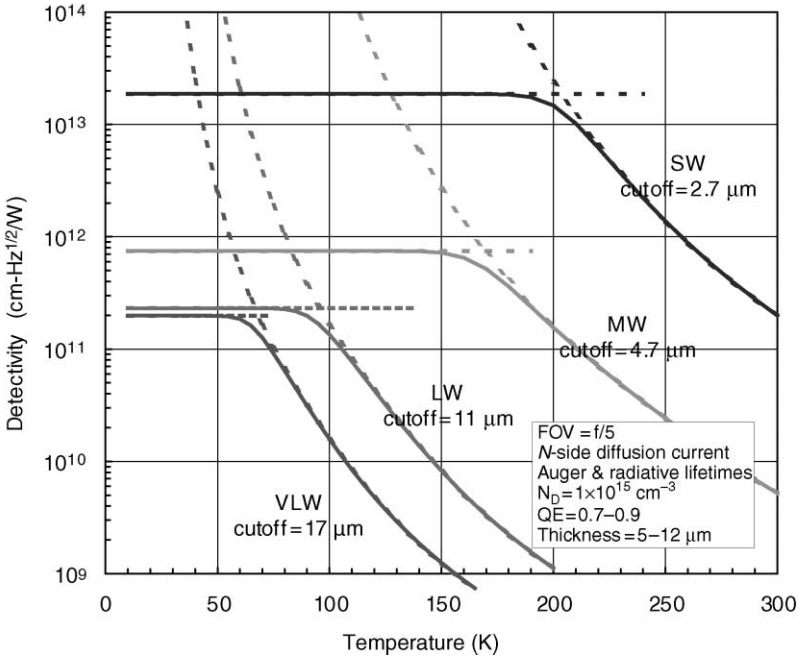

Figure 3 Calculated detectivity (D^*) for $Hg_{1-x}Cd_xTe$ infrared detectors for four technologically important wavelength regions, plotted versus operating temperature.

Figure 3 illustrates the sensitivities and operating temperatures that can be achieved for HgCdTe infrared detectors for four important wavelength regions. Detectivity, D^*, is the normalized signal-to-noise ratio that is the key figure of merit for the sensitivity of an infrared detector. At lower temperatures, detector thermal noise is negligible, and D^* is limited by detector noise due to

fluctuations in the arrival rate of photons from the thermal room-background radiation. This limit is referred to as the BLIP (background-limited infrared photodetector) limit, and is indicated in Figure 3 by the horizontal dashed lines. As detector temperature increases, the detector thermal noise increases exponentially, and eventually overcomes the background noise, causing D^* to decrease exponentially for further increases in temperature. Detector thermal noise is proportional to the thermal generation rate, which is inversely proportional to the carrier lifetime.

n-Type and p-Type Doping

HgCdTe can be made n-type or p-type by a number of relatively convenient methods, at carrier concentrations required for high-performance n-type photoconductor and p-n junction photodiode architectures. Common donors are indium and iodine. Arsenic has become the most commonly used acceptor dopant, although copper and gold are used in some cases. Some HgCdTe photodiode designs still employ native metal-vacancy point defects as acceptors, although the clear trend is toward the use of extrinsic acceptor doping to avoid the strong Shockley–Read recombination associated with the Hg vacancy. Residual electrically active impurity concentrations are generally less than $1 \times 10^{14}\,\mathrm{cm}^{-3}$, which allows controllable doping at low-$10^{14}\,\mathrm{cm}^{-3}$ concentrations.

Crystal Growth Methods

The first growth methods for HgCdTe were bulk growth. Liquid phase epitaxy (LPE) began to be developed around 1975, followed by metalorganic chemical vapor deposition (MOCVD) and molecular beam epitaxy (MBE) in the early 1980s. Bulk growth, LPE, MOCVD, and MBE techniques have been refined through the years, and each is still in use today. Each technique has found application for certain types of HgCdTe devices. Bulk growth methods are used for production quantities of n-type wafers, with diameters of 12–20 mm, for LW and VLW photoconductive arrays, which are more tolerant of dislocations. LPE is in use today for production quantities of photovoltaic (PV) HgCdTe arrays, and has also been used for certain photoconductive HgCdTe arrays. Vapor-phase epitaxy (VPE) methods such as MBE and MOVPE are in use for engineering and prototype quantities. Both run-to-run reproducibility and control as well as intra-wafer uniformity of HgCdTe alloy composition are well in hand, meeting or exceeding requirements.

LPE-based one-layer and two-layer photodiode technology is well established today, offering the lowest defect densities and highest operabilities for production quantities of high performance FPAs. The VPE methods, MBE and MOVPE, will probably not entirely replace LPE in the near future, but will continue to improve, particularly with respect to lower defect densities, offering *in situ* growth of advanced bandgap-engineered detector designs that are unwieldy or impossible with LPE, such as dual-band detectors, avalanche photodiodes, and planar buried junctions with *in situ* CdTe passivation. MBE has shown the potential for rapidly switching from growth of one HgCdTe alloy composition to another in successive growth runs, without the necessity of preparatory calibration growth runs. This compositional agility, important for the rapid and cost-effective adjustment from product to product, will be further enhanced by the ongoing efforts to implement and improve *in situ* real-time monitors and feedback controls.

Substrates for Epitaxial Growth

The lattice mismatch between HgTe and CdTe is small, approximately 0.3%. This allows epitaxial growth of high-quality HgCdTe films on IR-transparent CdTe or nearly-lattice-matched IR-transparent $Cd_{1-z}Zn_zTe$ ($z \approx 0.04$) substrates, with dislocation densities in the mid-$10^4\,\mathrm{cm}^{-2}$ range. It also allows the *in situ* growth of various isotype and anisotype heterojunctions with tolerably low or negligible densities of misfit dislocations. This has led to an increasing number of bandgap-engineered HgCdTe photodiode structures, such as dual-band or two-color detector arrays and Auger-suppressed photodiodes with the potential for greatly increased operating temperature.

Sapphire and silicon are IR-transparent substrates that are less costly, that are available in much larger areas, and that are more rugged than CdTe and CdZnTe. Both sapphire and silicon can be used for epitaxial growth of HgCdTe films with dislocation densities that are acceptably low (mid-$10^6\,\mathrm{cm}^{-2}$) for many important photodiode applications, such as for the MW and SW spectral ranges, and for the LW spectral range for high background photon fluxes. LPE growth of HgCdTe($x = 0.4$) is done on 3-inch diameter sapphire substrates with MOCVD-grown CdTe buffer layers. MBE growth of HgCdTe($x = 0.3$) on 4-inch diameter (211) silicon substrates, with ZnTe/CdTe buffer layers, has recently been reported.

Dielectric Constant

The relatively low dielectric constant ($\varepsilon_S = 18\varepsilon_0$) of HgCdTe, in contrast to those of PbTe and PbSnTe, permits low junction capacitance. This is important for fast response in laser pulse detectors where small $R-C$ time constants are needed. It is also important for suppressing preamplifier noise below the detector noise, and thereby achieving high detectivity (D^*), in photodiodes operating at low temperature and low background fluxes, where the junction resistance is sufficiently high that the junction capacitance becomes an important contribution to the junction impedance at frequencies of interest.

Surface Passivation

Passivation of the exposed HgCdTe surfaces is critical for both device performance and long-term stability. The favorable surface properties of HgCdTe have enabled practical surface passivation schemes to be developed for both n-type photoconductors and p-n junction photodiodes of both planar and mesa configurations.

n-type HgCdTe photoconductors are commonly passivated with a native oxide that accumulates the surface, resulting in surface recombination velocities as low as 50 cm s^{-1}, along with low $1/f$ noise (knee frequencies less than 50 Hz). The surface accumulation layer also provides a layer of surface electrons with high mobility, though lower than the bulk electron mobility, such that the shunt conductance of this layer is tolerably low compared to the bulk conductance of the detector itself. Several methods have been used for growing this native oxide, including plasma deposition and electrochemical (anodic) oxidation.

HgCdTe photovoltaic detectors require quite different passivation because usually both n-type and p-type surfaces are exposed as well as the depletion region. The CdTe/HgCdTe heterostructure is an important passivation for HgCdTe photovoltaic detectors and arrays. CdTe passivation has enabled arrays of HgCdTe photodiodes with negligible $1/f$ noise (knee frequencies less than 1 Hz), radiation hardness well in excess of the 20–40 kRad(Si) usually encountered in Earth-resource space missions, and excellent stability to thermal bake and to exposure to moisture.

CdTe has a number of important advantages as a passivant for HgCdTe junctions. It is a 'native' passivant that is chemically compatible with HgCdTe. Adhesion is excellent. The valence band edge of CdTe is approximately 0.4 eV below that of HgTe, thereby allowing repulsive barriers to form in the underlying HgCdTe for both electrons in the conduction band and holes in the valence band. Both mesa and planar photodiodes have been successfully passivated with CdTe. A wide variety of methods has been reported for deposition of CdTe passivating layers, including MBE, MOVPE, e-beam evaporation, sputtering, and hot wall epitaxy.

Electron-to-Hole Mobility Ratio

The small values for the conduction band effective mass ratio lead to large values for the electron mobility, as large as 4.5×10^5 cm^2/V-s for $x = 0.195$ at 77 K. The heavy hole effective mass ratio is quite large, approximately 0.5 for all alloy compositions, leading to low values for the heavy hole mobility, on the order of 500 cm^2/V-s. This gives large values for the electron-to-heavy hole mobility ratio, b, as high as 1000 for $x = 0.194$ at 77 K.

These large values of b were of great benefit to n-type HgCdTe photoconductors. Most such devices have small active areas, on the order of 50×50 μm^2, and the drift length for minority carriers (holes) becomes comparable to the interelectrode spacing at modest bias voltages. In this case, when the contacts have a high recombination velocity, the photoconductive gain saturates to the value $b/2$. High values of b in HgCdTe allowed sufficiently high photoconductive gains to be achieved to raise the detector noise above the preamp noise, an essential condition for achieving BLIP sensitivity.

HgCdTe Infrared Detector Configurations

Three different types of infrared detectors can be realized in the $Hg_{1-x}Cd_xTe$ alloy semiconductor: the photoconductive (PC) detector, the photodiode, also referred to as the photovoltaic (PV) detector, and the metal–insulator–semiconductor (MIS) detector. These are illustrated in Figure 4.

In all three types of HgCdTe detector – PC, PV, and MIS – excess electron–hole pairs are photogenerated by the same mechanism: valence-to-conduction band absorption of infrared radiation with photon energy greater than the bandgap energy E_G. All three types can achieve high quantum efficiencies, approaching 100% for well-designed devices. All three types have the same fundamental recombination mechanisms (Auger-1 and radiative) that determine the highest possible operating temperature to achieve a given sensitivity (signal-to-noise ratio).

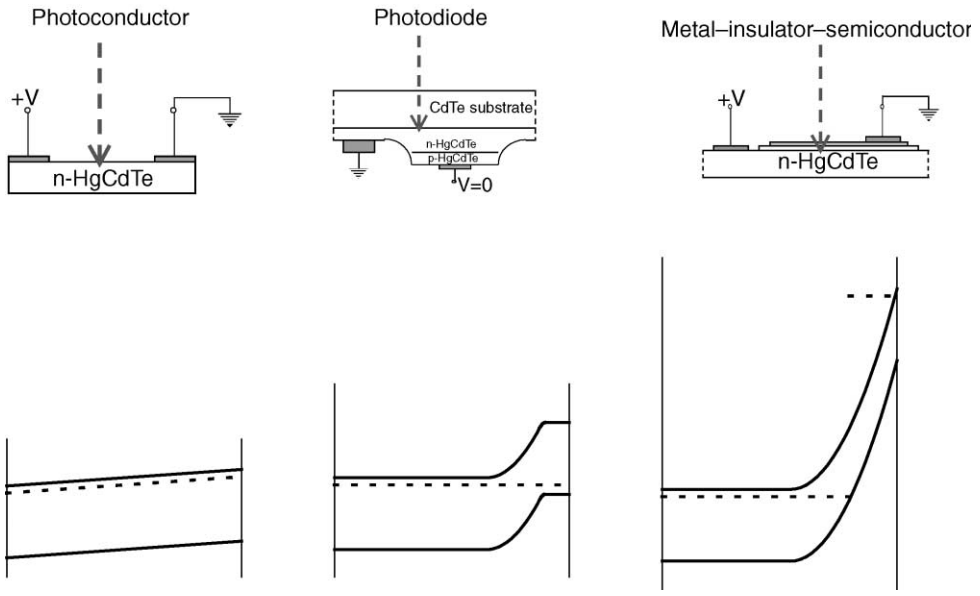

Figure 4 Three different types of infrared detectors have been realized in the $Hg_{1-x}Cd_xTe$ alloy semiconductor: the photoconductive (PC) detector, the photodiode or the photovoltaic (PV) detector, and the metal–insulator–semiconductor (MIS) detector. HgCdTe PC and PV detector arrays are being manufactured for a wide variety of applications. The MIS detector was abandoned in the mid-1980s because it placed unachievable demands on material quality.

The differences among PC, PV, and MIS HgCdTe detectors are due to the way in which the photogenerated electron–hole pairs are manifested electrically in the terminal characteristics of the device. In the PC detector, the excess electron–hole pairs are sensed as a small increase in the conductivity of what is basically a two-terminal resistor. In the PV detector, the excess electron–hole pairs are sensed as a photocurrent in a short-circuited p-n junction photodiode. In the MIS detector, the excess electron–hole pairs are sensed as a small change in the voltage due to minority photocarriers filling a transient charge storage well that has been biased to deep depletion.

PC HgCdTe Detectors

The HgCdTe PC detector is a low-resistance two-terminal device. Resistances are typically 25–100 ohms per square. A dc bias current is applied to convert the conductivity change to an observable voltage change. The device operates under near-equilibrium conditions, with small dc bias voltages typically on the order of 0.1 V. The dc bias electric field within the photoconductor is quite small, generally in the 20–50 $V\,cm^{-1}$ range. The low-resistance device requires a low-noise bipolar preamplifier, usually external to the dewar. Each PC detector element requires one lead through the dewar wall, thus limiting the practical number of PC elements in an array to about 200–300.

The basic HgCdTe photoconductor is a rectangular area, photolithographically defined in an n-type HgCdTe layer approximately 8–15 μm thick, with two ohmic contacts on opposite edges. Surface passivation is straightforward: a thin native oxide strongly accumulates the surface of n-type HgCdTe, thereby reducing the surface recombination velocity to negligibly small values.

Many useful variations on the simple rectangular geometry are possible because of the favorable material properties of HgCdTe. Several contact geometries have been devised to minimize the recombination of photocarriers at the contacts. Serpentine designs have been used to increase detector resistance and reduce bias power dissipation, especially important issues for large-area and very long-wavelength detectors. The SPRITE (signal processing in the element) design reduces the number of electrical connections and dewar leads for scanned arrays by performing both detection and integration within an elongated HgCdTe bar.

PV HgCdTe Detectors

The HgCdTe photodiode is a more complicated device than the photoconductor, requiring both n-type and p-type layers, and having a surface

depletion region that makes stringent demands on surface passivation technology.

The PV detector is a high-resistance p-n junction device. The photodiode is operated very close to equilibrium conditions, either at zero bias voltage or at a small reverse bias voltage whose magnitude is several kT, typically 20–30 mV. The absorber layer is usually n-type HgCdTe about 5–15 μm thick, with the thicker values required for longer-wavelength radiation. A p-n junction is formed by a thin p-type layer. A wide variety of junction formation methods are used. Wide-gap-p on narrow-gap-n heterojunctions are formed by two-layer LPE. Planar p-on-n or n-on-p junctions are formed by arsenic or boron implantation into n-type or p-type layers grown by LPE or MBE. Vertical-geometry p-on-n junctions are formed by a damage mechanism during ion beam milling. Both single-junction and multijunction devices are grown *in situ* by vapor phase epitaxial methods such as MBE and MOVPE. Surface passivation is generally accomplished by CdTe. The high-resistance PV device can match well with low-noise silicon CMOS preamplifiers that can be integrated with two-dimensional arrays to form large back-illuminated hybrid focal plane arrays (FPAs). Typical array formats for HgCdTe FPAs are 256×256 and 480×640, and can be as large as 1024×1024 and 2048×2048.

MIS HgCdTe Detectors

The metal–insulator–semiconductor (MIS) detector, also referred to as a photocapacitor, is usually formed on an n-type HgCdTe absorber layer. The insulator of choice is a thin native oxide. The gate electrode is a thin semitransparent metal film.

In contrast to the PC and PV detectors, the MIS detector operates in a strongly nonequilibrium mode.

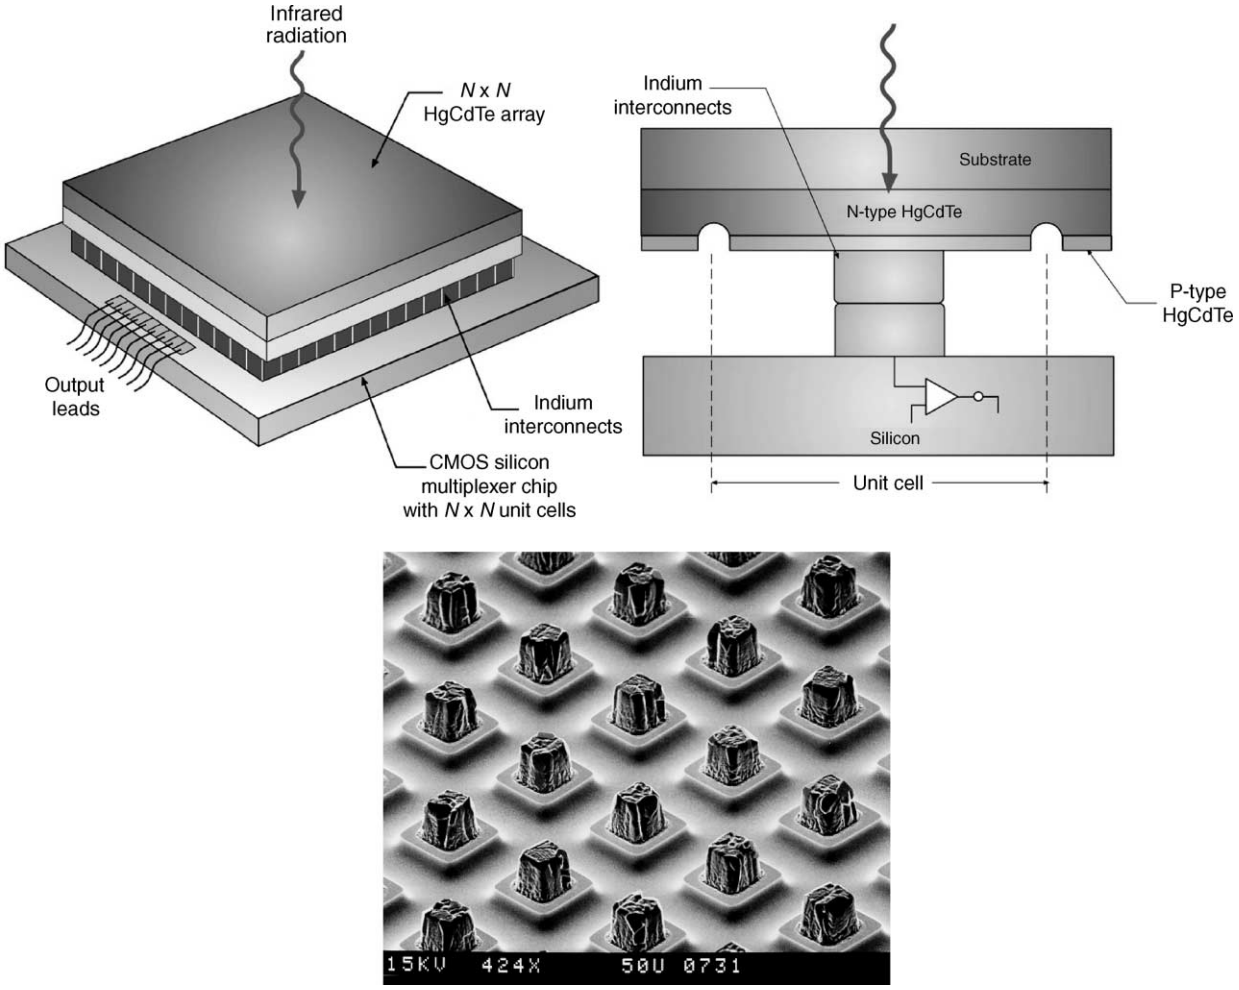

Figure 5a Back-illuminated bump-interconnected HgCdTe FPA architecture. The SEM photo shows an LPE P-on-n HgCdTe mesa photodiode array with 60×60 μm^2 unit cells and 33×33 μm^2 mesa (junction) areas.

A bias voltage pulse of several volts is applied across the capacitor to drive the HgCdTe surface into deep depletion. Excess electron–hole pairs are photogenerated in the absorber layer and diffuse to the edge of the depletion region, where the holes are collected in the charge well. After a period of time, called the integration time, the voltage across the capacitor is sensed, giving a measure of how much charge was collected, and the cycle is repeated.

Because of the nonequilibrium operation of the MIS detector, much larger electric fields are set up in the depletion region than in the p-n junction, resulting in defect-related tunneling dark current that is orders of magnitude larger than the fundamental dark current. The MIS detector requires much higher material quality than PV or PC detectors, which still has not been achieved. For this reason, all development of the HgCdTe MIS detector was abandoned in the mid-1980s.

Two-Dimensional HgCdTe Infrared Focal Plane Arrays

Among the most important applications of HgCdTe are large two-dimensional electronically scanned hybrid arrays, referred to as focal plane arrays (FPAs). A hybrid HgCdTe FPA consists of a two-dimensional HgCdTe photovoltaic detector array that is interfaced electrically, thermally and mechanically with a matching two-dimensional array of input circuits in a silicon CMOS ROIC chip. Each HgCdTe detector element in the array has one electrical connection to its matching input circuit node in the silicon ROIC.

The thermal expansion coefficient of HgCdTe is sufficiently close to that of silicon to allow several technologically viable hybrid arrangements of HgCdTe detector arrays and silicon multiplexer chips.

There are two main types of hybrid HgCdTe FPAs being developed and manufactured today: the back-illuminated bump-interconnected configuration, shown in Figure 5a, and the front-illuminated or 'loophole' configuration shown in Figure 5b. Each configuration successfully solves the problem of the thermal expansion mismatch between silicon and HgCdTe in different ways, and each requires fundamentally different HgCdTe photodiode designs and processing.

In the back-illuminated configuration, illustrated in Figure 5a, the HgCdTe detector array is bump-mounted onto the silicon ROIC by cold-welded or thermally reflowed indium interconnects. Incident radiation reaches the detectors through an infrared-transparent substrate such as CdTe, CdZnTe, sapphire, or silicon.

In the front-illuminated (or 'loophole') FPA architecture, shown in Figure 5b, the thin HgCdTe layer is epoxied to the silicon ROIC chip, and undergoes elastic deformation when the FPA is cooled. This allows large arrays to be made without need for engineering the thermal expansion of the silicon ROIC chip. Low-temperature processing techniques

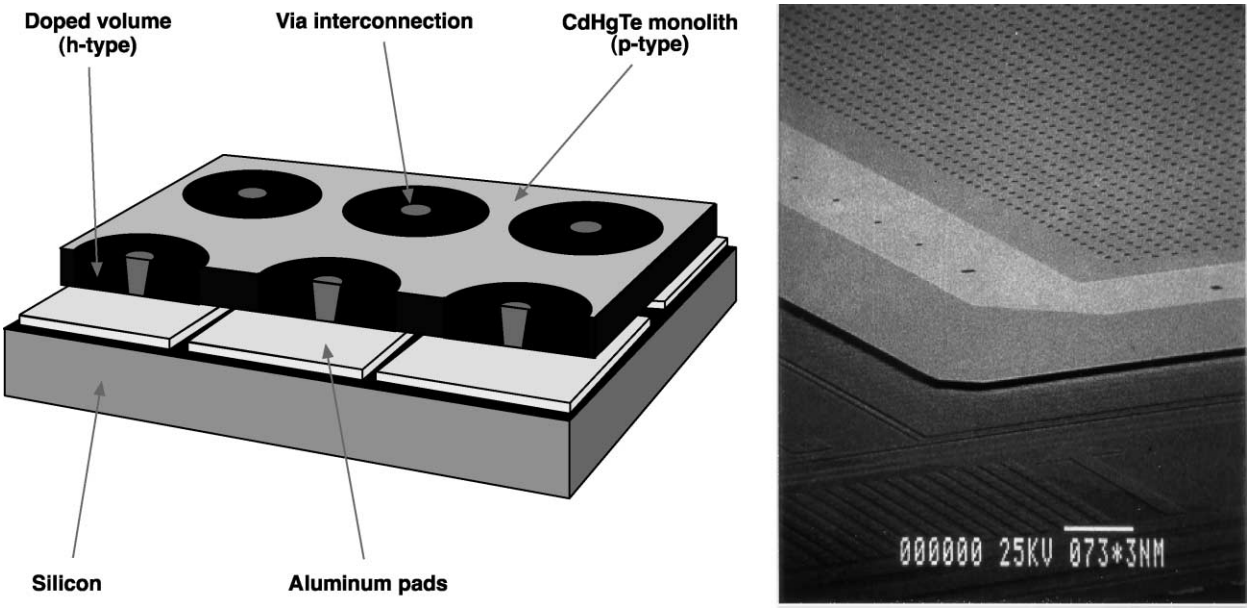

Figure 5b Front-illuminated loophole HgCdTe FPA architecture. The SEM photo shows one corner of a FPA. The metalized via holes are on 20 μm centers.

for junction formation and passivation are required because of the presence of the epoxy.

Conclusions and Trends

There has been enormous progress in HgCdTe material science and device technology over the past 45 years. This progress has been fueled by the many military and space applications for which HgCdTe PC and PV infrared detectors provide nearly ideal solutions. It is important to recognize that the progress so far in HgCdTe detector technology has been possible only through advances in basic materials growth and processing technology.

Further progress can be expected. The fundamental performance limits of HgCdTe photodiodes have not yet been reached. Continued reduction of material defects, both grown-in and process-induced, will reduce thermal generation rates, increase junction impedance, and allow higher operating temperatures for a number of important applications. Continued development of the *in situ* VPE growth methods – MBE and MOVPE – will allow bandgap-engineered heterojunction devices of increasing quality and complexity. Continued development of VPE growth on alternative substrates such as silicon will reduce the cost of two-dimensional arrays, and will make larger arrays practical.

List of Units and Nomenclature

BLIP	Background limited infrared photodetector
CdTe	Cadmium telluride
CdZnTe	Cadmium zinc telluride
CMOS	Complementary metal-oxide-semiconductor
FPA	Focal plane array
HgCdTe	Mercury cadmium telluride
$Hg_{1-x}Cd_xTe$	Mercury cadmium telluride
IR	Infrared
LPE	Liquid phase epitaxy
LW	Long wavelength
LWIR	Long wavelength infrared
MBE	Molecular beam epitaxy
MCT	Mercury cadmium telluride
MIS	Metal-insulator-semiconductor
MOCVD	Metal-organic chemical vapor epitaxy
MOVPE	Metal-organic vapor phase epitaxy
MW	Medium wavelength
MWIR	Medium wavelength infrared
PC	Photoconductive
PV	Photovoltaic
QWIP	Quantum well infrared photodetector
ROIC	Readout integrated circuit
SPRITE	Signal processing in the element
SW	Short wavelength
SWIR	Short wavelength infrared
VLW	Very long wavelength
VLWIR	Very long wavelength infrared
VPE	Vapor phase epitaxy

Modulation Spectroscopy of Semiconductors and Semiconductor Microstructures

Y-S Huang, National Taiwan University of Science and Engineering, Taipei, Taiwan

Introduction

Modulation spectroscopy is a versatile and powerful optical technique for obtaining valuable information relevant to a large variety of semiconductor systems including bulk/thin films, surfaces/interfaces [semiconductor/air (vacuum), semiconductor/electrolyte, semiconductor/metal, semiconductor/semiconductor (homo- and heterojunctions)], micro- and nanostructures (quantum wells, multiple quantum wells, superlattices, quantum wires, quantum dots), the effects of growth/processing, as well as the characterization of actual device structures [heterojunction bipolar transistors (HBTs), pseudomorphic high electron mobility transistors (PHEMTs), edge-emitting and vertical-cavity surface-emitting (VCSEL) quantum well lasers, etc.].

Modulation spectroscopy deals with the measurement and interpretation of changes in the optical response of a sample which are effected by the modification of the measurement conditions. This can easily be accomplished by periodically modulating either (1) the measurement conditions themselves ('internal' modulation) or (2) some parameters applied to the sample ('external' modulation). The observed normalized changes are usually small so that the difference signals are closely related to a derivative of the absolute spectrum with respect to the modifying parameters. The derivative nature of modulation spectroscopy emphasizes structure localized in the photon energy region of the interband (intersub-band) transitions of semiconductors (semiconductor microstructures) and suppresses uninteresting background effects. As a result, weak features that may not be detected in the absolute spectra are often enhanced. Because of this derivative-like nature a large number of sharp spectral features may be observed, even at room temperature.

The ability to perform a lineshape fit is one of the great advantages of modulation spectroscopy. Since for the modulated signal the features are localized in photon energy it is possible to account for the lineshapes to yield accurate values of energies and broadening parameters of the associated interband transitions. For example, the energies of various interband (intersub-band) transitions may be evaluated to within a few meV, even at room temperature. Thus, the effects of static external perturbations such as electric and magnetic fields, temperature, hydrostatic pressure, uniaxial stress, etc., can be conveniently studied.

A particularly useful form of modulation spectroscopy is electromodulation (EM) since it is sensitive to surface/interface electric fields and can be performed in contactless modes that require no special mounting of the sample. Under appropriate conditions the EM spectrum may exhibit above bandgap oscillatory features, called Franz–Keldysh oscillations (FKOs), which are a direct measure of the relevant electric field (built-in and/or applied).

Two of the most widely used forms of EM are photoreflectance (PR) and contactless electroreflectance (CER). In PR, modulation of the built-in electric field is caused by photo-excited electron–hole pairs created by a pump source of ~3–5 mW power of either (1) an internally modulated laser diode or (2) a mechanically chopped dc laser. The modulating frequency is typically ~100–200 Hz. CER utilizes a condenser-like system consisting of a front wire grid electrode with a second metal electrode separated from the first electrode by insulating spacers, which are ~0.1 mm larger than the sample thickness. The sample is placed between these two capacitor plates. Thus, there is nothing in direct contact with the front surface of the sample. The probe beam is incident through the front wire grid. EM is achieved by apply an ac voltage (~1 kV peak to peak at ~200 Hz) across the electrodes.

Instrumentation

Shown in Figure 1 is a schematic drawing of the experimental arrangement for a general 'external' modulated reflectance experiment (except for PR). Light from an appropriate light source (xenon arc or tungsten halogen lamp) passes through a monochromator. The exit intensity at wavelength λ, $I_o(\lambda)$, is focused onto the sample by means of a lens (or mirror). The modulation (electric field, stress, temperature) is applied to the sample at frequency Ω_m. The reflected light is collected by a second lens (mirror) and is focused onto an appropriate detector

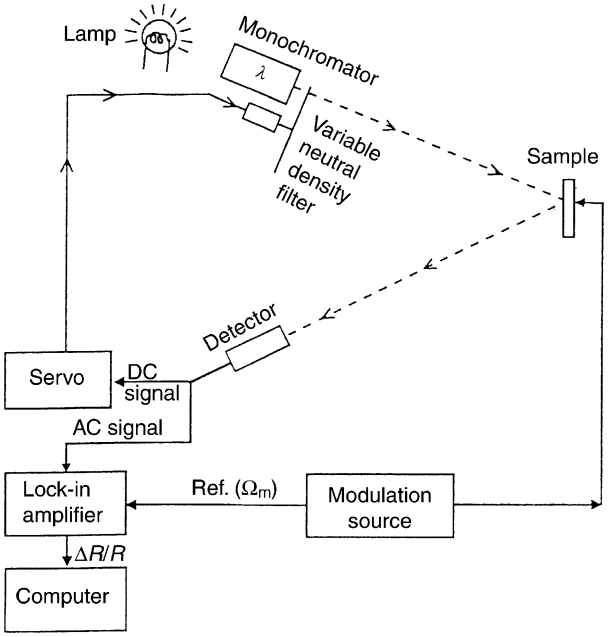

Figure 1 Schematic representation of external modulation experimental apparatus.

(photomultiplier or photodiode). For the sake of simplicity the two lenses (mirrors) are not shown.

The light striking the detector contains two signals: the dc is given by $I_o(\lambda)R(\lambda)$, where $R(\lambda)$ is the dc reflectance of the material while the modulated value (at frequency Ω_m) is $I_o(\lambda)\Delta R(\lambda)$, where $\Delta R(\lambda)$ is the change in reflectance produced by the modulation source. The ac signal from the detector, proportional to $I_o(\lambda)\Delta R(\lambda)$, is measured by a lock-in amplifier. Typically $I_o\Delta R$ is 10^{-4}–10^{-6} of I_oR. In order to evaluate the quantity of interest, i.e., the relative change in reflectance $\Delta R/R$, a normalization procedure must be used to eliminate the uninteresting common feature $I_o(\lambda)$. This can be done in several ways, one of which is shown in Figure 1, where the normalization is performed by a variable neutral density filter (VNDF) connected to a servo mechanism. The dc signal from the detector, which is proportional to $I_o(\lambda)R(\lambda)$, is fed into the servo which moves the VNDF in such a manner as to maintain a constant $I_o(\lambda)R(\lambda)$, i.e., $I_o(\lambda)R(\lambda) = C$. Under these conditions the ac signal $I_o(\lambda)\Delta R(\lambda) = C\Delta R(\lambda)/R(\lambda)$. Subsequently, the signal to the lock-in amplifier is proportional to the quantity of interest, i.e., $\Delta R(\lambda)/R(\lambda)$.

Bulk/Thin-Film Material

Modulation spectroscopy has been used to study the properties of bulk/epitaxial layered semiconductors such as ordering in $GaInP_2$, piezoelectric fields in strained GaN, the influence of isotopes, the properties of low-temperature grown GaAs, the space charge region, carrier concentration, the nature of the band bending (carrier type), impurity effects, deep levels, alloy composition, the influence of static external or internal perturbations such as temperature, external uniaxial stress, lattice-mismatch strain, hydrostatic pressure, the effects of crystal growth/processing/annealing procedures, and amorphous and microcrystalline materials.

The dashed lines in Figure 2 are the piezoreflectance (PZR) spectra in the region of the direct gap of ReS_2 in the temperature range $25\,K < T < 450\,K$. The data at low temperatures exhibit two well-resolved features labeled E_1^{ex} and E_2^{ex}. The solid lines are lineshape fits to the first derivative of a Lorentzian profile which yields the energies indicated by arrows and also the related broadening parameters. The solid/open squares and circles in Figure 3 are the temperature dependence of E_1^{ex}/E_2^{ex} of ReS_2 and $ReSe_2$, respectively. The solid, dot-dashed, and dashed lines in the figure are fits to the Varshni, O'Donnel–Chen, and Bose–Einstein expressions, respectively. The Varshni equation is:

$$E_i^{ex}(T) = \frac{E_i^{ex}(0) - \alpha_i T^2}{\beta_i + T} \qquad [1]$$

where $i = 1$ or 2, $E_i^{ex}(0)$ is the excitonic transition energy at 0 K and α, β are the Varshni coefficients. The O'Donnel–Chen expression is:

$$E_i^{ex}(T) = E_{i0} - S_i\langle\hbar\Omega_i\rangle\left(\frac{\coth\langle\hbar\Omega_i\rangle}{2kT} - 1\right) \qquad [2]$$

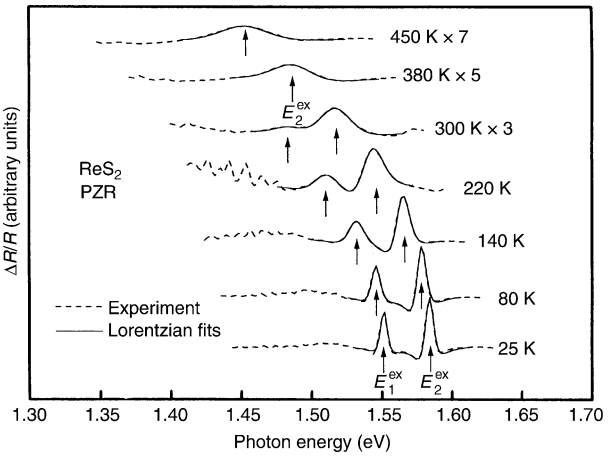

Figure 2 The PZR spectra (dashed lines) in the region of the direct gap of ReS2 in the temperature range $25\,K < T < 450\,K$. The solid lines are lineshape fits yielding the energies indicated by the arrows.

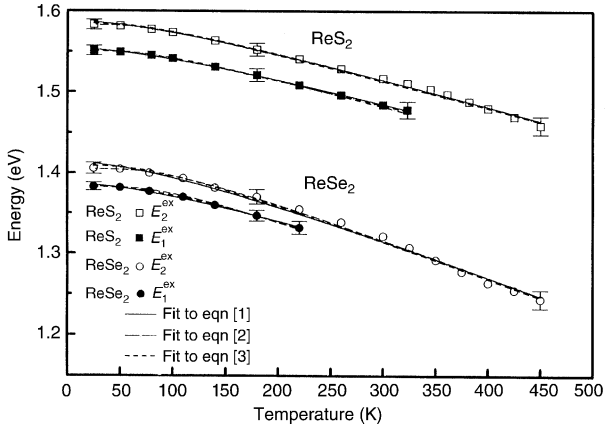

Figure 3 The temperature dependence of the excitonic transition energies of ReS_2 and $ReSe_2$. The solid, dot-dashed, and dashed lines in the figure are fits to the Varshni, O'Donnel–Chen, and Bose–Einstein expressions, respectively.

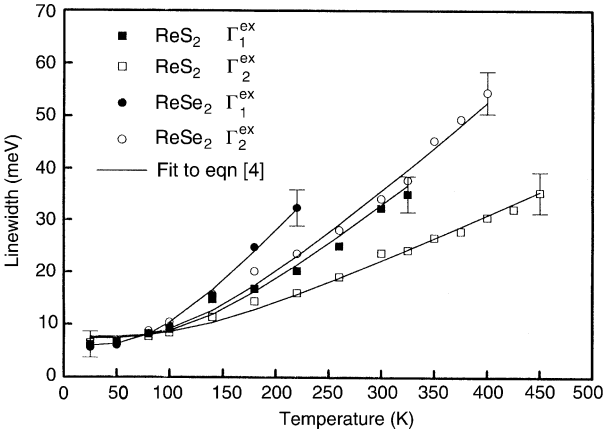

Figure 4 The solid/open squares and circles are the temperature dependence of the broadening parameters of E_1^{ex}/E_2^{ex} of ReS_2 and $ReSe_2$, respectively. The solid lines are fits to the Bose–Einstein-type expression.

where E_{i0} is the excitonic transition energy at 0 K, S_i is a dimensionless coupling constant related to the strength of the electron–phonon interaction, and $\langle \hbar\Omega_i \rangle$ is the average phonon energy. The Bose–Einstein-type expression can be written as

$$E_i^{ex}(T) = E_{iB} - a_{iB}\left[1 + \frac{2}{\exp(E_{ap}/kT) - 1}\right] \quad [3]$$

where a_{iB} represents the strength of the electron (exciton)–phonon interaction, and E_{ap} corresponds to the average phonon energy.

The temperature dependence of the broadening parameters, $\Gamma(T)$, is due only to the electron–phonon interaction and can also be described by a Bose–Einstein-type equation. For the lowest lying direct gap only the longitudinal optic (LO) phonon is involved. In Figure 4 the solid/open squares and circles are the temperature dependence of the broadening parameters of E_1^{ex}/E_2^{ex} of ReS_2 and $ReSe_2$, respectively. The solid lines are fits to the Bose–Einstein-type expression:

$$\Gamma_i(T) = \frac{\Gamma_i(0) + \Gamma_{i,ep}}{\exp(E_{i,LO}/kT) - 1} \quad [4]$$

where $i = 1$ or 2. The first term of eqn [4] corresponds to broadening mechanisms due to intrinsic lifetime, electron–electron interaction, impurity, dislocation, and alloy scattering effects. The parameter Γ_{ep} is an electron (exciton)–phonon coupling coefficient and E_{LO} is the zone-center LO phonon energy. The obtained values of Γ_{ep} for these materials have been compared with those for the direct gap in GaAs and ZnSe.

Surfaces/Interfaces

Almost since the inception of modulation spectroscopy it has been recognized that EM could be used as an effective probe of surfaces and interfaces. For EM this is true not only because of the sharp, derivative-like spectral features but also due to its sensitivity to electric fields, i.e., FKOs. In addition, PR and CER are of considerable interest and usefulness since they are contactless, employ low light levels, require no special mounting of the sample, and can be performed in any transparent ambient including ultrahigh vacuum (UHV).

Of particular usefulness in the study of Fermi level pinning at surfaces are UN(SIN)/UP(SIP) and δ-doping configurations. The UN(SIN)/UP(SIP) structures are made by fabricating an undoped layer of thickness L (~1000 Å) on a buried doped $n^+(p^+)$ buffer on a doped $n^+(p^+)$ substrate. In the $n^+(p^+)$ buffer/substrate the Fermi level occurs near the conduction (valence) band edge. At the surface the Fermi level is pinned at some value, V_F. Therefore, there exists in the undoped region, which has a small broadening parameter, a large, almost constant electric field, F. A similar constant field can be created by placing a δ-doping layer a distance L from the surface.

The relation between F, as observed from the FKOs, and V_F is given by:

$$FL = V_F - (kT/q) - SCC - V_p(T) \quad [5]$$

where the second, third, and fourth terms on the right-hand side are the Debye length, space charge layer, and temperature dependent photovoltaic effect corrections, respectively.

The properties of the metal–semiconductor interface have been reported by a number of investigators using PR and/or ER. Jonker *et al*. have demonstrated that an epitaxial Fe film on GaAs (UN structure) provides a ferromagnetic contact, suppresses midgap state formation, and does not pin the Fermi level. Four samples were investigated: a native oxide reference sample, the same sample after sulfur passivation, Al/GaAs-(2 × 4), and Fe/GaAs-(2 × 4). The width of the undoped GaAs layer was 1070 Å for the first three samples and 1500 Å for the last sample. These results are shown in Figure 5a–d, respectively. The fields obtained from the FKOs are 58 kV/cm, 61 kV/cm, 55 kV/cm and 60 kV/cm. For the first three samples the measured barrier height is about 0.64 eV (not corrected for the photovoltaic effect) while for the Fe/GaAs material it is about 40% higher (~0.9 eV). Another significant feature of the Fe/GaAs spectrum is the large number of FKOs (in relation to the other samples) extending to about 2 eV. The significant reduction in damping indicates a substantial increase in carrier lifetimes.

Micro- and Nanostructures

Modulation spectroscopy is a very powerful tool for investigating many of the fundamental aspects of compositional single quantum wells (SQWs)/multiple quantum wells (MQWs), superlattices (SLs), quantum wires, and quantum dots (QDs). Various phenomena can be studied, including band offset, well and barrier widths, excitons, strain, coupling and decoupling between wells, miniband formation, two-dimensional electron gas (2DEG) effects, zone-folding in short-period SLs, built-in electric fields, etc. Work on a large variety of GeSi, III–V and II–VI systems has been reported, including both lattice-matched and strain-layer configurations. In addition the effects of various external perturbations can be evaluated.

The properties of a vertically coupled InAs/GaAs QD-based laser structure fabricated by a self-assembled technique have been investigated by CER (300 K and 20 K). Signals have been observed from all the relevant regions of the sample. The dotted lines are the CER spectra at 300 K and 20 K in Figure 6a,b, respectively. The solid lines are lineshape fits which yield the energies indicated by arrows. The low-energy features, labeled QD_0 (lateral coupling), QD_1 (vertical coupling) and QD_2 (vertical coupling), originate from the QDs while the resonances designated W_1 and W_2, correspond to the first conduction to first heavy- (1C-1H) and light-hole (1C-1L) transitions, respectively, in the QW (approximately one monolayer) formed by the

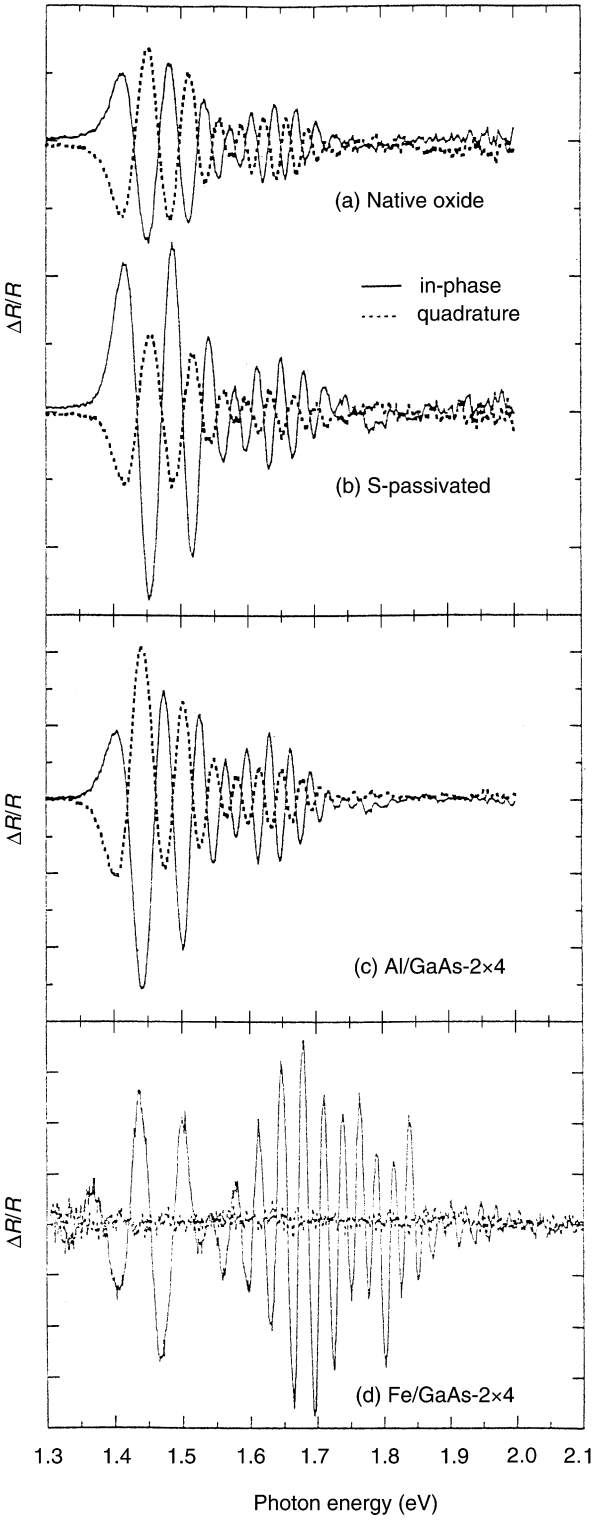

Figure 5 The PR spectra at 300 K for (a) a native oxide reference sample, $F = 58$ kV/cm; (b) the same sample following sulfur passivation, $F = 61$ kV/cm; (c) Al/GaAs-(4 × 2) sample, $F = 55$ kV/cm, and (d) Fe/GaAs-(2 × 4) sample, $F = 60$ kV/cm. The thickness of the undoped spacer region is 1070 Å for (a)–(c) and 1500 Å for (d).

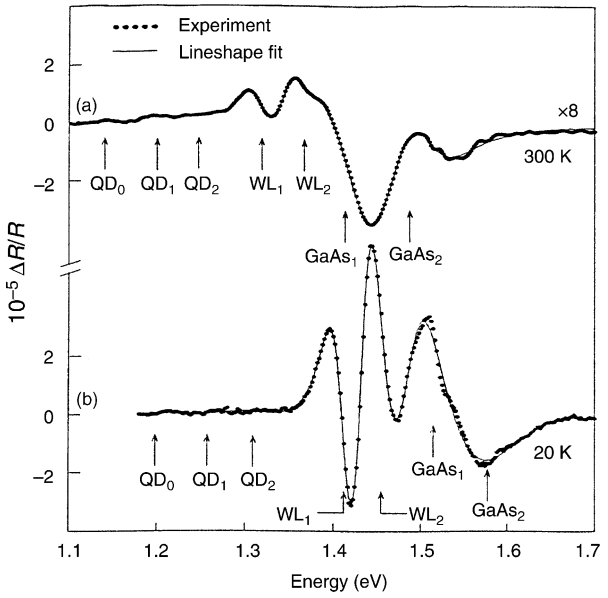

Figure 6 CER spectra (dotted lines) of an InAs/GaAs quantum dot-based laser structure at (a) 300 K and (b) 20 K. The solid lines are a lineshape fit to a first derivative Gaussian.

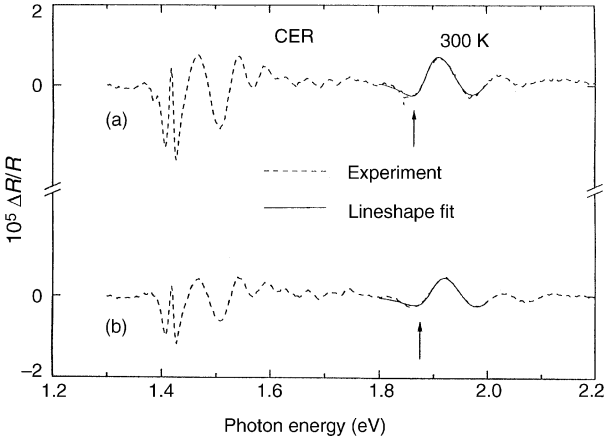

Figure 7 Room-temperature CER spectra (dashed lines) for a GaInP/GaAs HBT sample fabricated by metalorganic chemical vapor deposition for incident light polarized (a) $\boldsymbol{E}\|[110]$ and (b) $\boldsymbol{E}\|[1\bar{1}0]$. The solid lines are a lineshape fit which yields the bandgap energies denoted by arrows.

wetting layer (WL). Although the oscillator strength of the QD features is small compared to the WL resonances, they are clearly visible even at 300 K. The $GaAs_1$ and $GaAs_2$ features are attributed to GaAs-related transitions. The former at both 300 K and 20 K corresponds to the bandgap energy of GaAs and probably comes from the undoped 400 Å-thick GaAs layers which envelop the QD region. The $GaAs_2$ feature is most likely related to the p-doped 6000 Å-thick GaAs cap layer. The heavy doping of this layer induces a Burstein–Moss blue shift of the bandgap.

Device Structures

The methods of PR and CER are valuable tools in the evaluation of important device parameters for structures such as heterojunction bipolar transistors (HBTs), pseudomorphic high electron mobility transistors (PHEMTs), edge-emitting and vertical cavity surface-emitting (VCSEL) quantum well lasers, multiple quantum well infrared detectors, solar cells, superlattice optical mirrors, resonant tunneling structures, metal-oxide-semiconductor (MOS) configurations, among others.

The dashed lines in Figure 7a,b are the 300 K CER spectra of a $GaInP_2$(emitter)/GaAs(collector) HBT (fabricated by metalorganic chemical vapor deposition) for incident light with electric field vector $\boldsymbol{E}\|[110]$ (polarization A) and $\boldsymbol{E}\|[1\bar{1}0]$ (polarization B), respectively. Both collector and emitter signals exhibit well-pronounced FKOs. The solid lines are least-squares fits to a function which contains Lorentzian broadened electro-optic functions, yielding 1.873 ± 0.001 eV and 1.885 ± 0.001 eV for the $GaInP_2$ bandgaps for polarizations A and B, respectively, as indicated by the arrows. The ordering parameter of 0.3 deduced from the differences in the measured bandgaps for the two polarizations was consistent with transmission electron microscope measurements. The electric fields evaluated from the emitter and collector region FKOs were compared with a computer simulation of the field profiles using a comprehensive, self-consistent model, including the photovoltaic effect. The deduced emitter and collector doping densities were in good agreement with the intended growth conditions.

Summary

Modulation spectroscopy is a very powerful tool for investigating many of the fundamental and applied aspects of a wide variety of semiconductors and semiconductor micro- and nanostructures, including bulk/thin films, surfaces/interfaces, single quantum wells, multiple quantum wells, superlattices, quantum wires, quantum dots, etc. In addition the effects of various perturbations such as alloy composition, temperature, electric and magnetic fields, hydrostatic pressure, internal and/or external stain, processing, etc., can be evaluated. Recently these methods have also been applied for the characterization of actual device structures such as HBTs, PHEMTs, quantum well lasers, etc.

Quantum Dots

Introduction

Quantum dots are nanometer-sized clusters of semiconductor material. An island of low-bandgap material is embedded in a sea of high-bandgap material so that both electrons and holes are spatially confined in all three directions. In an unstructured semiconductor, the electron energy levels of the individual atoms hybridize to form energy bands. In a quantum dot, however, there are discrete energy levels. This can be understood from the band structure of the unstructured material where there is a so-called dispersion relation connecting the energy, E, and the momentum, k. The confinement potential of a quantum dot quantizes the k-values, giving rise to discrete energy levels. If the energy levels of a quantum dot are separated by more than the typical energy level broadenings and by more than the thermal energy then the quantum dot will behave quite differently to the bulk material. The quantum dot will exhibit atom-like properties – discrete energy levels with small degeneracies – despite the fact that it is embedded in a semiconductor matrix. It is this ability to prepare a variety of atom-like systems in a semiconductor environment which has driven the research into semiconductor quantum dots.

In some sense, nanosized quantum dots have been the subject of research for quite some time. Color filters, for instance, consist of nanosized particles dispersed in a glass matrix, and this is a very mature technology. Also, lithography of layered semiconductor systems already possessing confinement in one dimension has been pursued for at least 15 years. However, developments in the past few years have been rapid, all based on the discovery of self-assembly of quantum dots directly in the growth of semiconductor heterostructures. These quantum dots can be produced with standard materials in standard growth systems, and this allows an easy integration of quantum dots into devices such as diode lasers. Furthermore, the self-assembled quantum dots are of extremely high quality and this is of great value not just for devices but also for fundamental physics experiments, aimed at studying or exploiting the coherence of excitons confined in the quantum dots. For these reasons, this short review concentrates on the properties of self-assembled quantum dots, giving just brief descriptions of other systems. It should be noted that the bibliography is extremely limited and

in no way does justice to the large number of research groups which have made valuable contributions to this field. Instead, the bibliography is simply a list of suggestions for finding out more about this fascinating research area.

Quantization in Quantum Dots

Quantum dots are on the one hand large enough that the bulk band structure of the host material can be used to describe the material's electronic properties. In the effective mass approximation, this amounts to giving both electrons and holes a quadratic dispersion on momentum, just as for a free electron, but with an effective mass, typically about 0.1 for the electrons, and 0.3 for the holes. On the other hand, quantum dots are small enough that confinement effects are important. For instance, the energy of an exciton in a nanometer-sized quantum dot is a strong function of the quantum dot size. As the dots become smaller, confinement effects become larger, and the energy separating electron and hole levels increases. This does not increase indefinitely, however. There is a finite-size energy barrier to the matrix surrounding the dot such that in the limit of small dot sizes, the wavefunction spreads out into the barrier region and confinement effects become very weak. Ideally, an electron in a quantum dot has a confinement energy of at least several meV, and an energy barrier to the surrounding matrix of several 100 meV so that confinement effects are visible even at room temperature.

The motivation for the study of quantum dots is to combine the atom-like properties with the flexibility of a solid-state environment. This is perfectly illustrated by considering a quantum dot as the gain medium for a laser. In a conventional semiconductor diode, a band of levels has to be inverted in order to achieve population inversion. This is costly in terms of the threshold current and the temperature stability. In a quantum dot, inversion can be achieved simply by inverting the population of the two-fold degenerate ground state, which is clearly trivial. Furthermore, a strong confinement energy and a large barrier to the surrounding matrix imply that this population inversion is stable against rises in temperature, implying better room-temperature performance. This example also exemplifies the motivation for investigating quantum dots using well-developed inorganic semiconductor technology as in this case the dots can be integrated into established device geometries. Generally speaking, the important concept in quantum dot physics is spatial confinement of electrons in all three directions, giving rise to discrete energy levels.

Lithography for Quantum Dots

Developments in semiconductor growth technology, largely during the 1970s and 1980s, enabled thin layers of different semiconductors to be grown on top of each other. There are two principal growth techniques, molecular beam epitaxy (MBE), in which a heated substrate is bombarded with pure species in a high vacuum, and metal organic chemical vapor deposition (MOCVD), in which chemical precursors flow over a heated substrate and react. In the simplest structure, termed a quantum well, a thin layer of low-bandgap material is sandwiched between high-bandgap material. The discontinuities in the potentials at the interface give rise to confined electronic states for both carrier types, electrons and holes. The quantum well is an example of a two-dimensional system: there is confinement in one direction, the growth direction, but free dispersion in the other two directions. To make a quantum dot, it is necessary to confine the electron and hole in all three directions. An obvious approach is to take a quantum well, with perfect confinement in one direction, and process it laterally with lithographic techniques to complete the quantization. Note that an analogy can be made to the physics of the quantum Hall effect, where a two-dimensional electron gas is subjected to a very high magnetic field. The magnetic field quantizes the lateral motion in a similar way to the electrostatic potential in a quantum dot.

This approach to the formation of optically active quantum dots obviously has some advantages, notably that the shape and position of the quantum dots can be chosen in the lithography. However, there are some significant problems associated with these techniques. As most of these problems do not plague the properties of self-assembled quantum dots, self-assembled quantum dots are more suitable for advanced photonic devices.

A number of different lithographic techniques has been used to process quantum-well heterostructures into quantum dots. For research applications, electron-beam lithography is the method of choice. The sample is coated with a resist, for instance PMMA, and exposed with electrons in an area with nanometer size. A protective layer, either a metal or insulator, is transferred to the exposed area by developing the resist, by depositing the protective layer material, and by removing the unwanted material with a lift-off step. The wafer is then etched, typically in a dry environment, to produce a free-standing column.

The photoluminescence of these quantum dots has been measured by various research groups, and although the results vary quite widely there are some systematic trends. The photoluminescence

efficiency decreases rapidly for pillars smaller than a few microns. This is somewhat improved at low temperature, where reasonably strong emission can be observed down to 100-nm diameter pillars. For pillars with micron diameters, the lateral confinement effects are weak, and it is debatable if true quantum dots have been achieved. There are a number of effects which degrade the emission. First, pinning of the Fermi energy by surface states generates large electric fields near the surface, which can ionize electron–hole pairs. This is well known for quantum wells: if a GaAs quantum well for example is placed less than about 25 nm from the surface, the photoluminescence is very weak because of the surface electric field. In an etched pillar, these effects are clearly magnified by the new surface area generated. Secondly, the etching process damages the material to a greater or lesser degree, and the damaged region contains centers for nonradiative recombination.

Other lithography techniques have also been used to generate semiconductor quantum dots for optical experiments. An elegant idea is to deposit small regions of a highly strained film onto the sample surface. In this way, a laterally varying strain film in an underlying quantum well can be set up, generating quantum dots through the effect of strain on the band gap. (This idea has also been married with self-assembly, by using Stranski–Krastanow-grown InP stressors on a GaAs surface, generating lateral confinement in an underlying InGaAs quantum well.) A further idea is to generate a quantum dot by deliberately growing a quantum well with rough interfaces. In such a system, there will inevitably be regions which confine an electron–hole pair through localization. Both of these approaches clearly circumvent the problems generated by the exposed surface in an etched quantum dot. However, they generate small lateral confinement potentials, typically a few meV. This is of value in a research environment where fundamental experiments can be carried out at low temperature, but in a possible device at room temperature, where the thermal energy is 25 meV, quantization effects will not be discernible.

Self-Assembled Quantum Dots

A solution to the difficulties inherent in quantum dots made by lithographic techniques began to emerge in the early 1990s. It was discovered that quantum dots can be produced directly in the semiconductor growth by depositing a material onto a substrate with a substantially smaller lattice constant. The most well-known example is the growth of InAs (lattice constant 6.05 Å) on GaAs (lattice constant 5.65 Å) where In-rich quantum dots form. Because billions of dots form spontaneously in this process, the dots are referred to as self-assembled quantum dots. Since the early experiments, considerable progress has been made, such that the state-of-the-art quantum dots possess many of the hoped-for properties: they are coherent (meaning that they contain no dislocations), highly homogeneous (meaning that fluctuations in shape and composition from dot to dot are small), and have large quantum efficiencies for the emission of light.

Growth of Self-Assembled Quantum Dots

When growing one material on top of another, three principal growth mechanisms have been identified: Frank–van der Merwe, Volmer–Weber, and Stranski–Krastanov. In the Frank–van der Merwe mode, material is deposited layer by layer, as in the growth of the lattice-matched pair GaAs and AlAs. In the Volmer–Weber mode, island formation occurs: the material does not wet the surface because it is energetically unfavorable. Another possibility arises if there is a lattice mismatch. In this case, the epilayer is strained, and the strain energy obviously increases with increasing epilayer thickness. In the Stranski–Krastanow mode, the initial growth is layer by layer, as in Frank–van der Merwe, but beyond a certain thickness, islands form, as shown schematically in Figure 1. On the one hand, the islands limit the strain energy, because some strain relaxation is allowed, which is not possible in a thin film. On the other hand, island formation results in an increase of the

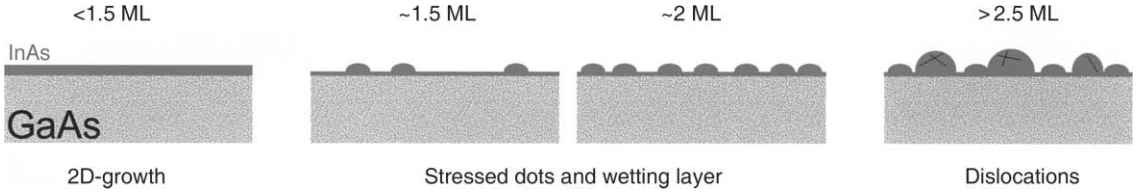

Figure 1 A schematic of the Stranski–Krastanow mode. The material deposited has a substantially larger lattice constant than the substrate, for example InAs on GaAs. Initially, a thin and uniform layer is deposited. At the critical thickness (1.5 monolayers for InAs on GaAs), islands spontaneously form. Further growth results in an increase in the number of islands. At large coverages, large and dislocated islands appear.

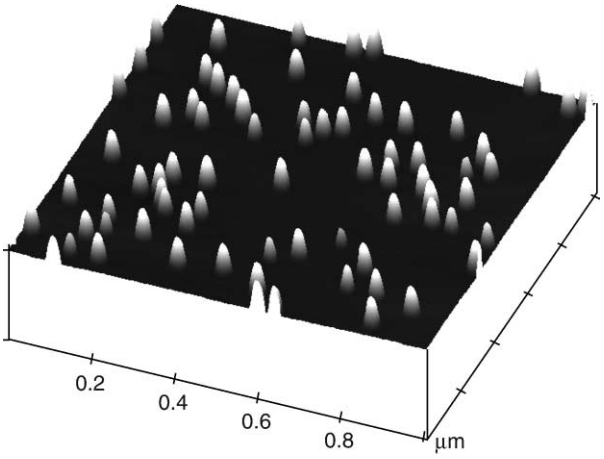

Figure 2 An atomic force micrograph of InAs quantum dots on a GaAs substrate. The InAs dots were grown by MBE at a growth temperature of 530 °C. The image was taken by Axel Lorke.

surface energy. This means that there is a size at which the total energy is minimized.

It is now well established that many combinations of semiconductors grow in the Stranski–Krastanow mode, and this can be utilized for self-assembly of quantum dots. The most studied example is InAs on GaAs where high-quality quantum dots can be grown with both MBE and MOCVD. Dots form at the so-called critical thickness of 1.5 monolayers, corresponding to just 4 Å of material. For thicknesses less than the critical thickness, the covering is not completely uniform; there are island-like structures, elongated along the $[0\bar{1}1]$ direction. At the critical thickness dots form, leaving a thin InAs layer (the wetting layer) between the dots. As more InAs is added, the density of dots increases with only small changes in the dot size. As an example, Figure 2 shows InAs dots on a GaAs substrate.

The dots grown in this Stranski–Krastanow mode are free of dislocations, which is an essential prerequisite in III–V compounds for a high quantum efficiency for optical emission. Furthermore, the dots are remarkably homogeneous. Statistical fluctuations during growth will always give rise to a distribution in dot size and height. Nevertheless, the fluctuations in dot size can be as small as ~10%. The dots are randomly arranged in the lateral plane if the growth proceeds on a flat substrate, and densities are between 10^9 and 10^{11} cm^{-2}. The shape and composition of the dots depend on the growth parameters. For instance, InAs/GaAs dots can have facets along particular crystal directions, or they can be lens-shaped without facets, depending on the growth technique, and in particular the growth temperature. In fact, measuring the shape and composition is a very challenging task, particularly for buried dots.

Stranski–Krastanow growth has turned out to be a robust phenomenon for III–V materials; quantum dots have been produced in this way for a number of material combinations. The most important condition is that the deposited material has a substantially larger lattice constant than the substrate. InAs forms dots not just on GaAs but also on InP. The InAs/InP dots are particularly interesting because they emit at the technologically important 1.5 μm wavelength. InP can also form the dot material by using GaInP substrates where the bandgap is pushed up into the red region of the spectrum. Dots can also be grown with II–VI materials; the growth of CdSe on ZnSe is analogous to the growth of InAs on GaAs. These II–VI dots emit in the green. Finally, dots can also be formed in the nitrides, for instance by depositing InGaN on an AlGaN surface. In fact, the high emission efficiency of GaN, despite the large defect density, has been attributed to the formation of quantum dot-like structures in the active layers.

It is a challenge to arrange the dots in the plane of the substrate. An easy route with self-assembly has not been found to accomplish this. Nevertheless, dots can be encouraged to grow at particular positions by pre-patterning the substrate. This obviously limits the separation of the dots in any such array to the limits set by lithography. However, self-assembly does provide a means to order the dots in the growth direction: if the separation between successive layers is small enough (less than 15 nm for InAs/GaAs) then the dots grow directly above one another, as shown in Figure 3. In a new layer, the residual strain field from the dots in the layer below is sufficient to seed the dots. In this way, vertical stacks of dots can be built up. In fact, it has been argued that the dots tend to become more laterally ordered with each layer. The point is that if two dots are close together in one layer, their strain fields overlap, and provide only one seeding center in the subsequent layer.

Optical Properties

The main interest in quantum dot physics is the quantization in all three spatial directions, giving rise to atomic-like energy levels. For a system of self-assembled quantum dots, it is important to measure the fundamental bandgap, the energetic separation between the confined states both for electrons and for holes, the barriers to the electron continuum and hole continuum, and the oscillator strengths for the various interband transitions. All this information can be gleaned with optical spectroscopy.

Perhaps the simplest experiment to perform, if not to understand, is photoluminescence in which electron–hole pairs are excited with a laser beam.

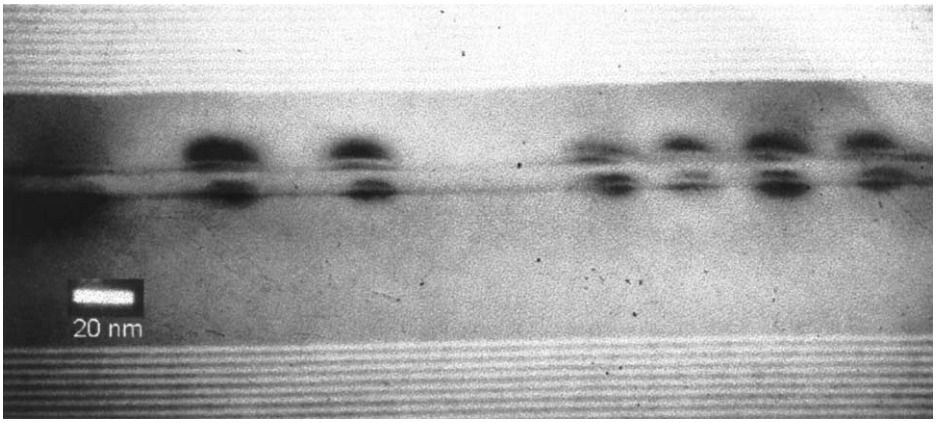

Figure 3 A transmission electron micrograph of two layers of InAs quantum dots in GaAs showing how the dots in the upper layer lie directly above the dots in the first. The image was taken by Gio Medeiros-Ribeiro.

The laser energy can be tuned to lie just above the bandgap of the wetting layer in which case the electron–hole pairs are excited in the wetting layer itself. Alternatively, if the laser energy is larger than the bandgap of the barrier material, electron–hole pairs are excited in the barrier. In both cases, the carriers relax into the dots, and then down the ladder of states in the dot, so that the dot electron and hole ground states are occupied. Emission is detected when an electron and a hole recombine. As such, the experiment measures only the energy of the ground-state exciton. However, if the pump intensity is increased such that electron–hole pairs are generated faster than they can recombine, the excited states of the dots are also occupied and recombination can also occur from excited states. An example of such an experiment is shown in Figure 4. At low pump powers, only the ground state emission is detected; at higher pump powers, the first excited state emerges, and at higher powers still, the second excited state also emerges, and so on. The spectra are broadened by the inhomogeneous broadening, i.e., from fluctuations from dot to dot, but the broadening is small enough that the excited state emission can be easily distinguished from the ground state emission. For these particular quantum dots, the energetic separation between the ground and excited state emission is 15 meV, and this corresponds to the sum of the electron and hole confinement energies. The separation between the other emissions is also about 15 meV, implying that the states are approximately equally spaced, implying in turn that the confining potential is approximately parabolic. Furthermore, in this experiment, emission from the wetting layer can also be made out, and this enables the electron and hole confining potentials to be estimated.

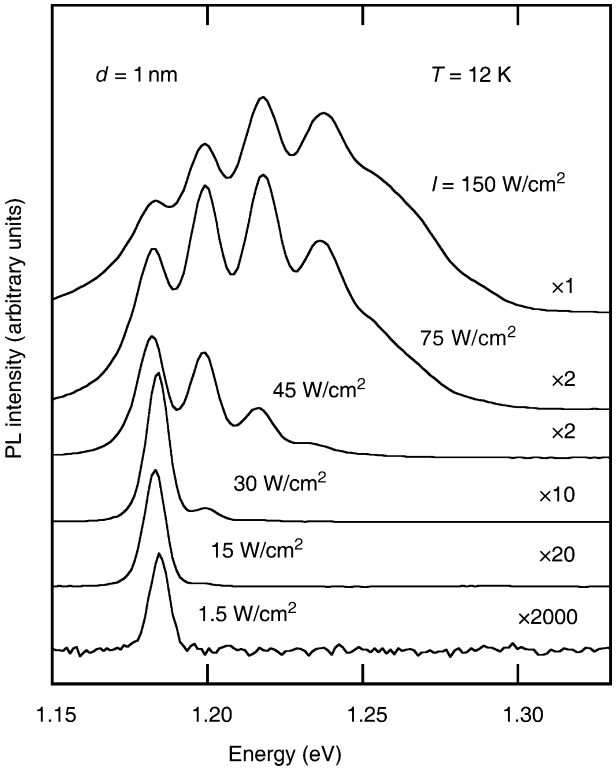

Figure 4 Photoluminescence from an ensemble of quantum dots as a function of laser excitation power. The measurement temperature was 12 K. The quantum dots are induced in an InGaAs/GaAs quantum well by a strain field generated by InP stressors on the sample surface. The stressors are grown in the Stranski–Krastanow mode, and are 1 nm away from the quantum well. At low excitation power, only the ground state emission is observed. As the power increases, emission from excited states is also observed through state filling. Reprinted with permission from Lipsanen H, Sopanen M and Ahopelto J (1995) Luminescence from excited states in strain-induced $In_xGa_{1-x}As$ quantum dots. *Physical Review* 51: 13868. Copyright 1995 American Physical Society.

Photoluminescence invariably yields the sum of electron and hole energies. In order to measure just the electronic properties, it is possible to occupy the dots with, say, two electrons (so that in each dot the two-fold degenerate ground state is fully occupied) and to excite electric dipole transitions between the electron levels. This has been accomplished with so-called charge-tunable heterostructures, with which electrons can be controllably loaded into the dots from an electron reservoir. The interlevel absorption lies in the far-infrared region of the spectrum; for InAs/GaAs quantum dots for instance, the transition is at a wavelength of 25 μm (an energy of 50 meV), as shown in Figure 5. The results of this experiment also point to an approximately parabolic confining potential from the fact that as electrons are added to the dots, the energy of the far-infrared absorption does not change much. (In the limit of a perfect parabolic potential, a famous result known as Kohn's theorem states that the long-wavelength absorption should show no energy dependence on the electron occupation.)

In self-assembled quantum dots, the confining potential can be thought of as very steep in the growth direction, and relatively shallow in the lateral plane. In other words, the dots are essentially two-dimensional disks. The electron ground state is, in analogy with atomic physics, s-like, and the excited state p-like. However, because of the disk-like nature of the dots, the p-state is four-fold degenerate, and not six-fold degenerate as in a conventional atom. One way to demonstrate this is to perform interband absorption experiments on charge-tunable structures, as shown in Figure 6. The first transition corresponds to the transition from the hole s-state to the electron s-state, and disappears when the dots are occupied with two electrons. This is simply because the Pauli principle forbids the transition once the final level is fully occupied. The second transition corresponds to the transition from the hole p-state to the electron p-state, and disappears when the dots are occupied with four electrons, confirming the degeneracies of

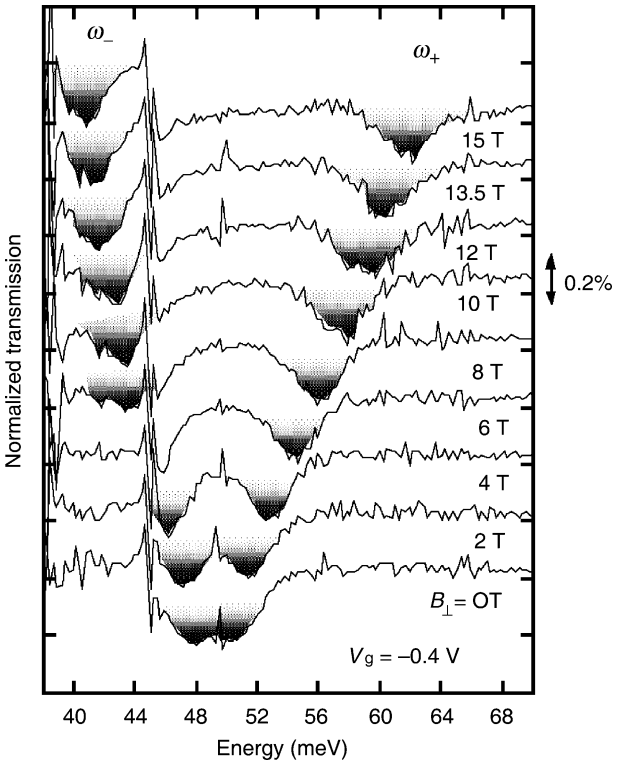

Figure 5 Transmission in the far infrared of an ensemble of InAs/GaAs quantum dots where each quantum dot is occupied with two electrons. The data were taken at a temperature of 4.2 K. The shaded transmission minima correspond to absorption from the quantum dots. The transitions are between the electron ground state and the first excited state. Two peaks are observed even at zero magnetic field, suggesting that the dots are slightly oval in shape. In a magnetic field, the two peaks move apart, which is a consequence of the Zeeman effect. The strong feature at 45 meV arises from an electronic interaction with an interface phonon. Reprinted with permission from Fricke M, Lorke A, Kotthaus JP, Medeiros-Ribeiro G and Petroff PM (1996) Shell structure and electron-electron interaction in self-assembled InAs quantum dots. *Europhysics Letters* 36: 197. Copyright 1996 European Physical Society.

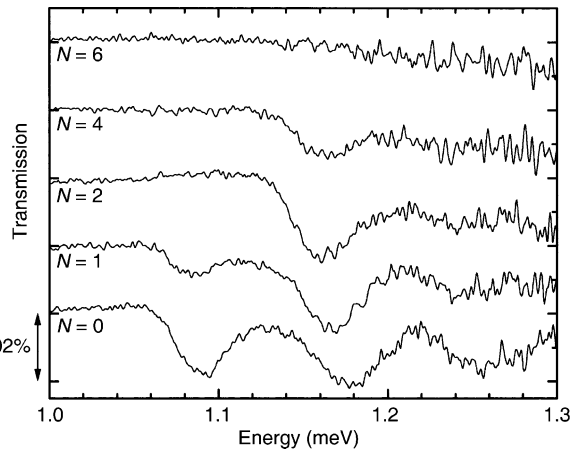

Figure 6 Transmission in the near infrared of an ensemble of InAs/GaAs quantum dots at 4.2 K. Spectra are shown for different values of N, the electron occupation. At $N = 0$, there are three transitions corresponding to transitions from a valence state to an electron state. These are the s–s, p–p and d–d transitions, where the states are labeled in analogy to atomic physics. At $N = 2$, the electron ground state is fully occupied, and the s–s transition disappears because it is blocked, a consequence of the Pauli principle. Similarly, the p–p transition is blocked at $N = 6$ when both the electronic s and p states are fully occupied. Reprinted with permission from Warburton RJ, Dürr CS, Karrai K *et al.* (1997) Charged excitons in self-assembled semiconductor quantum dots. *Physical Review Letters* 79: 5282. Copyright 1997 American Physical Society.

the confined states. This experiment, unlike a photoluminescence experiment, also yields a value for the oscillator strength. The result can be understood simply in terms of the overlap integral between the hole and electron states. In other words, these dots are in the strong confinement regime where the confinement energies are larger than the exciton binding energy. In the other limit, the weak confinement regime, the exciton binding energy dominates over the confinement energies, and it makes sense only in this limit to think of an exciton moving as a coherent entity throughout the dot. In the weak confinement regime, the oscillator strength is actually larger than in the strong confinement regime.

An important issue in interpreting photoluminescence experiments is the rate at which a highly excited electron–hole pair can relax to the ground state of a quantum dot. Relaxation in the continuum is known to occur on a picosecond time-scale: electrons and holes relax by emitting LO-phonons if possible; and if not, acoustic phonons. Capture by a dot also occurs quickly (apart from in low-density samples where capture may take a few hundred picoseconds). It was initially thought that relaxation of carriers once captured by a quantum dot would be hindered by the discrete nature of the density of states. The argument is that the energy separation between the levels is too large for acoustic phonon emission; and there is no reason why the separation between the levels should match the LO-phonon energy (which has a very weak dispersion). Nonetheless, experiments have shown that relaxation from excited dot states to the ground state is rapid, occurring on a picosecond time-scale, pretty much as for quantum wells. Auger processes can be important, whereby an electron in a dot loses energy by promoting an electron in the continuum to a higher energy. But relaxation can also be fast without a large population of mobile carriers in the wetting layer, and this is thought to arise through multiphonon processes. The radiative lifetime is typically 1 ns for self-assembled quantum dots, depending to some extent on the size and material system. As for quantum wells, relaxation occurs much faster than recombination.

Lasers and Self-Assembled Quantum Dots

The motivation for using quantum dots as the gain medium for semiconductor lasers is that they should have advantageous properties over quantum wells. These include a lower threshold current, better temperature stability, and a higher modulation frequency. All of these possible advantages stem from the quantization. In a quantum dot, there are discrete levels each with low degeneracy so that population inversion is easy to achieve. Also, there are large potential barriers to the continuum of states in the surrounding matrix, and an energy separation between levels in the dot at least comparable to the thermal energy at room temperature. This should make a quantum dot device relatively insensitive to temperature. The threshold current of a semiconductor laser usually behaves as $I = I_0 e^{T/T_0}$ where T is the temperature, T_0 is the characteristic temperature, and I_0 the low-temperature threshold current. Generally speaking, lasers are desirable with a small I_0 and a large T_0.

The main obstacle to realizing the benefits of full spatial confinement in self-assembled quantum dots is the inhomogeneity. For a particular lasing wavelength only a fraction of the dots can contribute to the lasing signal. Additionally, the dot densities are typically about 10^{11} cm^{-2} for these applications, implying that in the layer plane there is more unoccupied space than dot material. All in all, the gain at a particular wavelength is limited. Nevertheless, it would appear that even with inhomogeneous dot ensembles the advantages inherent in zero-dimensional states can be exploited.

In addition to the density of states, there is an important difference in the nature of the gain spectrum between quantum well and quantum dot lasers. In a quantum well, gain exists over a range of energies through band filling. If an electron–hole pair is stimulated to emit by the lasing field, then the vacancies will be quickly filled by carrier–carrier scattering in the bands, maintaining a quasi-thermal equilibrium in the conduction and valence bands. In quantum dots at low temperature, capture into a particular dot is a random process, and given the rapid relaxation and the high barriers to the continuum, an electron–hole pair is very likely to emit from the dot where it was created. In other words, the system is not in thermal equilibrium. At higher temperatures, thermal escape out of the dots becomes likely, enabling the system to come into thermal equilibrium. The transition into thermal equilibrium will depend critically on the barrier height, and with appropriate design may take place close to, or even above, room temperature.

Quantum dot lasers have now been realized, and emit continuous wave at room temperature. Progress has been rapid in the past few years. In fact the best quantum dot lasers now have the lowest I_0 and the highest T_0 of any semiconductor laser diode.

Even if the intrinsic advantages of quantum dots are largely offset by the inhomogeneous broadening for laser applications, there are some other advantages. The InAs/GaAs quantum dot emission wavelength is

significantly higher than that of InGaAs/GaAs quantum wells, and with subtle changes in the growth can be increased to 1.3 μm, corresponding to one of the low-loss windows in optical fiber. Also, much higher powers have been realized with quantum dot lasers than with quantum well lasers. In quantum well lasers, device failure occurs at high current, often due to degradation of the end mirrors. It would appear that the carrier localization in quantum dots is sufficiently strong to prevent diffusion to the end facets, allowing the devices to withstand higher currents.

Colloidal Quantum Dots

Progress has been made recently in making inorganic quantum dots with techniques from organic chemistry. Organometallic precursors are employed. The growth temperature is typically below 200 °C which has been found to give material with quite high crystalline quality. A crucial development has been the use of various organic groups to passivate the surface so that the quantum dots have bright photoluminescence. The II–VIs, being more polar than the III–Vs, are easier to produce with these techniques, and most work has concentrated on CdS and CdSe quantum dots which emit in the visible. Nevertheless, it is also possible to produce III–V quantum dots with this technology, and although the bulk GaAs bandgap lies in the near-infrared, the quantum confinement effects can be so high as to push the photoluminescence into the visible. Furthermore, HgCdTe has also been developed as a material system for quantum dots, and the emission can be tuned to the all-important 1.5 μm.

The spectral width of emission from these colloidal quantum dots tends to be very large because of a large spread in particle size. However, techniques are being developed to isolate a specific size. With a selective precipitation technique for instance, the spectral width can be reduced considerably to the extent that a fine structure can be observed in the optical response.

The advantage of these quantum dots lies in the possibility of mass-production for applications such as solar cells. The ease with which one material system can be used to cover a large spectral bandwidth is already attracting a lot of interest, for instance in using passivated and water-soluble quantum dots as biological labels. By using different materials, a huge spectral range can be covered with this technology, as illustrated in Figure 7. Of course, there are still challenges to be met in this field. The quantum dots tend to degrade in the course of time, losing their high quantum efficiency for emission,

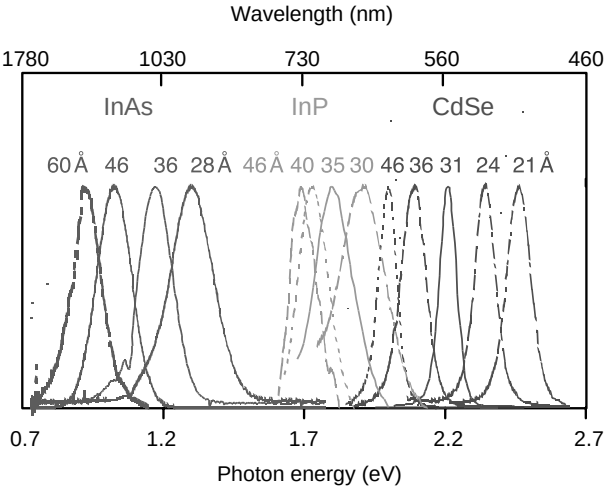

Figure 7 Room temperature emission spectra of surfactant-coated colloidal quantum dots. The quantum dots consist of InAs (left), InP (middle), and CdSe (right). Selection of the size has been used to give a particular wavelength in each band. presumably as a result of changes to the surface structure. Improvements have been made recently by capping the dots with a high-bandgap semiconductor, such as ZnS, which hinders interactions of the exciton with the surface states. The emission from organic-based dots also tends to show temporal fluctuations in wavelength, revealed experimentally from the emission of a single dot. This is thought to come about through the charging and discharging of traps in the vicinity of the quantum dot. Fundamentally, there are difficulties injecting carriers across an interface into the colloidal dots. However, progress can be expected in all these areas, and these quantum dots may well find applications in novel photonic devices.

Single-Dot Spectroscopy

No matter how quantum dots are prepared, there is always a distribution in emission energy. This constitutes an inhomogeneous broadening mechanism. For self-assembled InAs dots on GaAs, the lowest emission width from an ensemble of dots is about 20 meV. This energy is large compared to several other energies in the system. For example, the binding energy of a charged exciton, or of an exciton–exciton complex (a biexciton), is about 2 meV in this system. Also, the width of single dot emission is two to three orders of magnitude smaller

than the ensemble width at low temperature. The width of single-dot emission is inversely related to the time over which the exciton maintains its coherence, and this should be as long as possible for future applications of quantum dots which manipulate the phase of the excitonic wavefunction. In order to investigate the properties of quantum dots in detail it is clearly necessary to measure the optical response of a single quantum dot rather than the response of a large ensemble of dots. The development of this field has been aided by the techniques developed for single-molecule spectroscopy which was first reported in the late 1980s and has subsequently become almost a standard experimental technique.

Typical densities of self-assembled quantum dots correspond to 100 per μm^2. Given that the emission wavelength is around 1 μm, it is clear that an optical technique with subwavelength spatial resolution is required to excite and detect a signal from just one quantum dot. The techniques employed include cathodoluminescence, where a focused electron beam provides the spatial resolution, and near-field optics where a subwavelength-sized aperture in a metal mask determines the spatial resolution. In the latter case, the aperture is either permanently connected to the sample surface, or it is formed on a tapered optical fiber positioned just a few nanometers away from the sample surface. An example is shown in Figure 8: with a confocal microscope the spatial resolution is not high enough to isolate spectroscopically a single dot. With increased spectral resolution, however, just a small number of peaks remain, each corresponding to the emission from a single dot. A further technique is to etch nanometer-sized mesas in the sample such that each mesa contains on average just one quantum dot. In some cases, single quantum dot emission has been detected with a conventional optical microscope (usually a confocal microscope) by adjusting the growth conditions to give particularly low dot densities. This can be achieved with colloidal nanocrystals by spinning a dilute suspension of the dots onto a substrate, a technique which has been frequently used in single-molecule spectroscopy. In each case, the photoluminescence signal from a single quantum dot is not large, and a detector capable of counting individual photons with a high quantum efficiency is required. A cooled silicon CCD camera is very convenient, giving not only a very low dark count and high quantum efficiency, but also a huge multiplexing advantage. However, the response of a Si detector tails off in the visible, and decreases rapidly at about 1050 nm in the near infrared, so it is by no means a universal solution.

The most striking feature of the emission from a single inorganic quantum dot is its spectral purity. Linewidths as small as a few μeV (a few hundred MHz) have been reported at low temperature for

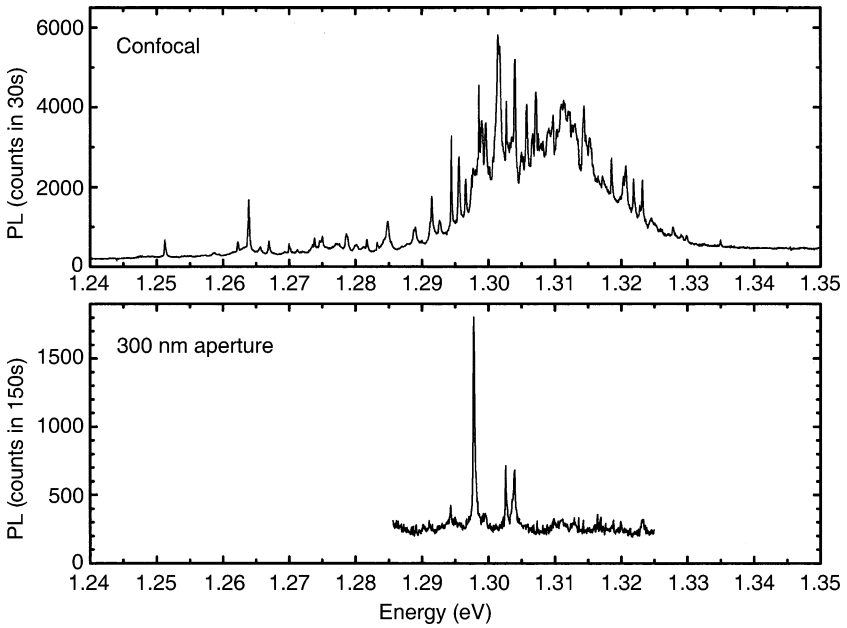

Figure 8 Emission from quantum rings from a 1 μm^2 area of the sample, and from a 0.07 μm^2 area of the sample, both taken at 4.2 K. The quantum rings are generated with a Stranski–Krastanow growth procedure using InAs and GaAs. The first spectrum was taken with a low-temperature confocal microscope; the second with a near-field technique. It can be seen how large statistical fluctuations arise in the first spectrum, because the number of rings probed is not sufficient to give a smooth distribution function. In the second spectrum, just a few peaks can be discerned above the noise level, each arising from the emission from an individual quantum ring.

quantum dots formed in a localizing potential in a quantum well. These linewidths can be interpreted as de-phasing times of the excitons. The maximum possible de-phasing time is obviously the radiative lifetime, in which case the line is homogeneously broadened. This limit has been observed at low temperature on natural quantum dots, but not at elevated temperature: as the temperature increases, scattering of the excitons by phonons decreases the coherence time, observed through a broadening of the emission.

The sharp lines observed in single-dot spectroscopy give access to fine structure on a meV energy scale. Most of this fine structure arises through Coulomb interactions between the electrons and holes. For example, two recent experiments have explored the emission as a function of electron occupation, and exciton population. In both cases, new lines emerge when a single dot is populated by more than one electron–hole pair.

Perspectives

The field of semiconductor quantum dots has made rapid advances in the past decade largely through the discovery of self-assembly in the growth of lattice-mismatched inorganic semiconductors. The most immediate application of these defect-free nanostructures is as the gain medium for semiconductor laser diodes, the aim being to reduce the threshold currents beyond those achievable with quantum wells. This approach is already proving highly successful. However, there are also other possibilities for novel photonic applications of quantum dots. These include memory elements for image processing, detectors and sources for single photons, and perhaps even elements for the coherent manipulation of wavefunctions.

Type-II Quantum Wells and Superlattices

Introduction

When thin layers of two semiconductor materials are combined to form a heterojunction, quantum well (QW), or superlattice, the properties of the resulting 'quantum heterostructure' are to a large extent governed by the alignment of the conduction and valence bands at the interfaces. Usually the overall conduction-band (CB) minimum lies in the same material as the overall valence-band (VB) maximum, as for example in the $GaAs/Al_{0.3}Ga_{0.7}As$ QW illustrated in Figure 1a. In such a type-I structure,

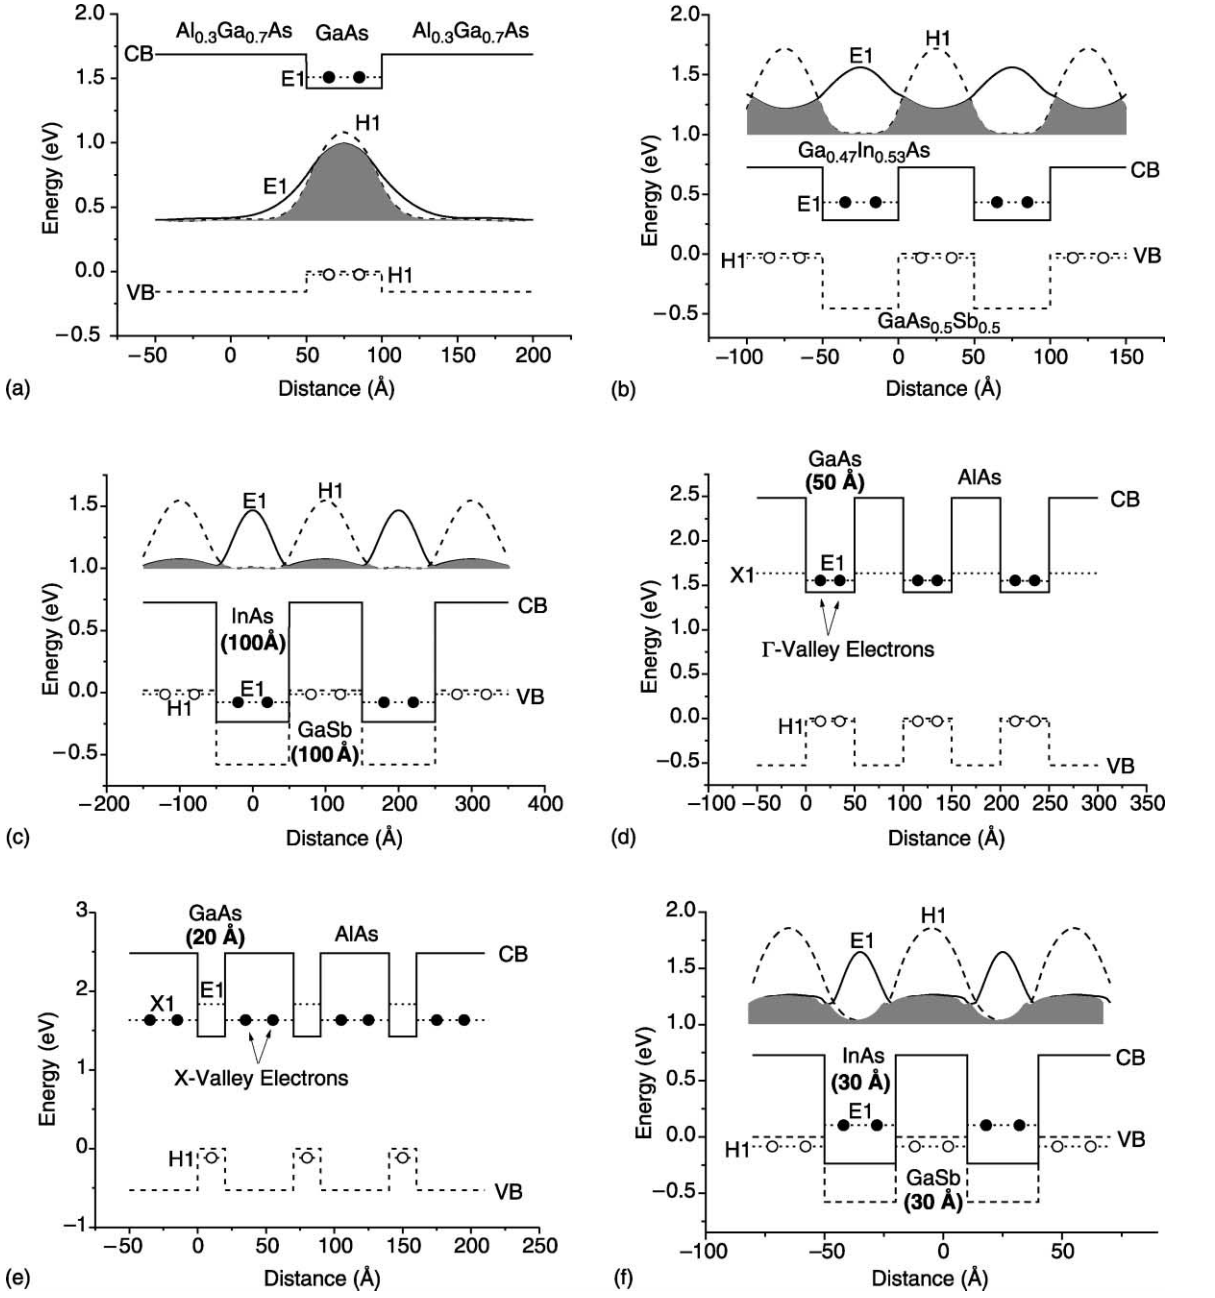

Figure 1 Conduction band (CB) and valence band (VB) profiles along with selected sub-band energies and wavefunctions for: (a) 50 Å GaAs/$Al_{0.3}Ga_{0.7}As$ type-I quantum well (GaAs substrate); (b) 50 Å/50 Å $Ga_{0.47}In_{0.53}As/Ga_{0.5}As_{0.5}Sb$ type-II staggered-gap superlattice (InP substrate); (c) 100 Å/100 Å InAs/GaSb type-II broken-gap semimetallic superlattice (GaSb substrate); (d) 50 Å/50 Å GaAs/AlAs type-I superlattice (GaAs substrate); (e) 20 Å/50 Å GaAs/AlAs type-II superlattice with indirect band alignment both in real and momentum spaces; and (f) 30 Å/30 Å InAs/GaSb type-II semiconducting superlattice. E1, H1, and X1 represent the first sub-band in the Γ-valley conduction band, Γ-valley valence band, and X-valley conduction band, respectively. The overlap between the electron and hole wavefunctions is shown in gray.

the electrons and holes both reside mostly in the GaAs and their wavefunctions overlap almost perfectly as shown in the figure.

There are cases, however, when the CB minimum is in one layer while the VB maximum is in the other. For this so-called type-II alignment, which is exemplified by the $Ga_{0.47}In_{0.53}As/GaAs_{0.5}Sb_{0.5}$ superlattice of Figure 1b, the electrons and holes tend to separate spatially. It should not be surprising that this significantly influences many of the basic optical and electronic properties. Just one example is the band-edge absorption, whose strength is proportional to the square of the wavefunction overlap integral.

In contrast to the staggered type-II heterostructure of Figure 1b, another possibility is the broken-gap type-II alignment of the InAs/GaSb superlattice shown in Figure 1c. Since the CB minimum in InAs actually lies below the VB maximum in GaSb, this combination becomes a semimetal even though the bulk constituents are both semiconductors.

The nature of the band alignment can also be strongly influenced by shifts of the electron and hole energy levels induced by quantum confinement. Figure 1d illustrates a type-I GaAs/AlAs superlattice with relatively thick GaAs layers. Notice that the same superlattice becomes type-II if, as in Figure 1e, the GaAs layers are thin enough that the GaAs Γ-valley electron level (center of the Brillouin zone) is pushed to a higher energy than the AlAs X-valley level (boundary of the Brillouin zone). Similarly, quantum confinement can turn the broken-gap (semimetallic) type-II InAs/GaSb superlattice of Figure 1c into a staggered (semiconducting) type-II superlattice as in Figure 1f.

Although many different type-II heterostructures have been identified over the last three decades, only a few are likely to have long-term technological importance for optics or electronics. The system that has received the most attention in terms of both fundamental scientific studies and opto-electronic device development is InAs/GaSb and related alloy combinations such as InAs/GaInSb. Following a brief overview of wider-gap type-II heterostructures, this article will concentrate primarily on that interesting narrow-gap system.

Wide-Gap Type-II Heterostructures

The best-known wide-gap type-II heterostructure is the GaAs/AlAs superlattice of Figure 1e. The band lineup is type-II provided the GaAs thickness is no greater than ≈10 monolayers (28 Å) and the AlAs layer is no thinner than the GaAs layer. Since the CB minimum is in the AlAs X-valley and the VB maximum is in the GaAs Γ-valley, this structure has an indirect energy gap in both real space and momentum space. In type-II GaAs/AlAs, the X-valley states at the CB minimum form one or more superlattice minibands, which display relatively low resistance at small biases, negative differential velocity, etc. A related structure is the GaAs/AlAs/GaAs/AlAs/GaAs double-barrier intervalley resonant tunneling diode, in which resonant or sequential phonon-assisted tunneling proceeds via intervalley transitions whenever the Fermi level in the GaAs emitter lines up with the X-valley minimum in AlAs. Structures containing AlGaAs do not necessarily need quantum confinement to establish a type-II alignment, since it occurs naturally in $Al_xGa_{1-x}As$/AlAs heterojunctions with $x > 0.3$.

The device potential of wide-gap type-II heterostructures is rather limited, owing to their low luminescence efficiencies (due in large part to the doubly indirect band alignment) and low mobilities (due to the heavy X-valley effective mass). A few proposals have focused on modulation of the band alignment between the type-I and type-II regimes. The $Ga_{0.47}In_{0.53}As/GaAs_{0.5}Sb_{0.5}$ superlattices of Figure 1b and related structures have been investigated as alternative active regions for semiconductor lasers emitting in the important 1.3–2 μm wavelength range.

InAs/GaSb/AlSb-Based Type-II Superlattices and Quantum Wells

Molecular beam epitaxy (MBE) was used to fabricate the first InAs/GaSb-based superlattices in 1977, only a few years after the initial GaAs/AlGaAs superlattice growths. It was quickly demonstrated that for relatively thick layers the band alignment is broken-gap type-II, with 100–150 meV overlap between the conduction band minimum in InAs and the valence band maximum in GaSb. In this semimetallic superlattice, GaSb valence-band electrons spill over into the InAs and leave behind holes (see Figure 1c). It was also observed that at equal layer thicknesses of ≈90 Å quantum confinement induces a semimetal-to-semiconductor transition (Figure 1f), and that the gap becomes increasingly positive when the thickness is reduced further. This is no mere scientific curiosity, since being able to tune in a wide range of energy gaps spanning 0 to >0.5 eV has enormous practical consequences for infrared (IR) emitters and detectors. Such a capability cannot be replicated by any other III–V heterostructure system.

Another happy accident is that the lattice constants of InAs (6.058 Å) and GaSb (6.096 Å) are matched closely enough to allow them to be grown together by MBE or metalorganic chemical vapor deposition (MOCVD). A third binary member of the 'antimonide' or '6.1-Å' family of growth-compatible heterostructures is AlSb (6.136 Å), which is valuable in that it serves as a quantum barrier to both InAs conduction states and GaSb valence states. The extended family includes a variety of ternary alloys (GaInSb, GaAlSb, InAsSb, AlAsSb, etc.), whose energy gaps as a function of lattice constant are given by the curves in Figure 2, and also at least three quaternary alloys: GaInAsSb, AlGaAsSb, and InAlAsSb. Taken together, this menagerie of materials

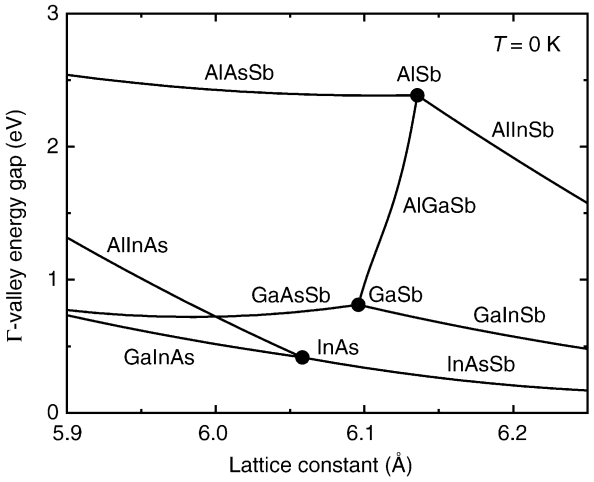

Figure 2 Direct energy gaps at zero temperature for III–V compound semiconductors and their ternary alloys with lattice constants in the vicinity of 6.1 Å.

provides the type-II IR device designer with an exceptional degree of configurational flexibility.

Type-II IR structures are typically grown on either a GaSb or InAs substrate. Since even a small amount of strain build-up can produce dislocation defects that seriously degrade the performance, one usually balances the net tensile strain (associated with layers having a lattice constant slightly larger than that of the substrate) with a compensating amount of net compressive strain (from layers whose lattice constant is slightly smaller than that of the substrate).

Band structures for complicated type-II layering configurations have been calculated by a variety of methods, including $k \cdot p$, tight-binding, and empirical pseudopotentials. While all reproduce the main features of the electron and hole sub-bands and dispersion relations near the center of the Brillouin zone, the relative merits of the different approaches remain controversial. Due to the small energy gaps, band-mixing effects are especially important in this system.

One consequence of the small type-II antimonide energy gap is that the electron and hole bands repel each other and both effective masses can be lighter than in any other III–V semiconductor (e.g., smaller than in the bulk constituents). This leads to high mobilities at room temperature, and promising possibilities for high-electron-mobility transistors (HEMTs). Also of interest are resonant tunneling diodes (RTDs) based on InAs/AlSb/GaSb/AlSb/InAs and related structures, in which interband tunneling via the GaSb valence states results in negative differential resistance with a very high peak-to-valley ratio. Since these devices are primarily electronic rather than optical, we will not discuss them further here.

While interfaces play an important role in any semiconductor heterostructure, they are especially crucial in InAs/GaSb and related type-II systems because the two materials on opposite sides of the interface have neither a common cation nor a common anion (unlike GaAs/AlGaAs, for example, in which both wells and barriers have As anions). By timing the shutter sequences in the growth, one can in principle end the InAs on an In layer and begin the GaSb on Sb, to produce InSb-like interface bonds. Alternatively, one can end the InAs on As and begin the GaSb on Ga to form GaAs-like bonds. Detailed characterizations by a variety of methods have shown that the device properties and even the band structure can be relatively sensitive to whether the interface bonds are InSb-like or GaAs-like.

With regard to opto-electronic devices, a potential limitation of InAs/GaSb superlattices is that in order to reach a long wavelength (small energy gap), the layers must be rather thick (e.g., ≈90 Å for zero gap). In such a structure the overlap between the electron and hole wavefunctions becomes quite small (see Figures 1c and 1f), and consequently the interband optical interactions are weak. However, Mailhiot and Smith pointed out that this issue can be circumvented to a large extent by employing $Ga_{1-x}In_xSb$ (with $x \leq 0.4$) rather than GaSb for the hole QWs. Compressive strain in the GaInSb produces a large splitting of the heavy and light hole sub-bands, along with a substantial increase of the type-II offset energy. The result is that much thinner layers (with large wavefunction overlaps) may be employed in conjunction with energy gaps corresponding to long IR wavelengths. In fact, the overlap for a short-period InAs/GaInSb superlattice such as that illustrated schematically in Figure 3 can be large enough to yield interband optical interaction strengths comparable to those in bulk materials and type-I superlattices.

While practical constraints on the minimum reproducible layer thickness set a lower wavelength limit on the order of 2 μm, the upper limit governed by uniformity considerations is quite high, perhaps in the $\lambda = 25-100$ μm range. This makes type-II antimonide quantum heterostructures a natural choice for mid-IR to far-IR photodetectors and lasers.

Type-II IR Photodetectors

Because IR detectors sense the radiant black-body emission from warm objects rather than relying on reflected visible light, they can be used for 'night vision.' Both photoconductive (PC) and

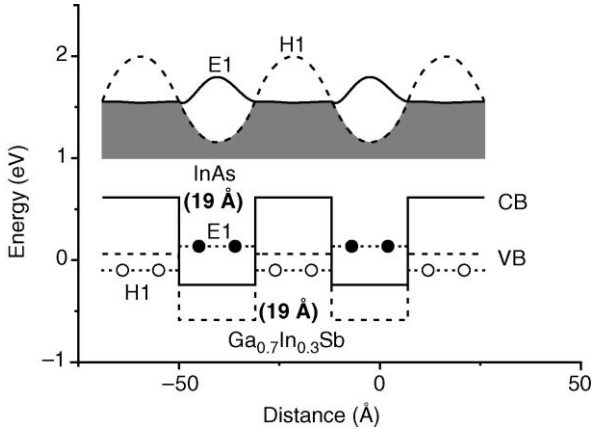

Figure 3 Conduction and valence band profiles along with electron (E1) and hole (H1) sub-band energies and wavefunctions for a 19 Å/19 Å InAs/$Ga_{0.7}In_{0.3}Sb$ type-II superlattice (GaSb substrate) with an energy gap equal to that of the InAs/GaSb superlattice in **Figure 1d**.

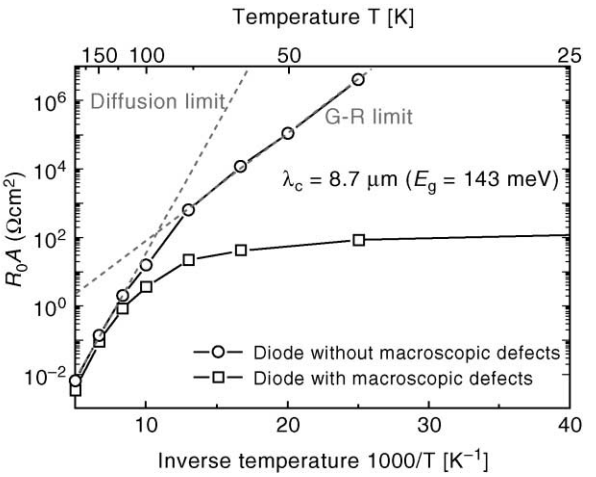

Figure 4 Temperature dependence of the dynamic impedance at zero bias R_0A for two different InAs/GaInSb superlattice diodes with cutoff wavelengths of 8.7 μm. The generation-recombination (G-R) and diffusion-limited R_0A values are indicated by the dashed lines. Reproduced with permission from Bürkle *et al.* (2000) *MRS Symp. Proc.*, 607, pp. 77–82.

photovoltaic (PV) IR detectors are now being developed with type-II active regions, usually consisting of simple InAs/GaInSb superlattices. The PV geometry, in which a reverse bias is applied to a p–n junction, is ultimately preferred since it is easily adaptable to pixelation in a 2D array with many discrete detector elements. That allows an IR camera to construct a detailed thermal picture of any given scene.

An optimized PV photodetector must have high absorption in the active region, unimpeded vertical transport to assure collection of the photogenerated carriers, and a low dark current. The thin layers of a type-II InAs/GaInSb active region help to satisfy the first two criteria, since they assure both a large wavefunction overlap (**Figure 3**) and rapid electron and hole tunneling through the superlattice minibands.

The dark current in a high-quality diode tends to be dominated by generation-recombination currents at low temperatures and diffusion currents at higher *T*. However, trap-assisted tunneling via dislocations and other macroscopic defects can significantly increase the dark current. **Figure 4** plots the resistance–area product (R_0A) for diodes with and without macroscopic defects. Surface leakage resulting from inadequate sidewall passivation can also lead to a substantial contribution that is proportional to the perimeter of the mesa. The diffusion current scales as $1/\tau^{1/2}$, where τ is the recombination lifetime. To date, the defect-mediated Shockley–Read lifetimes of <100 ns have been significantly shorter than in competing HgCdTe IR materials (>1 μs). However, Auger lifetimes are substantially enhanced, as will be discussed further in the context of type-II IR lasers. In an Auger event, the energy and momentum of the recombining electron–hole pair is transferred to a third carrier, which scatters to a higher-lying state in either the same or a different band. Because three different carriers must interact simultaneously, the recombination rate scales with the cube of the carrier density. Usually Shockley–Read recombination dominates at lower temperatures and Auger processes at higher *T*.

Typically the n-side of a type-II diode is heavily doped ($10^{18}\,cm^{-3}$ range) and relatively thin, while most of the absorption occurs on the lightly doped ($10^{16}\,cm^{-3}$ range) p-side. A standard figure of merit is the detectivity (D^*), which is essentially the signal-to-noise ratio in a device of standard size. For 77 K operation, type-II PV detectors with cutoff wavelengths of 7.5 μm and 12 μm achieved D^* of 1×10^{12} cm $Hz^{1/2}$/W and 5×10^{10} cm $Hz^{1/2}$/W, respectively. Those values are nearly as high as typical results for the much more mature HgCdTe FPA technology.

It is anticipated that type-II detectors will be particularly attractive at very long wave IR (VLWIR), at which it becomes increasingly difficult to maintain adequate control over the HgCdTe compositional uniformity. Recent PC detectors operated out to 22 μm, and PV devices to 16 μm. Due in part to the strong suppression of Auger recombination, type-II detectors are also expected to be advantageous at noncryogenic temperatures where future systems will increasingly operate.

Type-II IR Lasers

At visible and near-IR wavelengths out to $\approx 2\ \mu m$, the QW diode laser is by now a mature technology that dominates the commercial marketplace due to its low cost (<$1 per laser in some cases), compactness, and reliability. However, the technical challenges become much more severe in the mid-IR spectral region ($3-5\ \mu m$). Before the advent of the type-II laser, no interband III–V semiconductor device emitting at $\lambda \geq 3\ \mu m$ had ever operated at room temperature. Alternatives are the lead salt laser, which is limited to very low-output powers, and the quantum cascade laser (QCL) that is based on optical transitions between two electron QW sub-bands rather than interband electron–hole processes. Mid-IR lasers are needed for high-power military applications such as IR countermeasures against heat-seeking missiles and for the sensitive detection of trace chemicals using the spectroscopic 'fingerprint' that distinguishes each species from any other.

From the 1960s to the late 1990s, conventional III–V double heterostructure (DH) and type-I QW lasers for the mid-IR never achieved the desired levels of performance because they failed to overcome certain fundamental limitations. Those included:

1. inadequate band offsets, which at higher temperatures made it difficult for the QW or DH active regions to retain the injected electrons and holes;
2. rapid Auger nonradiative decay, which led to excessive threshold current densities at higher temperatures; and
3. restricted spectral range, limited to wavelengths shorter than the cutoff for bulk $InAs_{1-x}Sb_x$.

However, it has more recently become apparent that all of these limitations can be either minimized or removed by employing a type-II InAs/GaSb-based active region.

For example, electrical confinement is far more effective because the GaSb conduction band confines InAs electrons and the InAs valence band confines GaSb holes (see **Figure 1f**). Auger recombination is also significantly suppressed, in part because the holes are nearly as light in the plane as the electrons, making it much more difficult to conserve both momentum and energy in the three-carrier process. Nearly an order-of-magnitude suppression of the room-temperature Auger rate has been reported, which translates directly into a similar reduction of the threshold current density. And as was discussed above in connection with IR photodetectors, very long wavelengths are readily attainable because the energy gap in a type-II active region can be arbitrarily small. Type-II lasers have already operated cw at $\lambda > 7\ \mu m$, and cryogenic operation out to wavelengths as long as $100\ \mu m$ has been projected theoretically.

In 1986 the first type-II semiconductor laser, which emitted at $\lambda = 1.86\ \mu m$ from single liquid-phase epitaxy (LPE)-grown heterojunctions, was demonstrated. Since the mid-1990s, $3-4\ \mu m$ GaInAsSb/InAs-based single-interface type-II diodes have been developed that operate up to 205 K in pulsed mode.

In 1995, lasing at $\lambda = 3.2-3.5\ \mu m$ was reported from type-II $InAs/Ga_{0.75}In_{0.25}Sb$ superlattice diodes grown by MBE. Subsequent work on these devices extended the temperature range to 255 K in pulsed mode and 180 K for cw operation, and the emission wavelength to $4.3\ \mu m$.

While the wavefunction overlap and hence the gain for a two-constituent type-II superlattice active region can be quite favorable, penetration of the electron wavefunctions into the thin GaInSb layers is in fact so great that a wide miniband forms along the growth axis. The electrons then have strong energy dispersion in all three dimensions, whereas present-generation near-IR and visible semiconductor lasers nearly always have QW active regions with 2D carriers. The stepped quasi-2D density of states yields a much higher differential gain per injected carrier at threshold, and also narrower spectral emission lines than are attainable with a 3D electron population. The most straightforward approach to blocking the formation of a miniband in the superlattice is to add a high electron barrier between the periods, e.g., InAs/GaInSb/AlSb. However, the drawback of that approach is that the wavefunction overlap becomes much smaller than in the simple superlattice, resulting in significantly lower gain.

On the other hand, if a second electron well is added on the other side of the hole well, the resulting structure with four constituents per period (e.g., InAs/GaInSb/InAs/AlSb) combines the large wavefunction overlap of the two-constituent superlattice with 2D electron and hole confinement. **Figure 5** illustrates band profiles, energy levels, and wavefunctions for the 'W' laser, which takes its name from the shape of the conduction-band profile.

Optically pumped type-II W lasers display high-power pulsed operation at temperatures well above ambient. Wavelengths have spanned the range $2.6-7.3\ \mu m$, and mid-IR vertical-cavity surface-emitting lasers (VCSELs) were also fabricated. Optical pumping is viewed primarily as a means of achieving high cw or quasi-cw output powers in the mid-IR, and in that regard W lasers have exceeded all other semiconductor approaches with 1.5 W peak output power being obtained at 71 K for $100\ \mu s$

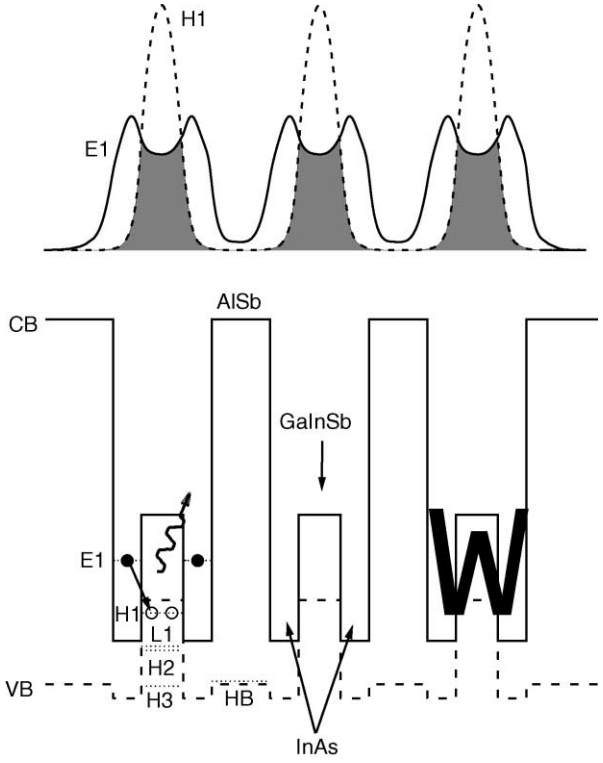

Figure 5 Conduction and valence band profiles along with selected sub-band energies and wavefunctions for InAs/$Ga_{0.7}In_{0.3}Sb$/InAs/AlSb type-II 'W' structure (GaSb substrate). Electron (E1), heavy hole (H1, H2, H3), light hole (L1), and barrier heavy hole (HB) sub-bands are indicated.

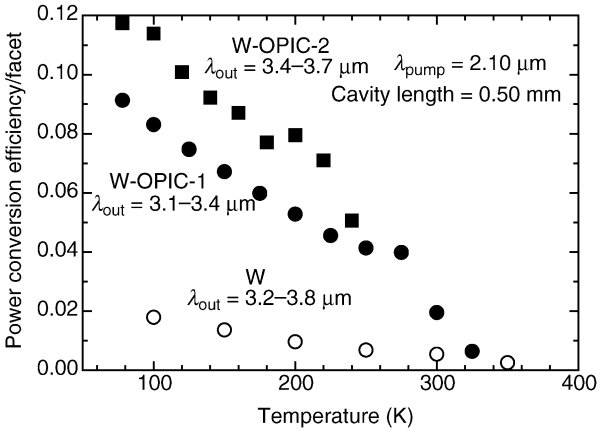

Figure 6 Power conversion efficiency per uncoated facet as a function of temperature for two different W-OPIC lasers emitting in the wavelength ranges of 3.1–3.4 μm (filled circles) and 3.4–3.7 μm (filled squares), respectively. For comparison, conversion efficiencies for a typical 'W' laser without an OPIC emitting in the same spectral range (open circles) are also shown. All of the lasers were optically pumped in pulsed mode by a 2.1 μm Ho:YAG laser, and the cavity length for all three devices was 0.5 mm.

pulses with a 10% duty cycle. The average output at 82 K for that device was up to 360 mW for 20 μs pulses and a 50% duty cycle.

Cw operation at $\lambda = 3.0$ μm was observed nearly to room temperature (290 K), and even a 6.1 μm emitter operated cw to 210 K. The cw output power of 540 mW/facet from a device with 80 W QW periods was the highest ever reported for 78 K operation in the mid-IR. Despite the rather high output power, however, the differential power conversion efficiency was only 2.5% at 78 K and fell to 1% at 140 K. Much higher efficiencies were obtained using the optical pumping injection cavity (OPIC) approach, in which the active region was surrounded by semiconductor quarter-wave mirror stacks that formed an etalon cavity resonant at the 2.1 μm pump wavelength. For pulsed operation, OPIC devices with uncoated facets and only 10 active QWs yielded lower thresholds, lower internal losses, and higher power conversion efficiencies than any previous results at $T \geq 200$ K. Figure 6 illustrates that the efficiencies were 7.1% at 220 K for one device and 4% at 275 K for another.

An alternative approach to maximizing the pump absorbance despite a small number of QWs is the 'integrated absorber' (IA) concept. In this approach, the W QWs are separated by intermediate-gap GaInAsSb absorbing layers which donate optically generated electrons and holes to the active wells. At 80 K with 35 μs pulses at 2.5% duty cycle, an IA laser with only five QWs separated by ≈1600-Å-thick absorber layers had a power conversion efficiency of 9.8% and peak output power of 2.1 W. Thus far the IA has not done as well as the OPIC at high temperatures, due mostly to an inadequate valence band offset between the absorber layers and the active QWs.

The beam quality for optically pumped type-II lasers was substantially improved by using the angled-grating distributed-feedback (α-DFB) approach pioneered at shorter wavelengths. Since both the grating and the facets are needed to produce optical feedback, only a narrow angular cone is fed back into the tilted cavity. For a pump-stripe width of 50 μm, the near-diffraction-limited output beam had 15 times narrower angular divergence (1.4° full width at half-maximum (FWHM)) than the double-lobed beam emitted from a conventional Fabry–Perot laser occupying an unpatterned portion of the same bar. Even more promising results have been reported using the photonic-crystal distributed-feedback (PCDFB) laser, in which the grating is defined on a two-dimensional rectangular lattice that is tilted with respect to the facets as in the α-DFB. For a pump-stripe

width of 200 μm, the beam quality for the direction along the laser stripe was four times the diffraction limit.

Although optical pumping is the simplest way to inject electrons and holes into the active region, type-II diode lasers will ultimately be much more inexpensive, convenient, compact, and energy efficient. However, generalization of the W configuration to electrical pumping is not entirely straightforward. This is because holes injected from the p-type cladding layer may have poor growth-axis transport, and hence hole populations in the various GaInSb QWs could be highly nonuniform. Whereas the holes in a superlattice are required to tunnel through only one InAs electron well at a time (see Figure 3), the barrier for the structure in Figure 5 consists of two InAs layers in addition to the AlSb barrier. To overcome this problem the AlSb was replaced with a specially designed quaternary $Al_{0.15}Ga_{0.85}As_{0.05}Sb_{0.95}$ barrier, which raised the L1 light-hole sub-band to within ≈100 meV of the H1 heavy-hole valence band maximum. That permitted thermally excited light holes to provide the needed tunneling transport to all of the QWs. Another key design element was the insertion of relatively thick (0.6 μm) undoped $Al_{0.35}Ga_{0.65}As_{0.03}Sb_{0.97}$ 'broadened-waveguide' layers on each side of the active region, in order to minimize free-carrier absorption in the doped $Al_{0.9}Ga_{0.1}As_{0.07}Sb_{0.93}$ cladding layers. Some of the devices also contained InAs/AlSb 'hole-blocking' layers, which prevented hole leakage into the n-type broadened waveguide layer.

A pulsed $\lambda = 3.27$ μm W-diode of this type with 10 active QW periods achieved the first room temperature operation (to 310 K) of an electrically pumped III–V interband laser in the mid-IR. Another device with five QWs operated in cw mode to 200 K, the highest T_{max} to date for any interband III–V laser beyond 3 μm. The threshold at 78 K was 63 A/cm^2, and Figure 7 shows that the cw output was 140 mW at 78 K and 20 mW at 180 K. Following optimization of the turn-on voltages, series resistances, and internal losses, cw diodes with one–three QWs are projected to operate in the thermo-electric cooler range and ultimately at room temperature.

A more exotic variation on the type-II diode emitter is the interband cascade laser (ICL) that was first proposed by RQ Yang. Like the intersub-band QCL, the ICL generates multiple photons per injected electron by making an optical transition at each step of a staircase-like QW structure. While the threshold current density for the QCL is high because of the inherently short lifetimes associated with intersub-band phonon scattering, the interband configuration of the ICL eliminates that nonradiative relaxation

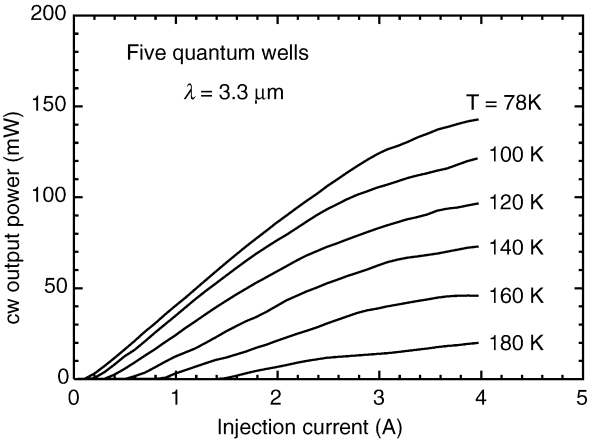

Figure 7 Cw output power as a function of injection current at temperatures between 78 K and 180 K for a 'W' diode laser with a 2-mm-long cavity and 100-μm-wide stripe emitting at a wavelength of 3.3 μm.

path. Early projections that the ICL should display low thresholds, high cw operating temperatures, high output powers, and high differential quantum efficiencies (well above the conventional limit of one photon/electron) have all been confirmed experimentally.

Figure 8 illustrates conduction and valence band profiles for a typical single stage of the ICL staircase. While this example employs a W configuration, in which two InAs electron QWs (19 Å and 13 Å) surround the active GaInSb hole QW (32 Å), some designs employ only a single InAs active well. Electrons tunneling into the InAs QWs from the preceding injection region at left emit a photon by making spatially indirect radiative transitions to the GaInSb valence band. They next tunnel into the valence states of the adjacent GaSb and GaInSb hole wells, whose function is to provide a thick barrier to prevent electron leakage from the active InAs QWs directly to the 70 Å InAs well that begins the next injection region. From the final GaInSb hole QW (40 Å), the carriers undergo near-elastic interband scattering into conduction states of the 70 Å InAs QW. Electrons traversing the superlattice miniband of the injection region, which in this case consists of eight digitally graded InAs wells, finally tunnel into the active electron QWs of the next period. This series of events is repeated at each step of the ICL staircase.

Following the first ICL demonstration in 1997, there have been reports of threshold current densities 13 A/cm^2 at 80 K, maximum operating temperatures of up to 300 K for pulsed operation and 150 K for cw (with epitaxial-side-up mounting), pulsed output powers of 6 W/facet and slope quantum efficiencies exceeding 600%. A cw wall plug efficiency of 22%

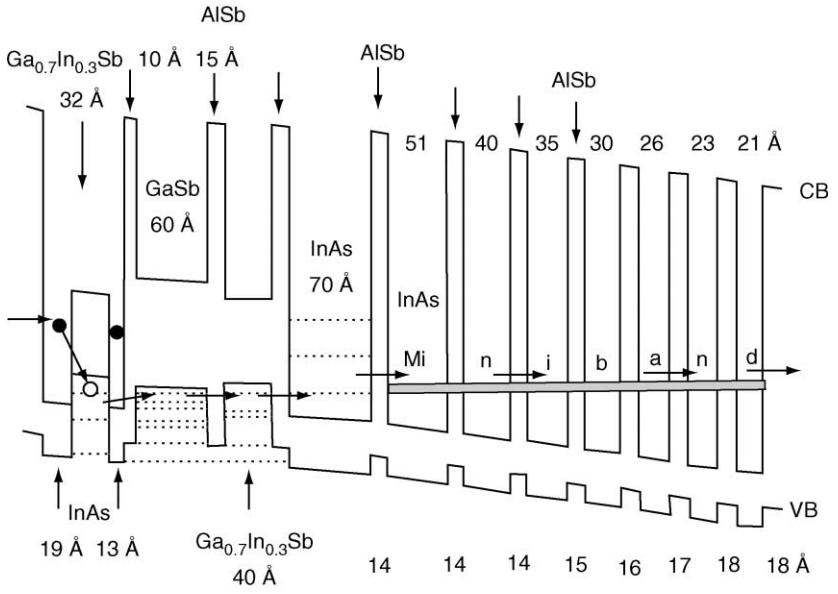

Figure 8 Conduction and valence band profiles for one period of an interband cascade laser with a W active region and three hole wells. Sub-band energy levels are also indicated.

at 80 K was recently reported. While substantial further improvements are expected, the primary disadvantage of the ICL is its complexity.

Despite numerous dramatic advances by type-II mid-IR lasers since their first demonstration in 1995, the performance has not yet progressed to the level that will be required to support a robust commercial technology. One key issue is the cw operating temperature, which must increase to at least the thermo-electric cooler range if the potential market is to extend beyond niche applications. Higher-temperature operation will result automatically once the number of QWs, and hence the threshold current density, can be reduced. Further suppression of the Auger decay rate would also be highly beneficial if it is proven possible.

The laser output power and efficiency are governed by the internal loss, which in type-II QWs tends to be dominated by resonant free-hole intersub-band transitions. The details of the valence sub-band structure are not well known at present, although recent experiments have apparently identified a number of the transition energies. As in the case of the threshold, reducing the number of QWs is highly beneficial since it reduces the number of free carriers that can absorb the lasing photons. The optically pumped OPIC and IA structures discussed above achieved dramatic reductions in the internal losses by following that strategy.

The beam quality attainable from a semiconductor laser is governed by the linewidth enhancement factor (LEF), which is proportional to the variation in the refractive index induced by a small change in the carrier density. A large positive value of the LEF leads to filamentation in broad-area lasers as tiny peaks in the optical intensity cause carrier depletion and a local increase in the refractive index, which in turn stimulates further focusing of the output beam. The output then consists of an incoherent superposition of many rapidly diverging filaments, resulting in a beam quality that is several orders of magnitude worse than the diffraction limit. While theoretical LEFs for optimized type-II W structures can be in the 1.5–2 range even at room temperature, recent Hakki–Paoli measurements have yielded values in the 2.5–5 range. This is possibly due to additional inhomogeneous broadening of the gain spectrum induced by interface roughness.

We briefly introduce the main concepts underlying the detailed treatment of specialist aspects of semiconductor physics in ensuing sections, viz: the free electron model, density of states, Fermi-Dirac statistics, energy bands and energy gaps, effective mass, electrons and holes, intrinsic and extrinsic conductivity, direct and indirect interband optical transitions, excitons and low-dimensional systems.

Introduction

A proper treatment of optoelectronic devices needs to include the physical properties of the materials from which the devices are made, and this subject is covered under the section of the Encyclopedia entitled 'Semiconductor Fundamentals'. This includes sections on the basic physics common to all semiconductors useful in optoelectronic applications, the experimental techniques used to investigate the optical properties of

these semiconductors and the more detailed properties of the most widely used semiconductors, and semiconductor systems. The properties of greatest importance here are those of electrons in crystalline solids, but the interaction between the electrons and the atoms of the crystal lattice is also significant. The combination of these microscopic effects is responsible for determining the macroscopic optical and electrical properties of semiconductors, and in this section we give the necessary background to these topics.

The classical treatment is extremely useful in describing the electrical conductivity of solids; the electrons are regarded as charged particles obeying Newton's laws of motion, and electrical resistance is assumed to arise from collisions with the vibrating lattice and/or impurities. However, the classical theory does not give a method of predicting the natural frequencies, or energies, of these electronic oscillators. To do this we need to use quantum mechanics, and the elements of this are reviewed here. We start with the free electron theory of metals, where the electrons are treated as particles constrained to move in a potential box. For convenience we begin by considering the situation in one dimension (1D).

Free Electron Theory of Metals

Free electrons in a 1D potential box of length L in the x-direction are described by a plane wave function that is normalized within the box, $\psi = (1/L)e^{ikx}$, and satisfies the Schrödinger equation in the x-direction:

$$\frac{\hbar^2}{2m}\frac{d^2\psi}{dx^2} + E\psi = 0 \qquad [1]$$

where E is the electron energy. This gives the familiar parabolic E–k dispersion relation (see Figure 1), $E = \hbar^2k^2/2m$ (with electron momentum $p = \hbar k$). In order to evaluate physical problems it is necessary to define the boundary conditions for the wave function. We assume fixed boundary conditions (i.e., $\psi = 0$ at $x = 0, L$) leading to the quantization condition $k = n\pi/L$ where n is a positive integer.

Density of States

Physical properties of solids depend on the number of allowed k-values per unit range of k (or E-values per unit range of E), a quantity referred to as the density of states, D(k) or D(E) – for example, the number of allowed states between k and $k + dk = D(k)dk$. From the fixed boundary condition ($k = n\pi/L$, the number of allowed values of k per unit range of k in 1D is just

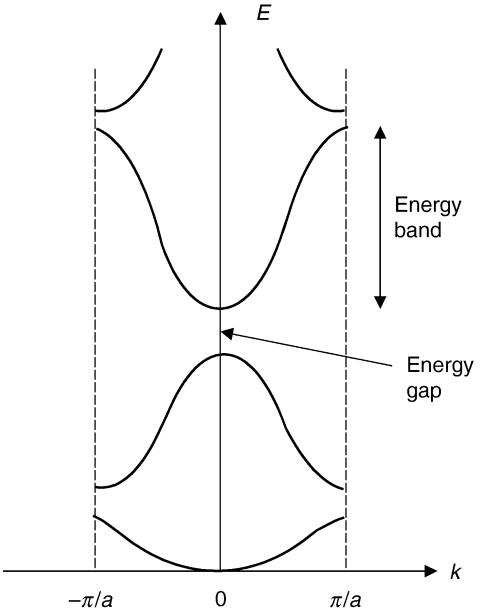

Figure 1 Schematic representation of energy bands in one dimension, characterized by gaps at the high symmetry points of the Brillouin zone.

$D(k) = L/\pi$. In terms of energy, using the E–k dispersion relation, we can write (including the factor 2 for two possible spin states):

$$D(E)dE = D(k)(dk/dE)dk$$
$$= (L/2\pi)(2m/\hbar^2)^{1/2}E^{-1/2}dE \qquad [2]$$

i.e., the density of states depends on $E^{-1/2}$ for the 1D situation.

For a cube of side L, in three dimensions we generalize the identity for fixed boundary conditions:

$$\frac{L^2k^2}{\pi^2} = n_x^2 + n_y^2 + n_z^2 = R^2 \qquad [3]$$

where $k_x = n_x\pi/L$ etc., and the states fill up the positive quadrant of a sphere of radius ($R = Lk/\pi$) in k-space. Thus, the number of states in a given volume of k-space is numerically equal to that volume, so that the number of states between R and $R + dR$ in the positive quadrant (hence $1/8^{th}$) of a spherical shell of radius R in k-space is

$$D(R)dR = 4\pi R^2 dR(1/8) \qquad [4]$$

i.e., $(1/8)^{th}$ of the surface area of the shell multiplied by the thickness of the element. Changing the variable to k, the number of states between k and $k + dk$ is

$$D(k)dk = D(R)\frac{dR}{dk}dk = \frac{V}{2\pi^2}2k^2dk \qquad [5]$$

where the volume $V = L^3$, and a factor of 2 has again been included to account for the two possible spin states of the electron. This in turn, through the relation between E and k, can be expressed in terms of the density of states per unit energy so that the number of states between E and $E + \mathrm{d}E$ is given by:

$$D(E)\mathrm{d}E = D(k)\frac{\mathrm{d}E}{\mathrm{d}k}\mathrm{d}E = \frac{2V}{2\pi^2}\left(\frac{2m^*}{\hbar^2}\right)^{\frac{3}{2}}E^{\frac{1}{2}}\mathrm{d}E \quad [6]$$

In two dimensions, by the same argument:

$$\frac{L^2k^2}{(\pi)^2} = n_x^2 + n_y^2 = R^2 \quad [7]$$

Therefore $D(R)\mathrm{d}R = (2\pi R/4)\,\mathrm{d}R$, where the factor 1/4 implies the positive quarter of the 2D ring between R and $R + \mathrm{d}R$ in k-space, $A = L^2$ and

$$D(k)\mathrm{d}k = D(R)\frac{\mathrm{d}R}{\mathrm{d}k}\mathrm{d}k = \frac{A}{\pi}k\mathrm{d}k \quad [8]$$

From the E–k relation we have the number of states between E and $E + \mathrm{d}E$ as:

$$D(E)\mathrm{d}E = D(k)\frac{\mathrm{d}E}{\mathrm{d}k}\mathrm{d}E = \frac{A}{\pi}\left(\frac{m}{\hbar^2}\right)\mathrm{d}E \quad [9]$$

Thus, in 2D systems we have the important result that $D(E)$ is a constant.

Fermi-Dirac Distribution of Electrons

At zero temperature an atom exists in what is known as the ground state. All the electrons rest in the lowest energy states allowed to them by the Pauli principle, and fill the allowed states up to an energy known as the Fermi energy, E_F. Above absolute zero of temperature this is no longer the case, and thermal energy allows some electrons to exist in higher energy states. The probability $f(E)$ that a state of energy E will be occupied for an ideal electron gas in thermal equilibrium (thermal energy kT) is governed by Fermi-Dirac statistics:

$$f(E) = \frac{1}{1 + \exp\left(\dfrac{E - E_\mathrm{F}}{kT}\right)} \quad [10]$$

For a metal at room temperature the difference between the Fermi energy and the energy of the conduction band minimum is much greater than the thermal energy, $(E_\mathrm{F} - E_\mathrm{co}) \gg kT$; this is also true for a strongly n-type semiconductor (see below) and the distribution is said to be degenerate.

Energy Bands and Energy Gaps: Semiconductors

In the presence of the (perturbing) periodic crystal potential, $V(r)$, the above simplicity is lost: this is the so-called 'nearly free electron model', and the perturbed Schrödinger equation is now:

$$-\frac{\hbar^2}{2m}\frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} + V(x)\psi = E\psi \quad [11]$$

for the x-direction. This topic is discussed in all undergraduate texts on solid state physics, but we list the main results of the model as follows:

1. The electrons that we are concerned with are confined within a periodic lattice. Consequently the wave function ψ is modulated with the periodicity of the lattice. By symmetry arguments the correct wave function can be shown to be:

$$\psi_k(x) = \frac{1}{\sqrt{L}}\mathrm{e}^{ikx}u_k(x) \quad [12]$$

   where $u_k(x)$ is a function that has the symmetry of the lattice. $\psi_k(x)$ is known as the Bloch function and is a satisfactory solution to the Schrödinger equation. Because of the periodic nature of the Bloch equation, it is always possible to select the wavevector index k of any Bloch function to lie within the range $\pi/\mathrm{a} < k < \pi/a$. This region is referred to as the first Brillouin zone, and the representation where the E–k dispersion is mapped back entirely into the first Brillouin zone is called the 'reduced zone scheme' (Figure 1).
2. Regions of E appear where solutions $\psi_k(x)$ are not allowed, corresponding to Bragg reflections of the electron waves by the lattice; these are the so-called energy gaps (forbidden energy regions) which separate energy bands (allowed energy regions). In 3D these discrete bands of energy form the conduction and valence bands within materials. The forbidden energy gap separates these bands. An additional quantum number n is required to label the individual energy bands corresponding to successive Brillouin zones in the wavevector, $2n\pi/a$ (where $n = 0, 1\ldots$). The position of the Fermi level determines the electron population of the energy bands, and the character of the solid (see below).
3. The parabolic E–k dispersion relation is retained near $k = 0$, and at other symmetry points of the Brillouin zone, but with the substitution of an effective mass, m^* (see below) for the free electron mass, i.e., $E = \hbar^2k^2/2m^*$ for $k \ll \pi/a$. This is referred to as the effective mass approximation.

The nearly free electron model is one limit for the description of the formation of energy bands and energy gaps in a solid. In real crystals the energy bands derive from, and retain the symmetry of, the parent atomic states of the host atoms. In this limit, the model that starts out from the wave functions of the free atoms is known as the tight binding model or the LCAO (linear combination of atomic orbitals) approximation. As neutral separated atoms are brought together to form a crystal, their wave functions overlap and the Coulomb interaction between the atom cores and the electrons splits the atomic energy levels, spreading them into bands. Each state of given quantum number of the free atom is spread in the crystal into a band of energies; a given s, p, d-state in N separate atoms will produce the corresponding N-orbital s, p, d-energy band in the solid. Including the factor of 2 for spin, a full s-band would contain 2N electrons, a full p-band 6N electrons and so on. The width of the band is proportional to the strength of the overlap interaction between neighboring atoms. Each energy band will not have the same energy as any other band over any substantial range of the wavevector.

Metals, Insulators and Semiconductors

The position of the Fermi level distinguishes whether the solid is a metal, insulator or semiconductor. Generally those bands that derive from full atomic orbital states will be fully occupied with electrons, those that derive from empty atomic states lead to empty energy bands, and those from partially full atomic states lead to partially full energy bands. The highest band of those that are filled with electrons is called the valence band; the next highest band is called the conduction band (the fundamental energy gap, E_G, is the valence/conduction band separation, referred to from now on as simply the energy gap). For a metal, E_F is in the conduction band at all temperatures; for an insulator, E_F is close to the middle of the energy gap. Semiconductors are a class of crystals with small energy gaps; they are insulators at $T = 0\,K$, but are conductors at finite temperatures due to either thermal excitation of electrons across the gap or doping, n- or p-type (see below).

Effective Mass

Consider what happens to an electron when an external electric field F is applied. Suppose the electron is initially in a state k. When the field has acted on the electron for a small time dt, it has gained an energy:

$$dE = eFv\,dt = (eF/\hbar)(dE/dk)dt \qquad [13]$$

since the group velocity of the de Broglie wave (energy, $E = \hbar\omega$) is $v = \hbar^{-1}(dE/dk)$. Or simplifying we have: $dk/dt = eF/\hbar$. This gives for the resulting acceleration:

$$a = dv/dt = (1/\hbar)(d^2k/dt^2)(dk/dt)$$
$$= (eF/\hbar^2)(d^2E/dk^2) \qquad [14]$$

Comparing this result for the acceleration of a free electron of mass m under the influence of F, $a = eF/m$, it follows that the electron behaves as if it had an effective mass, m^*, given by

$$\frac{1}{m^*} = \frac{1}{\hbar^2}\frac{d^2E}{dk^2} \qquad [15]$$

Thus, the electron effective mass m^* gives a measure of the conduction band curvature near the minimum at $k = 0$. We note that the same result is achieved by differentiating twice the 'nearly free electron' E–k relation, $E = \hbar^2k^2/2m^*$.

Electrons and Holes

Consider the situation where a single electron is excited either optically or thermally from the top of the filled valence band to the bottom of the conduction band of a 1D lattice, and consider the collective behavior of the valence band when an external electric field is applied. Denoting the charge of an electron by $-e$ and the velocities of the electrons by v_i, we may write for the current associated with all electrons in the completely filled valence band in the absence of an external field:

$$I = -e\sum_i v_i = -e[v_j + \sum_{i\neq j} v_i] = 0 \qquad [16]$$

Thus, if the electron j were missing, we should have current

$$I' = -e\sum_{i\neq j} v_i = ev_j \qquad [17]$$

Applying an external field F, the rate of change of the current due to the field is:

$$dI'/dt = e(dv_j/dt) = -e^2F/m_j^* \qquad [18]$$

Since the holes are at the top of the valence band, m_j^* is negative and the right hand side of the equation is positive – i.e., a positive external field F gives a positive change of current at the top of the valence band. Thus, a band in which an electron is missing behaves as a 'positive hole' with an effective mass $m_h = -m_e$, and positive charge $+e$. Since m_e is negative near the top of the valence band, m_h is positive.

Impurities, Intrinsic and Extrinsic Conductivity

The key point about semiconductors from a device point of view is that one can control their conductivity. The basic method is by doping the host crystal with impurities either of valence greater than the host (donors giving excess electrons, called n-type) or of valence less than the host (acceptors giving excess holes, called p-type). The conductivity is referred to as intrinsic conductivity (from intrinsic carrier concentration, N_i) and extrinsic conductivity (from extrinsic carrier concentration, N_e) for undoped and doped material, respectively.

The impurities are chosen to have very low binding energies, so that the electrons (holes) are substantially ionized at room temperature to provide n-type (or p-type) conductivity. These shallow impurities can be treated using the simple Bohr theory of the hydrogen atom, substituting the electron orbiting around the proton in the hydrogen atom under the Coulomb potential e/r, by the electron in the crystal (electron effective mass m^*) orbiting round the ionized (donor/acceptor) impurity atom under the Coulomb potential $e/\varepsilon r$ in the crystal – where ε is the static dielectric constant of the crystal. As with the hydrogen atom, this gives a set of discrete energy levels:

$$E = \frac{m^*/m_o}{\varepsilon^2}\frac{13.6}{n^2}\text{eV} \qquad [19]$$

where 13.6 eV is the binding energy of the H-atom and n is the principal (Bohr) quantum number. The binding energy is then

$$E_B = \frac{m^*/m_o}{\varepsilon^2} \times 13.6\ \text{eV} \qquad [20]$$

For typical semiconductors (Ge, Si…) we have $m^*/m_o \sim 0.05$, $\varepsilon \sim 16$. Thus, E_B is in the range of a few meV (i.e., much less than E_G, and kT at room temperature). The energy level scheme for a doped semiconductor is shown schematically in real space (at room temperature) in Figure 2.

The total conductivity will be $\sigma = \sigma_i + \sigma_e$, where the intrinsic conductivity $\sigma_i = n_i e^2\tau/m^*$ and the extrinsic conductivity $\sigma_e = n_e e^2\tau/m^*$. τ is the so-called carrier scattering time. The intrinsic carrier concentration is related to temperature by $n_i = n_0 \times \exp(-E_G/2kT)$, where n_0 is a constant. In the extrinsic regime ($n_e \gg n_i$), at temperatures such that $kT \gg E_d$ (so that the impurities are all ionized), the conduction (valence) carrier concentration $n_e \rightarrow n_d$ (or n_a), the donor (or acceptor) concentration.

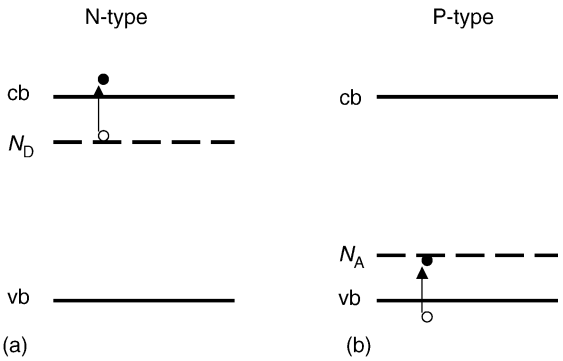

Figure 2 Doping in semiconductors. In n-type material (a), carriers are excited thermally from the donor states to the conduction band where they can contribute to the conductivity. In p-type material (b), electrons are effectively 'captured' by the acceptor states, leaving behind holes in the valence band which can also contribute to conduction. N_D and N_A are the concentration of donor and acceptor impurities, respectively.

Infrared Absorption – Interband Optical Transitions, Excitons

Apart from thermal promotion of electrons and holes via interband (valence to conduction band) transitions responsible for intrinsic conductivity, it is possible to directly excite such transitions optically by subjecting the sample to radiation with $\hbar\omega > E_G$. If the lowest conduction band minimum is situated vertically above the valence band maximum (usually at $k = 0$), then the optical transition process is referred to as a direct transition. If the lowest conduction band minimum is situated at some other point in k-space than that of the valence band maximum, the process is referred to as an indirect transition; this requires the participation of optical phonons (i.e., quantized lattice vibrations) to satisfy momentum conservation, and is therefore a weaker (higher order) process. The semiconductors are respectively referred to as Direct Gap and Indirect Gap Semiconductors. Simplified energy band diagrams for direct and indirect transitions are shown in Figure 3.

The optical spectrum corresponding to the onset of interband electric dipole transitions is referred to as the absorption edge. The most widely used indirect gap materials are the group IV semiconductors Si and Ge. The best known direct gap materials are the III–V's (InSb, GaAs, GaP, etc.), II–VI's (HgTe, CdTe, ZnSe, etc.) and IV–VI's (lead salts PbTe, PnSe, SnTe) and alloy combinations of all these. An important additional effect, which becomes progressively stronger as the energy gap becomes larger in a semiconductor is the Coulomb interaction between the electrons and holes created by interband optical transitions. The electron is raised into an excited state but remains bound in a hydrogen-like orbit

around the positive hole creating a two particle excitation called an exciton. The composite particle can then move throughout the crystal. In an ideal crystal, therefore, the absorption spectrum should consist of a series of discrete lines corresponding to the ground and excited exciton states, followed at somewhat high energies by the continuum associated with interband electronic transitions. The energy levels of the exciton spectrum measured from the beginning of the ionization continuum will be given by the Bohr formula:

$$E_{ex} = \frac{\mu}{\varepsilon^2}\frac{13.6}{n^2}\text{eV} \qquad [21]$$

where μ is the reduced mass given by: $1/\mu = 1/m_e + 1/m_h$ (m_e, m_h are electron and hole effective masses). A schematic diagram of the absorption edge is shown in Figure 4 (dashed line – in the absence of excitons; solid line – in the presence of excitons).

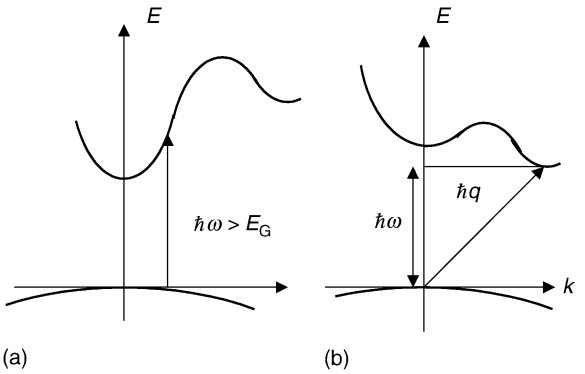

Figure 3 (a) Direct and (b) indirect gap semiconductors. Direct gap transitions involve only the absorption or emission of a single photon and are therefore very nearly 'vertical' transitions in k-space. On the other hand, indirect transitions have a 'two-stage' nature, involving the participation of both a photon and an optical phonon that carries sufficient momentum $\hbar q$ to allow the conduction band electron created in the absorption process to have a large non-zero wavevector.

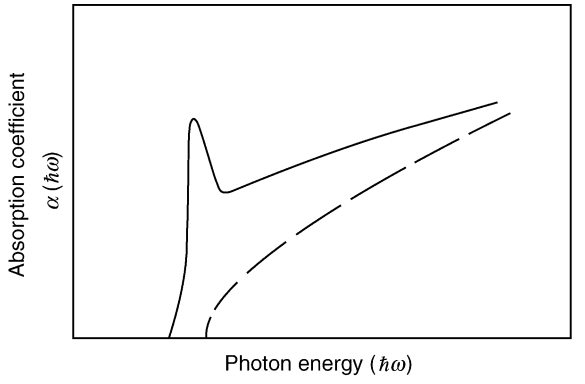

Figure 4 Absorption edge spectra without (dashed curve) and with (solid curve) the excitonic effect.

Conduction and Valence Band Parameters in Typical Semiconductors

As has been described earlier in real semiconductors the conduction and valence bands retain the symmetry of the parent atomic states from which they derive. For example, the conduction and valence bands of silicon can be regarded as deriving from 3s and 3p electrons, and it is generally true that for all group IV, III–V and II–VI semiconductors commonly used in electronic applications the conduction band has s-like symmetry and the valence band has p-like symmetry. This means that the valence band has the additional complication that it is triply degenerate (c.f. the p_x, p_y, p_z components of the hydrogen atom p-orbital); and further, in the presence of spin-orbit coupling (familiar from atomic physics) part of this degeneracy is raised, resulting in doubly degenerate (at $k = 0$) so-called heavy hole (hh) and light hole (lh) bands, and a band split-off by the spin-orbit splitting, Δ:

$$E_{hh} = -\hbar^2k^2/2m_{hh}\ ;\ E_{lh} = -\hbar^2k^2/2m_{lh}\ ;$$
$$E_{so} = -\Delta - \hbar^2k^2/2m_{so} \qquad [22]$$

The resulting conduction and valence bands near $k = 0$ are shown in Figure 5.

Low Dimensional Systems: Quantum Wells

So far we have been concerned almost entirely with the bulk properties of crystalline solids. Such properties can normally be specified in terms of coefficients that are independent of the shape and size of a particular specimen. Thus, for example the electrical

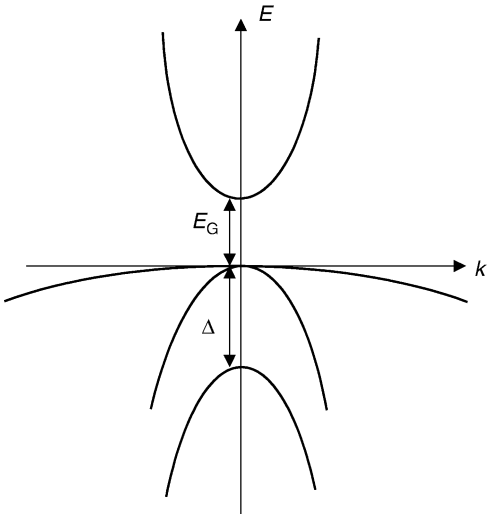

Figure 5 Energy bands (s-like conduction and p-like valence bands) of a direct gap semiconductor near the Brillouin zone center.

conductivity and resistivity, or the optical absorption coefficient and refractive index are properties only of the material and not of the sample dimensions. When one or more dimensions of a solid are reduced sufficiently, the properties are no longer given by these bulk coefficients. The sample is then described as a low-dimensional system (LDS). Such systems form the basis of many optoelectronic devices. LD systems can be classified according to the number of dimensions that are small: thin films (and heterojunctions) are two-dimensional since only the thickness is reduced, and these form so-called quantum wells; fine wires are one-dimensional since two dimensions are reduced, forming quantum wires; dots or specks are zero-dimensional, forming quantum dots.

From an optoelectronic point of view, the most important example is that of electrons confined to a semiconductor film or junction; this system is called the two-dimensional electron gas (2-DEG) and the structure a quantum well. Thus, it is possible to create a narrow electric potential junction region so that the electrons are restricted in 1D (say z) according to the quantum mechanics of a particle in an infinite potential well (described earlier), but 'free' within the xy junction plane.

Introduction

The purpose of this article is to describe the influence of the electronic energy band structure of semiconductors on their optical properties. By the band structure one understands the energy–wavevector dispersion relation $\varepsilon(\mathbf{k})$ for the electron energy bands and the relative positions of band maxima and minima in the Brillouin zone.

The main problem in calculating the band structure of a semiconductor is that of the periodic potential of the lattice in which the electrons move. It is, in fact, a self-consistent problem since the moving electrons partly screen the potential. Different approximations have been developed to deal with the question, and in all of them the symmetry of the lattice is of fundamental importance. Thus, in the so-called empty-lattice approximation one deals exclusively with the symmetry and periodicity of the lattice without specifying the potential. This can give qualitative ordering and symmetry of the bands but no quantitative results. In the opposite limit one uses the tight binding approximation, in which the bands are constructed from the atomic states of separate atoms. This method gives quite a good description of lower (valence) bands but poor results for higher (conduction) bands. A powerful way to describe real energy bands is obtained by various forms of pseudopotential calculation, where one approximates the potential near actual atoms by simple parametrized forms and then adjusts the parameters to fit experimental (mostly optical) data. The pseudopotential methods give a good overall description of various bands in the entire Brillouin zone, but they do not provide sufficiently precise results near the band extrema. A semi-empirical way to serve the latter purpose is called $\mathbf{k}\cdot\mathbf{p}$ theory which we describe below. Various methods of band structure calculation are reviewed in books on solid state physics as outlined in the suggestions for Further Reading at the end of this article.

In the majority of important semiconductor materials (Si, Ge, many III–V and II–VI compounds) the maxima of the valence bands are at the center of the Brillouin zone (Γ point). The minima of the conduction bands in Si and Ge are not at the Γ point. This means that the fundamental optical interband transitions in these materials are indirect (in the ε–$\mathbf{k}$ diagram), i.e., they require phonon assistance. On the other hand, the minima of conduction bands in important III–V and II–VI compounds are at the Γ point, so that the interband optical transitions are direct and they do not require phonon assistance.

Both systems are utilized in opto-electronic devices, particularly for detectors. However, for emitters (light-emitting diodes and lasers) we are mostly concerned with the second case, on which we concentrate here.

Bloch States

The Bloch theorem states that if the potential $V(\mathbf{r})$ in which the electron moves is periodic with the periodicity of the lattice, then the solutions $\Psi(\mathbf{r})$ of the Schrödinger wave equation

$$\left[\frac{\mathbf{p}^2}{2m_0} + V(\mathbf{r})\right]\Psi(\mathbf{r}) = \varepsilon\Psi(\mathbf{r}) \qquad [1]$$

are of the form $\Psi(\mathbf{r}) = \exp(i\mathbf{k}\cdot\mathbf{r})u_k(\mathbf{r})$, where $u_k(\mathbf{r})$ is periodic with the periodicity of the direct lattice, and $\mathbf{k}$ is the wavevector ($\hbar\mathbf{k}$ is the pseudomomentum). The proof of this theorem can be found, for example, in undergraduate textbooks on solid state physics.

k·p Theory

The underlying idea of semi-empirical $\mathbf{k}\cdot\mathbf{p}$ theory is to describe the energy bands in the vicinity of a given point of the Brillouin zone (usually near a band extremum). Symmetry properties are used to minimize the number of unknown band parameters (effective mass, energy gap, etc.) which are then determined by experiment. The initial Schrödinger equation for an electron in the periodic potential $V(\mathbf{r})$ of the crystal lattice reads

$$[\mathbf{p}^2/2m_0 + V(r) + H_{so}]\Psi = \varepsilon\Psi \qquad [2]$$

where m_0 is the free electron mass and H_{so} is the spin–orbit interaction. Since $H_{so}(\mathbf{r})$ is also periodic with the lattice periodicity, the solutions of eqn [2] are given by the Bloch states above.

We use $\mathbf{k}\cdot\mathbf{p}$ perturbation theory, as follows, to describe the energy bands near $\mathbf{k} = 0$ (i.e., the so-called Γ point of the Brillouin zone). Since we are interested in small values of $\mathbf{k}$, we expand our unknown cell periodic functions, $u_{l\mathbf{k}}(\mathbf{r})$, in terms of the set of Γ-point functions, $u_{lo}(\mathbf{r})$, whose symmetry we know. One defines a representation $\Phi_{l\mathbf{k}} = \exp(i\mathbf{k}\cdot\mathbf{r})u_{lo}(\boldsymbol{r})$, where $u_{lo}(\mathbf{r})$ is the periodic $\mathbf{k}$-independent function satisfying the equation

$$[\mathbf{p}^2/2m_0 + V + \mathrm{H_{so}}]u_{lo} = \varepsilon_{lo}u_{lo} \qquad [3]$$

whose solution we know in terms of the band-edge energies, ε_{lo}. This representation is sometimes referred to as the Luttinger and Kohn (LK) representation. The u_{lo} functions are in general mixtures of spin up and spin down states because of the spin–orbit interaction. One looks for the solutions of eqn [2] in the form

$$\Phi_{n\mathbf{k}} = \exp(i\mathbf{k}\cdot\mathbf{r})\sum_l c_l^{(n)}(\mathbf{k})u_{lo}(\mathbf{r}) \qquad [4]$$

where the sum is over all bands and $c_l^{(n)}(\mathbf{k})$ are the coefficients to be determined. Inserting the above form into eqn [2], performing the operation $\mathbf{p}^2$ (i.e., operating twice on the Bloch product function with the operator $\mathrm{p} = -i\hbar\nabla$) and using the property [3] one eliminates the unknown potential $V(\mathbf{r})$. Multiplying the resulting equation from the left by $u_{l'o}^*$, integrating over the unit cell Ω and using the orthonormality of u_{lo}, one finally obtains

$$\sum_l\left[(\varepsilon_{lo} - \varepsilon')\delta_{l'l} + \frac{\hbar}{m_0}\mathbf{k}\cdot\mathbf{p}_{l'l}\right]c_l^{(n)}(\mathbf{k}) = 0 \qquad [5]$$

for $l' = 1, 2, 3, \ldots$ Here $\delta_{l'l}$ is the Kronecker delta function, $\varepsilon' = \varepsilon - \hbar^2k^2/2m_0$, and $\mathbf{p}_{l'l}$ is the so-called matrix element of the momentum given by $\mathbf{p}_{l'l} = (1/\Omega)\int_\Omega u_{l'o}^*\mathbf{p}u_{lo}\,\mathrm{d}\mathbf{r}$. The index l' runs over all energy bands.

Equation [5] formulates the famous $\mathbf{k}\cdot\mathbf{p}$ theory. The nondiagonal part $\mathbf{k}\cdot\mathbf{p}_{l'l}$ can be eliminated by the perturbation procedure, and the method is referred to as $\mathbf{k}\cdot\mathbf{p}$ perturbation theory. In the second order of perturbation the bands are separated and in each band the carriers are described by a dispersion relation $\varepsilon_l = (\hbar^2/2)\mathbf{k}(\widehat{1/m_{lo}^*})\mathbf{k}$ where $(\widehat{1/m_{lo}^*})$ is an inverse effective mass tensor at the band edge in question. The inverse mass is generally a 3×3 tensor, but for cubic materials in the center of the Brillouin zone it is a scalar, so that $\varepsilon_l(\mathrm{k}) = \hbar^2\mathrm{k}^2/2\mathrm{m}_{lo}^*$ (where $1/\mathrm{m}_{lo}^* \equiv 1/\mathrm{m}_0 + (2/\mathrm{m}_0^2)\Sigma_{l\neq l'}(\mathrm{p}_{ll'}^2)/[\varepsilon_{l0} - \varepsilon_{l'0}]$). We then say that the band is spherical and parabolic. The second order of perturbation is a good approximation if the energy ε (as counted from a non-degenerate band edge) is small compared to forbidden energy gaps. For the triply degenerate p-like valence band one has to do degenerate perturbation theory and treat the bands together as a 3×3 matrix equation.

In the same approximation the wavefunction for a given band is: $\Psi_{l\mathbf{k}}(\mathbf{r}) = \exp(i\mathbf{k}\cdot\mathbf{r})\,u_{lo}(\mathbf{r})$. In the absence of spin–orbit coupling, H_{so}, the u_{lo} function would just have the symmetry of the parent band (i.e., labeled S for the s-like conduction band, and X, Y or Z for the triply degenerate p-like valence band – each with a single spin up or spin down component). In the presence of H_{so}, the triply degenerate valence band states become mixtures of X, Y and Z with mixed spin character and part of the degeneracy is raised.

In atomic notation the presence of H_{so} has transformed the basis from the (l,s) to the (J,m_J) representation. This results in the well-known light and heavy hole bands (degenerate at $k=0$) and the spin–orbit split-off band.

Under the influence of a radiation field, of vector potential $\mathbf{A}'$ and frequency ω, the optical transition probability for an electron to be raised from state Ψ_i (initial) to Ψ_f (final) is proportional to the square of $M=(e/mc)\langle\Psi_f|\mathbf{A}'\cdot\mathbf{p}|\Psi_i\rangle$ i.e., it is determined by the same momentum matrix element, p_{fi}, which governs the effective mass. For interband transitions one immediately gets the selection rule $\Delta k=0$ (i.e., direct transitions). The polarization selection rules are determined by the $u_{lo}(r)$ components of the initial and final states, through the momentum matrix elements.

Narrow-Gap Semiconductors

Semiconductors such as InSb and $Hg_{1-x}Cd_xTe$ (with $x<0.3$) have small energy gaps and are referred to as narrow gap semiconductors (NGSs). They are commonly used in opto-electronic applications which may be accessing energies in the conduction or valence band which are a significant fraction of the energy gap. Under these circumstances it is not valid to cut off the expansion to order k^2, and one has to deal with so-called nonparabolic bands. Thus, in NGSs (or indeed in any situation where the energy becomes an appreciable fraction of ε_g) the above procedure is not valid and an alternative approximation is in order. Following semidegenerate perturbation theory one includes exactly in eqn [5] a finite number of bands (near each other in energy) and neglects distant bands. This is referred to as the Kane model, and the energy bands near $k=0$ are shown for InSb-type III–V compounds and for HgTe-type II–VI compounds in Figure 1. In this case we include only the conduction and valence band in our set of states (eqn [5]). Including spin and degeneracy of the Γ_8 symmetry the set [5] then has eight equations. They can be solved analytically and the resulting energies are given by

$$\varepsilon'(\varepsilon'+\varepsilon'_g)(\varepsilon'+\varepsilon'_g+\Delta)-\left(\varepsilon'+\varepsilon'_g+\frac{2\Delta}{3}\right)\kappa^2k^2=0 \quad [6]$$

where $\varepsilon'=\varepsilon-\hbar^2k^2/2m_0$. We see that for this restricted set of states the only unknown parameters are the energy gap, ε_g, the spin–orbit splitting energy, Δ, and $\kappa=-i(\hbar/m_0)\langle S|p_z|Z\rangle$ (note that this is the only non-vanishing matrix element of the momentum). The fourth energy is $\varepsilon'=-\varepsilon_g$. All four energies are spin degenerate. In NGSs one may neglect the free electron term, i.e., set $\varepsilon'\approx\varepsilon$. For $\varepsilon\ll\varepsilon_g+(2/3)\Delta$ the resulting quadratic equation for the conduction and the light-hole bands is

$$\varepsilon(1+\varepsilon/\varepsilon_g)=\hbar^2k^2/2m_0^* \quad [7]$$

where $1/m_0^*=(4\kappa^2/3\hbar^2\varepsilon_g)(\varepsilon_g+2\Delta/3)/(\varepsilon_g+\Delta)$ defines the effective mass at the band edge. The root for the heavy holes is $\varepsilon=-\varepsilon_g$ i.e., this band is not correctly described within the three-level model. The bands given by eqn [6] are spherical but nonparabolic. For $\varepsilon\ll\varepsilon_g$ one recovers the standard dispersion, $\varepsilon=\hbar^2k^2/2m_0^*$.

For HgTe-type materials, setting the zero of energy at the Γ_8 edge and replacing ε_g by $-\varepsilon_0$ (cf. Figure 1), one obtains

$$\varepsilon'(\varepsilon'+\varepsilon_0)(\varepsilon'+\Delta)-\left(\varepsilon'+\frac{2\Delta}{3}\right)\kappa^2k^2=0 \quad [8]$$

For $\varepsilon'\ll(2/3)\Delta$ the dispersion [7] is valid with $1/m_0^*=4\kappa^2/3\hbar^2\varepsilon_0$. In this case the conduction and the heavy hole bands ($\varepsilon\equiv0$) are degenerate at $k=0$, i.e., the thermal gap is zero.

The important property of the above model is that it holds also in the limit of $\varepsilon_g\to0$ (i.e., for mixed $Hg_{1-x}Cd_xTe$ crystals). The effective mass in eqn [7] tends to zero, but the dispersion described by eqn [6] is valid and it gives $\varepsilon=(2/3)\kappa k$, i.e., a linear band.

The electron and hole wavefunctions in NGSs resulting from semidegenerate perturbation theory are given by eqn [4], in which the sum runs over

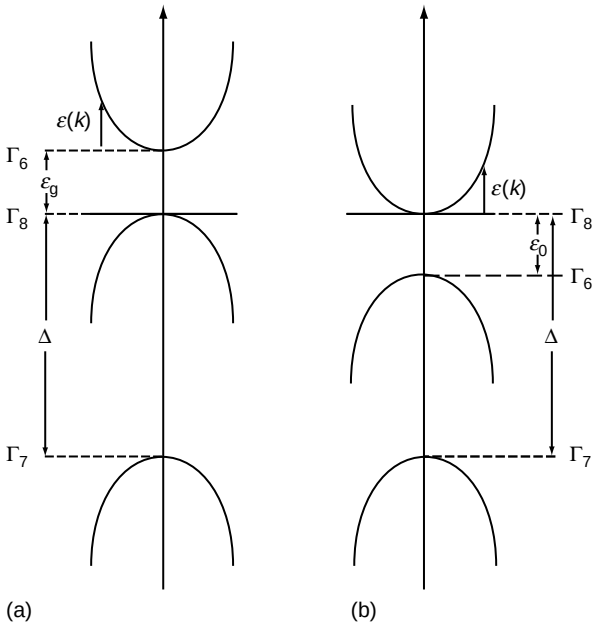

Figure 1 Three-level model of band structure near the Γ point of the Brillouin zone: (a) InSb-type semiconductors; (b) HgTe-type semiconductors.

all the included states. Thus they involve truly **k**-dependent amplitudes of the Bloch states, cf. eqn [1]. In addition, these functions are mixtures of spin-up and spin-down states. These features have important consequences for optical and dc transport phenomena.

If the conduction band minimum is not at the Γ point (Ge and Si), there are at least two different matrix elements of momentum and the resulting band is ellipsoidal.

Effective Mass

The nonparabolic dispersions $\varepsilon(k)$ in NGSs require generalizations of important relations. The momentum mass $\widehat{m}^*$ is introduced as a connection between the psuedomomentum and the velocity: $\hbar\mathbf{k} = \widehat{m}^*\mathbf{v}$. Since $v_i = \delta\varepsilon/\delta(\hbar k_i)$, one obtains for a spherical band

$$\frac{1}{m^*} = \frac{1}{\hbar^2 k}\frac{\mathrm{d}\varepsilon}{\mathrm{d}k} \qquad [9]$$

The above mass is a scalar, but it depends on the energy (or momentum). This mass is more useful than the one usually defined in textbooks, relating force to acceleration. The latter is not a scalar even for a spherical band. However, for the standard parabolic band, $\varepsilon = \hbar^2 k^2/2m_0^*$, both masses are the same and are equal to m_0^*. The mass [9] is related via velocity to the electric current, so that it enters naturally in transport phenomena (also free carrier optics). In particular, this mass enters the definition of mobility $\mu = q\tau/m^*$, where q is the charge and τ is the relaxation time. It enters the density of states (see below). Finally, it is the momentum mass [9] which is measured in cyclotron resonance.

For the dispersion [7] (the so-called two-level model), the mass [9] in the conduction band is

$$m^*(\varepsilon) = m_0^*\left(1 + \frac{2\varepsilon}{\varepsilon_\mathrm{g}}\right) \qquad [10]$$

Again, for $\varepsilon/\varepsilon_\mathrm{g} \ll 1$ the energy dependence of the mass is negligible, which represents the standard regime. Figures 2 and 3 illustrate energy dependences of the electron masses in InSb and HgSe, as measured by various optical and transport methods. The increase of the mass with energy is very strong in both cases.

Density of States

The density of states in energy space is calculated beginning with pseudomomentum space. For the spherical band one obtains

$$\rho(\varepsilon) = \frac{k^2}{\pi^2}\frac{\mathrm{d}k}{\mathrm{d}\varepsilon} = \frac{m^* k}{\pi^2\hbar^2} \qquad [11]$$

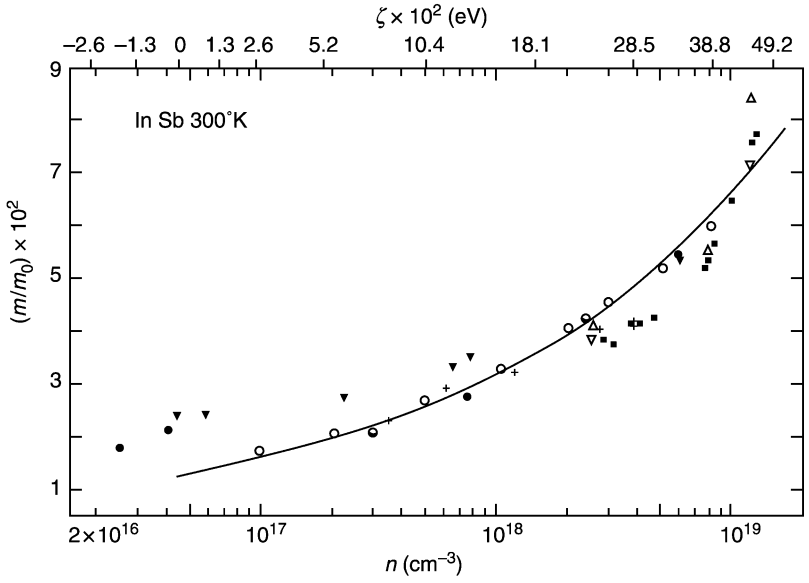

Figure 2 Electron effective mass in InSb at room temperature versus free electron concentration. The solid line, calculated for the two-level model, represents the mass value at the Fermi energy, as indicated on the upper abscissa. The experimental results of various authors are also indicated. Reproduced from Zawadzki W (1974) Electron transport phenomena in Sm all-gap semiconductors. *Advances in Physics* 23: 435–512.

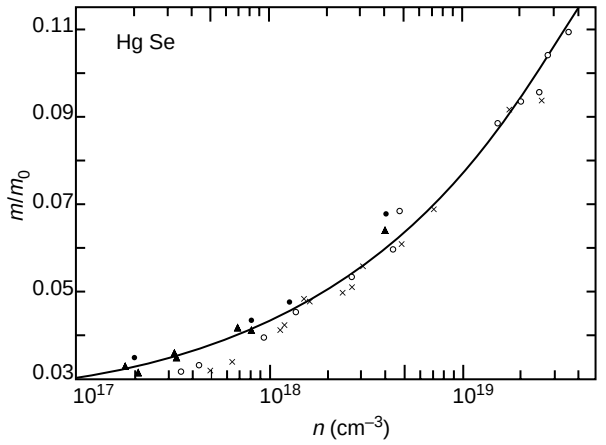

Figure 3 Electron effective mass in zero-gap material HgSe versus free electron concentration. The solid line is calculated for the three-level model. Experimental results of various authors are also indicated. Reproduced from Zawadzki W (1974) Electron transport phenomena in Sm all-gap semiconductors. *Advances in Physics* 23: 435–512.

The momentum mass [9] enters naturally into this important quantity. For the parabolic case $m^* = \text{const.}$ and $k \sim \varepsilon^{1/2}$, so that the standard result is recovered. In the general case one should use eqn [10] for $m^*(\varepsilon)$ and determine k from eqns [6] or [7].

Electron–photon Interaction

The electron–photon interaction can be introduced into the theory on two levels. If one replaces in the initial equation [2] the momentum $\mathbf{p}$ by $\mathbf{p} + (\text{e/c})\mathbf{A}'$, the interaction term is obtained in the scalar form $H_{\text{int}} = (e/m_0 c)\mathbf{A}'\cdot\mathbf{p}$, where $\mathbf{A}'$ is the vector potential of radiation. The wavefunctions to be used for the calculation of matrix elements are of the form [4], i.e., they include the periodic LK amplitudes. In fact, the matrix elements of momentum for optical transitions are identical to those of the $\mathbf{k}\cdot\mathbf{p}$ theory, as pointed out earlier. Since (as noted above) the wavefunctions for all bands have the same form [4], differing only by the coefficients $c_l^{(n)}(\mathbf{k})$, the matrix elements for interband and intraband optical transitions have the same form.

The electron–photon interaction can also be introduced directly to the $\mathbf{k}\cdot\mathbf{p}$ theory of eqn [5] replacing $\hbar\mathbf{k}$ by $\hbar\mathbf{k} + (e/c)\mathbf{A}'$. If the free electron term $\hbar^2k^2/2m_0$ is neglected, the interaction matrix involving $\mathbf{A}'$ terms is a number matrix. In this procedure the wavefunctions for initial and final states are simply columns and rows of $c_l^{(n)}$ coefficients and LK amplitudes no longer come into play. Here the $\mathbf{p}_{l'l}$ elements of $\mathbf{k}\cdot\mathbf{p}$ theory determine directly the electron–photon interaction. Both procedures described above give the same results.

Quantum Wells

If charge carriers are placed in a quantum well described by a potential $U(z)$, the motion in the z-direction is quantized while the motion in the x–y plane remains free. One takes the same LK basis (cf. eqn [3]), but the general form of solution is given by

$$\Psi = \sum_l f_l(\boldsymbol{r})u_{l0}(\boldsymbol{r}) \qquad [12]$$

since, in the presence of an external potential, $\mathbf{k}$ is not a good quantum number and the envelope functions $f_l(\mathbf{r})$ are unknown. If $U(z)$ is a slowly varying function within the unit cell the potential appears only on the diagonal of the set [5] and $\hbar\mathbf{k}$ is replaced by $\mathbf{p}$. One obtains

$$\sum_l \left[\left(\varepsilon_{l0} + \frac{\mathbf{p}^2}{2m_0} + U - \varepsilon\right)\delta_{l'l} + \frac{\mathbf{p}_{l'l}\cdot\mathbf{p}}{m_0}\right] f_l(\mathbf{r}) = 0 \qquad [13]$$

One can now eliminate the nondiagonal terms applying the standard Luttinger and Kohn scheme of second-order perturbation theory and arrive at the decoupled band equations with effective masses. This results in the standard quantization due to electric (and magnetic, if present) fields, and wavefunctions are of the form $\Psi_{lm} = f_m u_{l0}$ for the m-th sub-band of the l-th band.

For NGSs this procedure is a poor approximation and one should proceed as before including exactly a finite number of bands (cf. eqn [12]). This results in a set of coupled differential equations for the envelope functions $f_l(\mathbf{r})$. In some important cases one can find the eigenenergies without finding the functions by using the semiclassical approximation (the so-called WKB method).

We shall omit the calculations with coupled differential equations by using a semiclassical procedure also in another sense. Namely, we shall generalize the nonparabolic dispersion relation [7] to include the presence of external fields. To this end we observe that, including the potential $U(\mathbf{r})$ on the diagonal of eqn [13], one replaces $-\varepsilon$ by $-\varepsilon + U$. Further, if a magnetic field is introduced to the $\mathbf{k}\cdot\mathbf{p}$ theory one replaces $\hbar\mathbf{k}$ by $\mathbf{P} = \mathbf{p} + (e/c)\mathbf{A}$, where $\mathbf{A}$ is the vector potential of the magnetic field. Thus the semiclassical equation resulting from eqn [7] is

$$\left[\frac{\mathbf{p}^2}{2m_0^*} - (\varepsilon - U)\left(1 + \frac{\varepsilon - U}{\varepsilon_{\text{g}}}\right)\right]\Psi = 0 \qquad [14]$$

It can be seen that for $\varepsilon - U \ll \varepsilon_{\text{g}}$ one recovers the standard one-band approximation mentioned above. However, below we consider the general situation described by eqn [14].

Let us first consider the case of no magnetic field, i.e., $\mathbf{P} = \mathbf{p}$. For $U(\mathbf{r}) = U(z)$ one can separate the variables by looking for solutions in the form $\Psi = \exp(ik_x x + ik_y y)\Phi(z)$. One can now transform eqn [14] into

$$\left[\frac{1}{2m_0^*}p_z^2 - \frac{1}{\varepsilon_g}(\varepsilon - \varepsilon_\perp - U)(\varepsilon_g + \varepsilon + \varepsilon_\perp - U)\right]\Phi(z) = 0 \qquad [15]$$

where

$$\varepsilon_\perp = \frac{\varepsilon_g}{2} + \left[\left(\frac{\varepsilon_g}{2}\right)^2 + \varepsilon_g\frac{\hbar^2 k_\perp^2}{2m_0^*}\right]^{1/2} \qquad [16]$$

in which $k_\perp^2 = k_x^2 + k_y^2$. Equation (15) is suitable for the WKB semiclassical quantization with which one determines the eigenenergies ε by one integration.

For a magnetic field applied along the z-direction (parallel electric and magnetic fields) the effects of both fields are separated and the form of eqn [15] is valid, with $\hbar^2 k_\perp^2/2m_0^*$ in eqn [18] replaced by $\hbar\omega_c(n + 1/2) \pm (1/2)|g_0^*|\mu_B B$. Here $\omega_c = eB/m_0^* c$ is the cyclotron frequency, $n = 0, 1, 2, \ldots$ is the Landau quantum number, g_0^* is the spin splitting factor, and μ_B is the Bohr magneton. This results in nonequal spacing of Landau levels for a fixed value of B and in nonlinear B dependence of the Landau energies as functions of B (similarly but not identically to the bulk case). These features are illustrated by the cyclotron resonance experiment and theory shown in Figure 4.

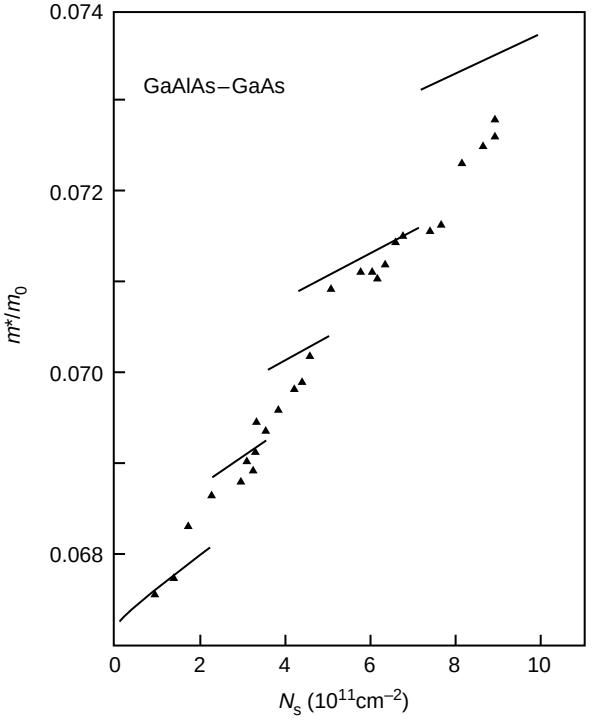

Figure 4 Electron effective mass versus two-dimensional electron density in GaAs/GaAlAs heterostructures, as measured by far infrared cyclotron resonance. The solid lines are calculated using the effective two-level model for GaAs. Reproduced from Zawadzki W, *et al.* (1994) Cyclotron emission study of electron masses in GaAs-GaAlAs heterostructures. *Semiconductor Science and Technology* 9: 320–328.

Selection Rules for Intersub-band Optical Transitions

For the one-band effective mass approximation the electron–photon interaction is $H_{int} \sim \mathbf{A}'\cdot\mathbf{p}$ (cf. above), and the wavefunctions for the initial and final sub-bands are $\Psi_m = \exp(ik_x x + ik_y y)\Phi_m(z)$, in which the $\Phi_m(z)$ must be orthogonal to each other since they describe different energies. It is then clear that the matrix element $\langle fn|\mathbf{A}'\cdot\mathbf{p}|in\rangle$ is finite only if $\mathbf{A}'$ is polarized along the z-direction (also called the growth direction) since for $\mathbf{A}'$ parallel to x or y the integral over z is $\langle\Phi_{m'}|\Phi_m\rangle = 0$ giving a vanishing matrix element. Experimentally this is a serious problem for spectroscopic applications involving intraband (i.e., intersub-band) transitions in n-type semiconductors, since it is not possible to access these using normal incidence radiation.

This selection rule is somewhat relaxed for p-type semiconductors as a result of the mixed spin states of the complex valence band. In addition the narrow-gap band structure introduces interesting new possibilities into the selection rules. The wavefunctions have the form [12] and for the light polarizations A'_x or A'_y the momentum operators p_x or p_y act also on the periodic amplitudes $u_{l0}(\mathbf{r})$, which leads to a nonvanishing transition probability for intersub-band transitions. This has indeed been observed in narrow-gap materials.

In semiconductors electron–hole pairs can lower their energy by correlating their motion in an exciton state. Such states dominate the bandedge optical properties of direct-gap semiconductors. The resultant absorption peaks are affected by quantum confinement, electric, and magnetic fields and carrier scattering.

Introduction

In the simplest, single-particle picture, the ground state of a semiconductor consists of a full valence band and an empty conduction band. The lowest lying excitation above the ground state in such a scheme is produced by excitation of one electron from the valence band to the conduction band. To achieve this optically requires a photon energy greater than the bandgap, E_g. However in many semiconductor materials this simple picture is unable to explain the observed absorption spectrum in the neighborhood of the fundamental bandgap. The origin of the discrepancy lies in the neglect of the Coulomb interaction between the negatively charged excited electron and the hole which is left in the valence band.

The term exciton refers to a two-particle excitation, consisting of a bound electron and hole. Such excitations dominate the bandedge optical spectra of most direct gap semiconductors, especially at low temperatures. In particular there exists a series of hydrogen-like bound states lying below the bandedge. These states are bound by energies

$$E_b^{3D} = \frac{\mu e^4}{8\mathrm{h}^2\varepsilon_r^2\varepsilon_0^2}\frac{1}{n^2} \qquad [1]$$

where $\mu = m_e m_b/(m_e + m_b)$, is the reduced mass, $m_{e(b)}$ the electron (hole) effective mass, e is the electronic charge, h is Planck's constant, ε_0 is the permittivity of free space, ε_r the relative permittivity of the material and $n = 1, 2, 3, \ldots\infty$ is the principal quantum number.

The binding energy of the lowest lying exciton state varies considerably from one semiconductor to another being, e.g., 0.5 meV in InSb and over 60 meV in Zn0. Similarly the spatial extent of the 1 s electron-hole relative wave function or effective Bohr radius is given by

$$a_0^{3D} = \frac{\hbar}{\sqrt{2\mu E_b^{3D}}} \qquad [2]$$

and ranges from 750 μm in InSb to ≈2 nm in Zn0. Typically, in semiconductors the exciton spatial extent is much larger than the lattice constant of around 0.6 nm, and such excitons are classed Wannier excitons. At the opposite limit, which occurs in many molecular materials, the exciton is localized around a particular atomic site and is termed a Frenkel exciton. Wannier excitons are characterized by the hydrogen-like quantum numbers of their relative motion and an overall center of mass momentum which describes the wave-like motion of the bound entity through the crystal.

Another type of exciton is often referred to as a bound exciton. This consists of an electron–hole pair bound to a neutral impurity center. Such excitons are localized around the impurity and cannot move through the crystal in the same way as a free exciton.

Optical Properties

Excitons manifest themselves primarily as strong modifications to the bandedge optical properties of semiconductors. In particular the bound states give rise to discrete absorption lines at lower energy than the bandgap energy. Several peaks corresponding to the different hydrogen-like bound states

(1s, 2s, etc.) can be seen provided the lines are sufficiently narrow. A theoretical calculation of this is shown in Figure 1.

Associated with these absorption changes are concomitant changes in the refractive index. Contributions to the spectral width of the absorption peaks are characterized as either homogeneous or inhomogeneous. Homogeneous broadening refers to broadening associated with the finite lifetime of a particular state, e.g., due to phonon scattering. Inhomogeneous broadening is due to non-uniformity in the system, e.g., in a sample having a spatially non-uniform strain field.

There is also enhancement of the absorption at photon energies above the bandgap due to the residual influence of the Coulomb attraction on the electron-hole scattering states. Although not bound, electrons and holes in these states still have an enhanced probability of being found close together. This is called the Sommerfeld Enhancement Factor (see Figure 1).

It is important to note that although there may be an excitonic peak in the absorption spectrum this does not imply that excitons form a stable population in such a sample. Often, especially at room temperature, the lifetime of an optically generated exciton is determined by the scattering time with optical phonons which may be very short (<1 ps). In this case the excitons are quickly ionized and the quasi-thermal equilibrium which is formed is dominated by essentially plasma-like behavior. In photoluminescence experiments, where carriers are generated high in the band and the spectrum of the resulting emitted luminescence is measured, peaks associated with the free exciton are often observed and taken as a signature of the presence of excitons. This view has been challenged recently by theoretical calculations which show that a photoluminescence peak at the exciton energy can be also be produced from an uncorrelated plasma if proper account of the Coulomb interaction is taken. This issue remains controversial.

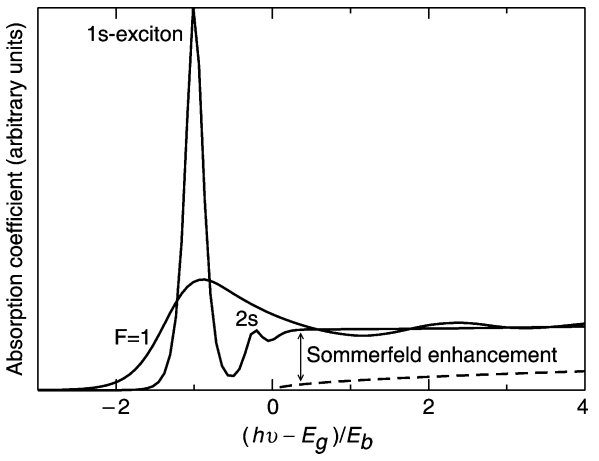

Figure 1 Calculated bulk absorption spectra including (solid-line) and neglecting (dashed line) the Coulomb interaction. The Sommerfeld enhancement is seen as photon energies above the bandgap. Also shown is the spectrum with an applied electric field of one exciton Rydberg per Bohr radius.

In bulk samples, experiments such as absorption and reflectivity are complicated by the existence of polariton effects. An exciton-polariton is a quantum mixture of the propagating photon inside the semiconductor sample and the material excitation. Where the photon dispersion and the exciton energy dispersion meet there is an anti-crossing and this is manifested in, for example, the appearance of two lines in the reflectivity spectrum.

It was hoped during the 1970s that laser action in wide bandgap material such as ZnSe would be possible based on excitonic lasing. In this process a quasi-equilibrium exciton population would form the injected excitation and stimulated recombination would occur with the associated emission of a scattering partner which would take up the necessary momentum to ensure overall momentum conservation. This leads to a light emission wavelength below the absorption edge which is advantageous for minimizing losses. In fact, this process has only been seen at low temperature for scattering with LO-phonons, electrons and other excitons. Each mechanism has its own characteristic lasing threshold and temperature dependence.

Influence of Quantum Confinement

The advent of Molecular Beam Epitaxy enabled the growth of semiconductor layers of thickness similar to the electronic de Broglie wavelength. By sandwiching a low bandgap semiconductor between two high bandgap layers, one can make quantum well structures in which the electronic motion is effectively confined to the plane of the layer. In such structures the excitonic properties are also radically altered by this confinement. An example of the absorption spectrum of a ZnCdSe quantum well embedded in ZnSe is shown in Figure 2. The heavy and light hole excitons correspond to different spin quantum numbers for the electron and hole making up the exciton.

The exciton binding energy is enhanced by a factor of 4 compared to the bulk case and the spatial extent of the 1s wavefunction is also reduced by half:

$$E_b^{2D} = \frac{\mu e^4}{8\mathrm{h}^2\varepsilon_r^2\varepsilon_0^2}\frac{1}{(n-\frac{1}{2})^2} \quad n = 1, 2, 3\ldots \qquad [3]$$

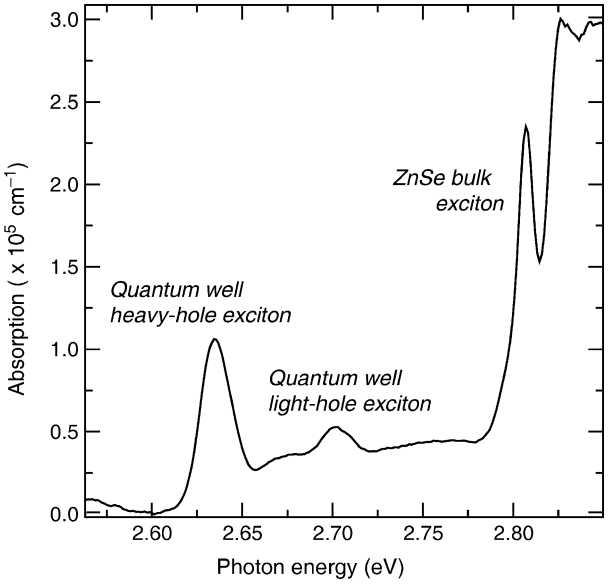

Figure 2 Heavy and light hole exciton absorption spectrum for ZnCdSe quantum wells embedded between ZnSe barriers. Also shown is the bulk exciton of the ZnSe barriers.

This enhancement can be understood since the particles are confined to lie in the plane and are hence closer together on average than in the three-dimensional case. In practice, a four-fold enhancement in the binding energy is never observed since the quantum wells are neither infinitely deep nor infinitely thin. Both these limitations lead to a reduction in the actual enhancement from 4 to about 2, depending on the structure. For example, the binding energy in a realistic quantum well corresponds to the bulk value of the well material for very wide wells and to the bulk value of the barrier material for very narrow wells. In between the value is enhanced by the quantum confinement. The maximum enhancement typically occurs when the well width is around half the bulk Bohr radius for the well material.

Accurate calculation of the exciton binding energy is complicated by the fact that the quantum confinement influences the band structure, making it strongly anisotropic and splitting heavy and light holes. A complete inclusion of these effects is at the limit of current computational power due to the need to calculate the electron-hole interaction matrix elements. Approximate schemes, including variational approaches, have proved successful in fitting a variety of samples, including GaAs and ZnSe based quantum wells. The limitation to such calculations is often the requirement for accurate values of the material parameters such as effective masses and energy band offsets.

The Sommerfeld enhancement of the absorption into the continuum states of quantum wells leads to a doubling of the absorption at the bandedge. This enhancement reduces only slowly as the photon energy is increased.

If multiple quantum wells with very thin barrier layers are used, the electronic states in the neighboring wells couple together to form a superlattice. The superlattice dispersion in the growth direction behaves like a heavy mass and the resulting exciton is three-dimensional but strongly anisotropic.

More extreme quantum confinement is possible making quantum wires, by etching or selective growth of quantum well samples. In these quasi-one dimensional structures, as in quantum wells, the exciton binding energy is again increased further. The Coulomb problem in one-dimension is pathological in that the ground-state binding energy diverges logarithmically, and higher states are pairwise degenerate. However, accounting for the finite cross-section of realistic wires eliminates this problem and recovers a finite binding energy. One consequence of this is that there is no simple enhancement factor which corresponds to the four-fold enhancement in going from bulk to two-dimensional excitons. The density of states in one-dimensional systems diverges at the bandedge, implying the existence of an infinite absorption in a perfect quantum wire. However, the influence of excitonic correlations cancels this divergence, resulting in an enhanced, but not divergent, bandedge absorption feature.

The ultimate limit in quantum confinement can be achieved in quantum dots, where the carriers are confined in all three directions. In this case the term exciton should be used with some care as there are no bandedge states to compare with. The discrete energy levels dictated by the confinement are affected by the Coulomb interaction and the energy is renormalized – in some cases substantially. The absorption spectrum should consist of a series of sharp atomic-like transitions corresponding to s-s, p-p, d-d,... transitions and indeed luminescence spectra obtained from single quantum dots do display such fine structure. Even in the best controlled material systems, such as InAs quantum dots, the spectra are strongly inhomogeneously broadened due to variations in the dot size, shape, and alloy composition.

In large quantum wells, where the width is larger than the exciton Bohr radius the center-of-mass part of the wavefunction can be confined by the barriers. This leads to a quantized motion for the exciton as a whole, rather than for the individual electron and hole separately. One implication of this is that for

such excitons the center-of-mass momentum is no longer a good quantum number.

The above effects are a controlled case of disorder induced effects in semiconductors. This is an area which is only now beginning to be understood. The presence of local potential fluctuations will influence the energy spectrum of excitons in that vicinity. Clearly both the depth and spatial extent of these fluctuations will be important – very short range (less than Bohr radius), shallow potential fluctuations will not have any influence on the exciton. While deep potentials can lead to the center of mass confinement above.

Influence of Electric and Magnetic Fields

Just as an externally applied electric field affects the absorption edge via the Franz–Keldysh Effect, broadening the edge itself and inducing oscillations in the continuum part of the spectrum, so, in the case of an excitonic bandedge, there is substantial modification due to the presence of the field. At low fields, when the Coulomb interaction is strong compared to the potential drop across the exciton diameter, the exciton will be little affected by the applied field. At higher fields the exciton will become gradually more polarized by the field until the exciton is field ionized. This ionization process is manifested in the field broadening of the exciton line (see **Figure 1**).

Of more technological importance is the influence of an electric field applied perpendicular to the plane of a quantum well. The field forces the electron and hole in opposite directions leading to a reduction in the exciton binding energy. This would lead to a blue shift in the exciton absorption peak were it not for an even larger reduction in the single particle electron and hole energy levels within the quantum wells. Overall a strong red-shift of the excitonic absorption peak is observed with increasing field. This is accompanied by a reduction in the oscillator strength due to the reduced electron-hole overlap. This is termed the Quantum Confined Stark Effect and is the basis for the operation of some semiconductor electro-optic modulators. An electric field applied in the plane of the quantum well gives rise to Franz–Keldysh oscillations analogous to the bulk case.

The influence of magnetic fields on excitons is more subtle and richer than the electric field. This is because the magnetic field seeks to induce a circular cyclotron orbit motion on the carriers, but this is influenced by their mutual Coulomb interaction. Two regimes exist where either the cyclotron energy:

$$\hbar\omega_c = \hbar(eB/\mu) \qquad [4]$$

or the exciton binding energy dominates. In the former strong field case, one can treat the Coulomb interaction as a small perturbation on the electron and hole states in the presence of the magnetic field. In exciton states, which have a finite magnetic moment at zero field, we find a linear Zeeman shift in the magneto-exciton energy. In the other case we must use the magnetic field as the perturbation which produces a mixing of the zero-field exciton states. For example, for the ground state the magnetic field induces an admixture of the p-like excited state with the s-like ground state. The total angular momentum of the mixed state is proportional to B and as the energy of a magnetic dipole in a magnetic field is also proportional to B the shift of the magneto-exciton is proportional to B^2. This distinction between linear and quadratic shifts has been used to identify the nature of carrier populations (excitons or unbound free carriers) in a variety of samples. Clearly there exists an intermediate regime where both the magnetic and Coulomb energies are comparable and in this case the precise energy shifts need to be evaluated numerically.

In quantum well samples the orientation of the magnetic field with respect to the confinement direction is crucial in determining the physics. When the field is perpendicular to the confinement plane the cyclotron orbits exist as before and essentially the same phenomenon as in the bulk emerge. For other orientations, the behavior is much more complex and beyond the scope of this article.

Exciton Scattering

An electron and hole in an excitonic bound state execute a correlated motion which can be disturbed by scattering of either partner. This may lead to the ionization of the exciton and the destruction of the correlation or, alternatively, it may change the center of mass momentum of the exciton as a whole. Almost all of the important scattering mechanisms for excitons arise from the charged nature of the electron and hole. Via the Coulomb interaction, excitons can scatter with lattice phonons, other excitons, free carriers, and impurities. Each of these scattering processes has its own regime of dominance, dependent on, for example, temperature or material quality.

When the scattering rate with other particles is much larger than the recombination rate for electrons

and holes, a quasi-equilibrium state is reached. The detailed nature of such an interacting electron/hole plasma remains a a long-standing open question. The reasons for this can be traced to interplay between the intrinsic Coulomb interactions within the plasma, which give rise to both bound and scattering states, and Pauli exclusion arising from the fermionic nature of the electrons and holes. This leads to a complex phase diagram which encompasses, e.g., electron-hole droplets, the ionized electron-hole plasma, biexciton phase, and the exciton gas which, some suggest, may undergo Bose–Einstein condensation. The parameters of this phase diagram are carrier density, temperature, and the semiconductor material parameters. Interest in this essentially fundamental question has remained high, stimulated by the stream of technological benefits that even partial answers have brought.

In this context it is worth mentioning that there have been two theoretical approaches to exciton physics which each have their advantages and problems. One approach is to treat excitons as bosonic quasi-particles and derive results from Hamiltonians formulated using bosonic operators. This approach has the appeal of simplicity and produces acceptable results in the low-density regime. It does, however, omit a key feature of the constituent particles making up an exciton namely the fermionic nature of electrons and holes. A more rigorous approach based around electron and hole operators has been followed but this is considerably more complex and numerically involved.

Excitonic Molecules

Just as two hydrogen atoms can lower their total energy by forming a bound hydrogen molecule, so two excitons can make a bound complex which has lower energy than the two isolated excitons. Such complexes are called biexcitons and are mostly important in high quality material and at low temperatures. Their binding energy is less than that of the exciton by a factor of about 0.1–0.3, depending on the ratio of electron to hole effective masses.

Three particle complexes have also been observed consisting of two electrons bound to a hole. These are termed trions or charged excitons. Their binding energy lies intermediate between excitons and biexcitons.

Introduction

A simple definition of a defect is any feature that disturbs the periodicity of the perfect lattice. This definition is sufficiently broad to encompass a whole range of different entities, which are normally divided into three categories based on their dimensionality, or extent in real space.

0D defects are those which have an extent of the order of only a few atomic spacings at most in any direction. They include all cases where one, or at most a few, atoms are removed or displaced, or are replaced by atoms of a different type.

1D defects are linear features within the crystal that extend over many atomic dimensions. The most

important type of 1D defect is the dislocation and in a single crystal it is possible for a dislocation to extend from one side of the crystal to the other.

2D defects include a variety of different features that occur primarily in one plane. Any junction between two different types of crystal in an epitaxially grown layer (a heterointerface) fits this description, as of course does the sample surface. There are also crystal defects which exist in two dimensions of which the most important is the stacking fault.

Finally, there are also 3D defects. This category includes voids and inclusions, which are both major perturbations in a crystal structure. In most pure crystals grown by modern techniques these are eliminated and they will not be discussed further.

In the sections below the main types of defect will be discussed according to the scheme described above. Despite the substantial research effort to understand the basic properties of many semiconductors, and of course the huge effort devoted to producing semiconductor devices, it remains true that the defect structure of most semiconductors is still poorly understood, with the exceptions of silicon and gallium arsenide. This is especially true in the case of the nitride semiconductors with the wurtzite structure which have recently been the subject of much commercial interest. In the following sections examples will mainly be taken from gallium arsenide.

Lastly, it is important to note that defects of different dimensionality interact. Several possible interactions are discussed in the last section.

0D Defects

Dopants

There are two basic types of 0D defects to consider: chemical defects, or impurities, and native or point defects caused by missing or misplaced atoms. Table 1 gives the major types of 0D defect found in compound semiconductors together with the symbol used in the common notation for point defects and impurities.

Impurity atoms are those which are introduced either accidentally during the production of the bulk crystal or epitaxial layer, or deliberately by the crystal grower in precisely controlled amounts to modify some property of the material. Usually, this means that the material added is a dopant, and has been added to create a surplus of either free electrons or holes in the semiconductor. Typically, the amounts of dopants added are between 10^{-6} and 10^{-3} mole fraction, giving doping levels between $10^{22}\,\mathrm{m}^{-3}$ and $10^{25}\,\mathrm{m}^{-3}$.

Table 1 Impurities and point defects in a compound *AB* with the zincblende lattice structure

Symbol	*Description*
X_A^n, X_B^n	Impurity atom, *X*, on *A* or *B* site with charge *n*
X_i^n	Interstitial impurity atom with charge *n*
V_A^n, V_B^n	Vacancy on *A* or *B* site with charge *n*
A_i^n, B_i^n	Interstitial *A* or *B* atom with charge *n*
A_B, B_A	*A* atom on *B* site or *B* atom on *A* site (antisite)

In general, any atom added to a material will introduce a localized state into the band structure of the semiconductor. This state may rarely occur in either the conduction or valence band, but is more likely to be located in the bandgap. If the localized energy level is within a few kT of the valance or conduction band edge, then the state is an electron acceptor or donor. If it is much further from the band edge then it is usually known as a deep level. In this case its main effect on the electrical properties will be to act as a trap for electrons or holes, and introduce noise into the current flow. Its effect on the optical properties of the material will be to reduce the radiative recombination rate for band-to-band transitions by acting as an alternate recombination pathway for either radiative or nonradiative transitions.

It is generally assumed that dopant atoms occur only on the site of the appropriate sublattice and are well behaved. While it is true that some elements are well behaved substitutional dopants, such as sulfur in gallium arsenide, which can be denoted S_{As}^{+} when acting as a singly charged donor, the behavior of other species is more complex. In many III–V compounds, silicon is an amphoteric dopant, occupying sites on both the metal and nonmetal sublattices which ionize as shown:

$$\mathrm{Si}_{\mathrm{Ga}}^{0} = \mathrm{Si}_{\mathrm{Ga}}^{+} + \mathrm{e}^{-}$$

$$\mathrm{Si}_{\mathrm{As}}^{0} = \mathrm{Si}_{\mathrm{As}}^{-} + \mathrm{h}^{+}$$

In molecular beam epitaxy (MBE) growth on GaAs(100) the ratio between the donor $\mathrm{Si}_{\mathrm{Ga}}^{+}$ and the acceptor $\mathrm{Si}_{\mathrm{As}}^{-}$ varies as the concentration of doping is increased. At low levels silicon is a donor, while at high concentrations the fraction which is an acceptor increases rapidly. The semiconductor is therefore compensated, effectively limiting the maximum concentration of free carriers.

Another type of behavior occurs with beryllium in III–V semiconductors and lithium in II–VI semiconductors. Here, the dopant atom is so small that it can easily be displaced from the lattice site. Thus, for example, in InGaAs, it is energetically favorable for the acceptor $\mathrm{Be}_{\mathrm{In}}^{-}$ atom to move from the lattice site to

an interstitial position:

$$Be_{In}^{-} = V_{In}^{-} + Be_{i}^{+} + e^{-}$$

The interstitial Be ion is a donor and causes some compensation, but even worse, is highly mobile. It can move a substantial fraction of a micron in an epitaxial device and in so doing completely destroys a carefully engineered abrupt p-n junction. It can be seen therefore that dopant interactions with the host lattice are important in determining device performance.

Native Defects

A large variety of native defect species are possible in semiconductors. Interstitial atoms and vacancies are found in both the diamond structure (silicon) and the zincblende structure (most III–V and II–VI semiconductors). In zincblende structures there is also the possibility of placing an atom on the wrong atomic site, or sublattice; for example in GaAs a Ga atom may be found on an As site. This type of defect is known as an antisite.

Bulk semiconductor crystals are grown under conditions close to equilibrium. In the long periods of time needed to grow the crystals, equilibrium concentrations of point defects are established. Epitaxial growth techniques (in particular molecular beam epitaxy, MBE and metalorganic chemical vapor deposition, MOCVD) operate under conditions far from equilibrium and the point defect concentrations may differ markedly from the equilibrium values. Some semiconductor processing operations can also increase point defect concentrations. Etching semiconductors with ion beams or energetic plasmas is a very efficient way of creating in the subsurface region high concentrations of point defects well above the equilibrium values.

It is possible to anneal crystals in the vapor of one of the constituent elements to alter the point defect concentrations. Interstitial and vacancy concentrations can be changed relatively rapidly over the course of several hours (interstitials) or days (vacancies) as these species are much more mobile than dopant atoms. Usually, annealing is done to reduce point defect concentrations, but on occasions, for example with the alloy HgCdTe, it is done to increase the concentration of a type of defect, in this case mercury vacancies which are used to dope the material.

Like dopant atoms, point defects can also introduce defect levels into the band structure of the semiconductor, and some defects, for example the gallium vacancy V_{Ga}^{n-}, exist in multiple charge states. In some materials, the native defects act either as dopants or as compensating traps, and are present in concentrations that can severely limit the maximum obtainable doping levels. The gallium vacancy, for example, is believed to limit the maximum doping level obtainable in n-type GaAs, and its concentration increases dramatically as the concentration of n-type dopant is increased.

It should be noted that the concentrations of the various types of defect are not independent of one another, and at any given growth (or annealing) temperature and applied partial pressures of the constituent elements, the equilibrium concentrations of the defects are fixed. Examples of the interactions between the types of defect may be seen by considering the displacement of a gallium atom from its lattice site to create a vacancy and an interstitial (the Frenkel reaction):

$$Ga_{Ga}^{0} = Ga_{i}^{0} + V_{Ga}^{0}$$

and the interaction of an arsenic interstitial with a gallium vacancy to create an arsenic antisite:

$$As_{i}^{0} + V_{Ga}^{0} = As_{Ga}^{0}$$

The relative importance of the types of defect varies between semiconductors. In compounds where one of the elements is very volatile, then high concentrations of vacancies on that particular sublattice are to be expected. Antisites occur only at very low concentrations in the ionic II–VI compounds, as the energy involved in placing an atom on the wrong sublattice is very high. However, in the more covalent III–V compounds, there is not such a large energy penalty, and it has been suggested that in GaAs the As_{Ga} antisite may be the most common point defect.

In addition to the simple defect types described above, there are other possibilities. One of these is that complexes of defects may form. The best known are the complexes that occur between dopant atoms and vacancies, for example the $[Te_{As}V_{Ga}]^{-}$ complex found in Te doped GaAs (**Figure 1**). In this material, partial compensation of the n-type dopant occurs with the formation of gallium vacancies, as described above:

$$\frac{1}{2}As_2(v) = V_{Ga}^{0} + As_{As}$$

$$V_{Ga}^{0} = V_{Ga}^{2-} + 2h^{+}$$

These vacancies are mobile and diffuse in the material. In the vicinity of Te_{As}^{+} they experience a strong Coulombic attraction and the complex forms when the vacancy and dopant atom are on nearest neighbor sites:

$$V_{Ga}^{2-} + Te_{As}^{+} = [V_{Ga}Te_{As}]^{-}$$

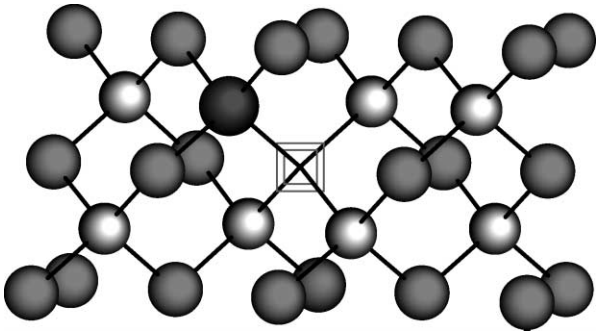

Figure 1 Diagram of the tellurium atom–vacancy complex in GaAs. Gallium and arsenic atoms are shown in mid-gray and white, respectively, while the tellurium atom is shown in dark gray.

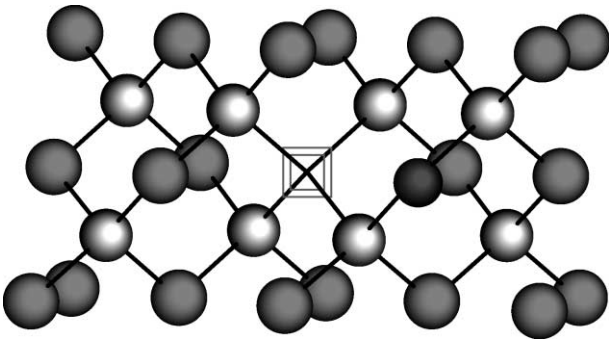

Figure 2 Diagram of the silicon atom–vacancy complex in GaAs. Gallium and arsenic atoms are shown in mid-gray and white, respectively, while the silicon atom is shown in dark gray.

A similar complex also forms in Si doped GaAs: $[Si_{Ga}V_{Ga}]^{-}$ (Figure 2), although here both species exist on the same sublattice, and consequently occur as next nearest neighbors in the complex.

In the description above it is assumed that all atoms which are located on a particular site are centered on that site. However, it is possible for a dopant atom to replace an atom of the host semiconductor, but not occupy the lattice site. *Ab initio* calculations of the bonding around the dopant atom suggest that it can be displaced away from one of its nearest neighbors towards the other three atoms (Figure 3). The dopant can be considered as having one bond weaker than the other three.

In the case of n- and p-type doped semiconductors the corresponding defects are known as DX and AX centers respectively. DX centers occur in many semiconductors but are particularly important in AlGaAs, where Si (or other n-type dopant) atoms form DX centers that partially compensate the material and reduce the electron mobility. However, irradiation with white light excites the DX center and converts it back to a normal dopant centered on the lattice site. In AlGaAs the DX center is the stable

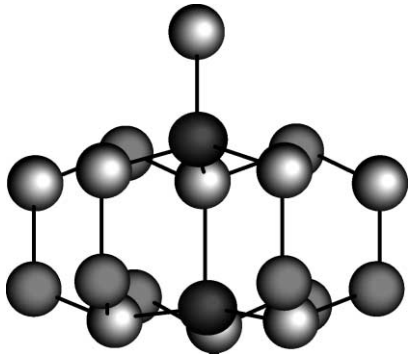

Figure 3 A GaAs crystal shown with [111] oriented vertically. Two Ga atoms have been substituted by silicon atoms which are shown in dark gray. One Si atom is on a substitutional site (top atom) and the other is displaced along [111] away from one of its nearest neighbors (bottom atom). This is one of the structures suggested for the DX center.

species and the dopant atom is a higher energy state. Conversion back to the DX center requires surmounting an energy barrier and thus the normal dopant is metastable. The irradiated semiconductor has a lower concentration of DX and a higher doping concentration than before, and consequently has a higher conductivity than the unirradiated material. This results in persistent photoconductivity in the irradiated material, which is a characteristic feature of semiconductors containing DX centers. At low temperatures, this effect can persist for many hours.

1D Defects

Within any crystal, there must exist a set of planes where the interplanar bonding is weakest. In both the diamond and zincblende crystal structures these are the {111} planes. When a crystal is subjected to a shear stress above its elastic limit, then the material accommodates that stress by changing shape, alternately breaking and reforming bonds across these planes where the bonding is weakest. The resulting movement is easily observable under a microscope in many materials and is known as slip or glide; the planes on which this happens are known as slip or glide planes.

Movement on a slip plane does not happen over the whole crystal at once, and there is always a boundary between the material in which slip has occurred and material where it has not. This boundary is the dislocation. A section through a piece of material where slip has occurred is shown in Figure 4. The curved line DD′ marks the dislocation and slip has occurred in the region marked DQD′. Because it marks a boundary, the dislocation may not end within the crystal and the only permitted ways that a dislocation may terminate are to finish at the surface of

the crystal (as shown) or to meet another dislocation, forming either a closed loop or a junction.

Across the slip plane, the material has moved by a certain amount, which is, typically, a lattice vector within the crystal. The direction of slip is known as the Burgers vector of the dislocation, and it is a constant for any one dislocation. The Burgers vector at any point may be determined by describing a simple loop in the crystal passing through adjacent lattice points lying in one plane. If a dislocation lies within the loop then the ends will not close, and the displacement needed to close the loop is the Burgers vector. This can be seen in Figure 4 on the left-hand face of the crystal around point D, where the Burgers vector is parallel to the line of the dislocation. It can also be seen on the right hand face of the crystal at point D′, where the Burgers vector, which has not changed direction, now lies perpendicular to the dislocation line. Dislocations where the Burgers vector is parallel or perpendicular to the dislocation line are known as screw and edge dislocations, respectively.

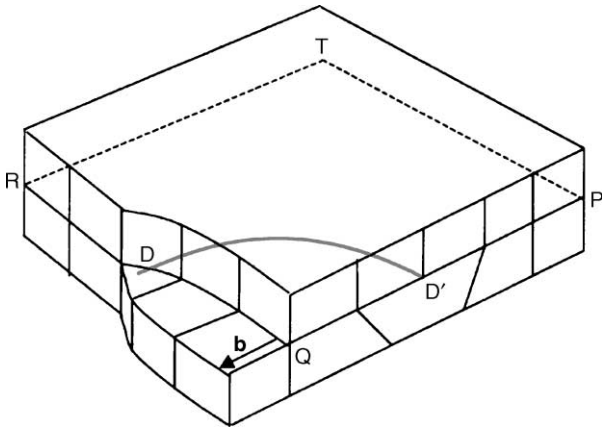

Figure 4 Diagram of a crystal showing a region where slip has occurred. For clarity only the lattice points are shown. The slip plane is PQRT and the slipped region is DQD′. The curve DD′ is the line of the dislocation and has a Burgers vector **b**.

Examples of edge and screw dislocations are shown in Figures 5 and 6, respectively. Edge and screw dislocations are considered to be 'pure' types of dislocations. If the Burgers vector makes any other angle to the dislocation line, the dislocation is referred to as a mixed dislocation. In semiconductors mixed dislocations are the most common type. There are many different ways of describing dislocations; however, the most common one is to give the angle between the dislocation line and the Burgers vector. In this system screw and edge dislocations are referred to as 0° and 90° dislocations.

At the core of the dislocation there is a small region, typically only one or two atoms wide, where the atoms have highly distorted bonding. Around this

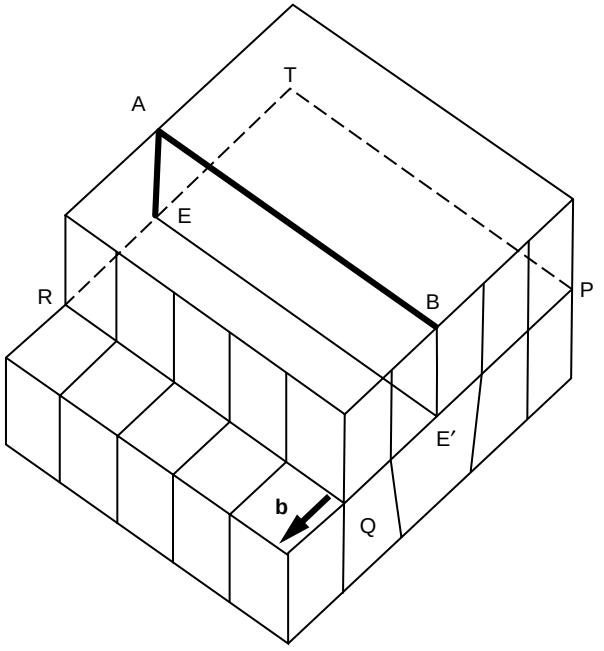

Figure 5 A schematic diagram of an edge dislocation. Only the lattice points are shown for clarity. The slip plane is PQRT and contains the Burgers vector denoted **b**. The line of the edge dislocation is EE′, which can be thought of as terminating a half-plane of atoms denoted ABEE′.

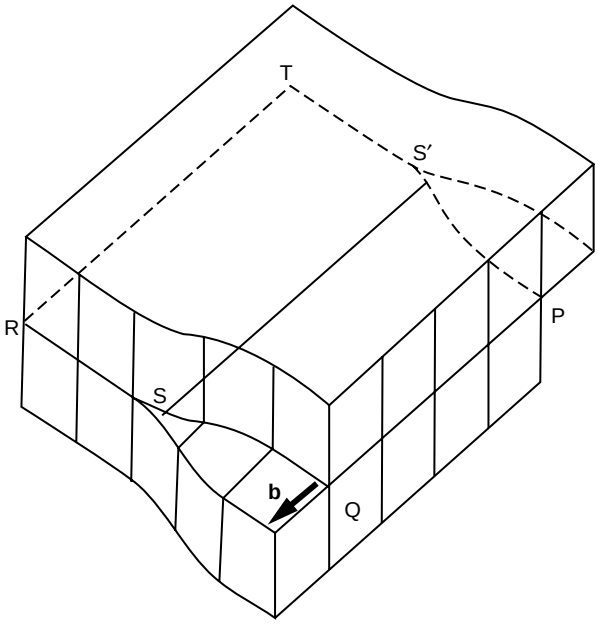

Figure 6 A schematic diagram of a screw dislocation. Only the lattice points are shown for clarity. The slip plane is PQRT and contains the Burgers vector denoted **b**. The line of the screw dislocation is SS′.

core the atoms adopt the normal (tetrahedral) bonding, although they are strained for many nanometers around the dislocation. The strain field around the dislocation means that low dislocation densities are very easy to detect using a technique such as X-ray topography, which images the strain introduced locally in a set of crystal planes by a dislocation. Using this technique, individual dislocations may be determined within crystals. Currently, it is possible to obtain silicon crystals which are essentially dislocation free, while the best GaAs crystals have dislocation densities of $<10^5$–$10^6\,m^{-2}$. In other materials the densities may be 100–1000 times higher.

The highly distorted bonding at the core of the dislocation inhibits dislocation motion. Under the action of an external stress, dislocations normally move on their glide plane to relieve the stress and deform the material plastically. This is dislocation glide. In covalent semiconductors, such movement means breaking and reforming strong bonds, and does not occur in silicon below the crystal growth temperature. Dislocations are also immobile in GaAs at room temperature, although they can be induced to move in softer, more ionic II–VI semiconductors. Dislocation densities are therefore usually considered 'frozen in' at room temperature.

In addition to macroscopic shear forces, each dislocation experiences the stresses introduced by other dislocations and point defects present in the crystal, and is either attracted or repelled by them. At high densities, therefore, the motion of dislocations is inhibited by the presence of the surrounding defects – the dislocations are said to be pinned.

Generation and movement of dislocations occurs in most semiconductors easily at their growth temperature, and is important in the relief of strain introduced in growing a material on a substrate with a different lattice constant. Edge dislocations always introduce, or remove, extra planes of atoms (Figure 5), and so an array of dislocations can add or remove atoms to accommodate the strain between two semiconductor layers of different lattice constant. These are known as mismatch dislocations and they occur frequently in epitaxial growth when strain relief has occurred.

Typically, growth in MBE or MOCVD occurs on the (001) surface. Mismatch dislocations lie on the {111} planes, which intersect this plane, and at low densities occur in crystals regularly spaced along [110] and $[1\bar{1}0]$ directions. The Burgers vectors are also of $\langle 110\rangle$ type and are typically at 60° to the dislocation line. The edge component of this vector, projected on to the (001) plane, gives the amount of strain relief to be expected.

Despite the distorted bonding that exists around the dislocation core, there are thought to be remarkably few broken bonds there. An exception to this is thought to be when the dislocation line is not straight, but kinked, the atoms at the kinks having broken bonds. As a result, nonradiative transitions involving dislocations are not strong. They are important, however, during operation of lasers and LEDs. Dislocations can be seen in electroluminescence of light-emitting devices as dark lines. These so-called dark-line defects (DLDs) are the result of nonradiative recombination occurring at dislocations. Not only do they reduce the efficiency of the device, but the energy released by the recombination of the electron and hole is deposited at the dislocation core as thermal energy. Under these conditions, dislocation movement becomes easy and DLDs propagate, eventually destroying the device.

2D Defects

In a simple description of metallic structures, the hexagonal close packed structure is described as a sequence of hexagonal sheets with the stacking pattern *ABABABAB*..., while that of the face centered cubic structure is *ABCABCA*... In a similar manner, we can describe the wurtzite crystal structure by the stacking sequence *ABABABAB*..., although the layers are no longer close packed and the stacking units comprise one metal and one nonmetal atom. The corresponding stacking sequence for the zincblende structure then becomes *ABCABCA*... These structures are shown in Figures 7a and b, respectively. It can be seen that the two atom units are oriented perpendicular to the stacking sequence, and it is possible to rotate the structure about the vertically oriented bonds between any two given planes. A rotation of 180° would place all the atoms back in registry but on the wrong site. For example, in a zincblende crystal, a rotation after the third layer in the sequence *ABCABCA*... would result in *ABCBCAB*... This means that the top part of the crystal is related to the bottom half by a rotation of 180°, and the two parts are said to be twinned. The twin plane extends throughout the crystal, and is a two-dimensional defect. Both above and below the twin plane, the stacking sequence is the usual *ABC*... found in the zincblende structure; however, at the junction there is a region denoted *BCB*. This region is three planes of the wurtzite stacking sequence, and is an example of what is called a stacking fault. In zincblende crystals, stacking faults introduce small regions of the wurtzite structure, while the reverse happens in wurtzite crystals.

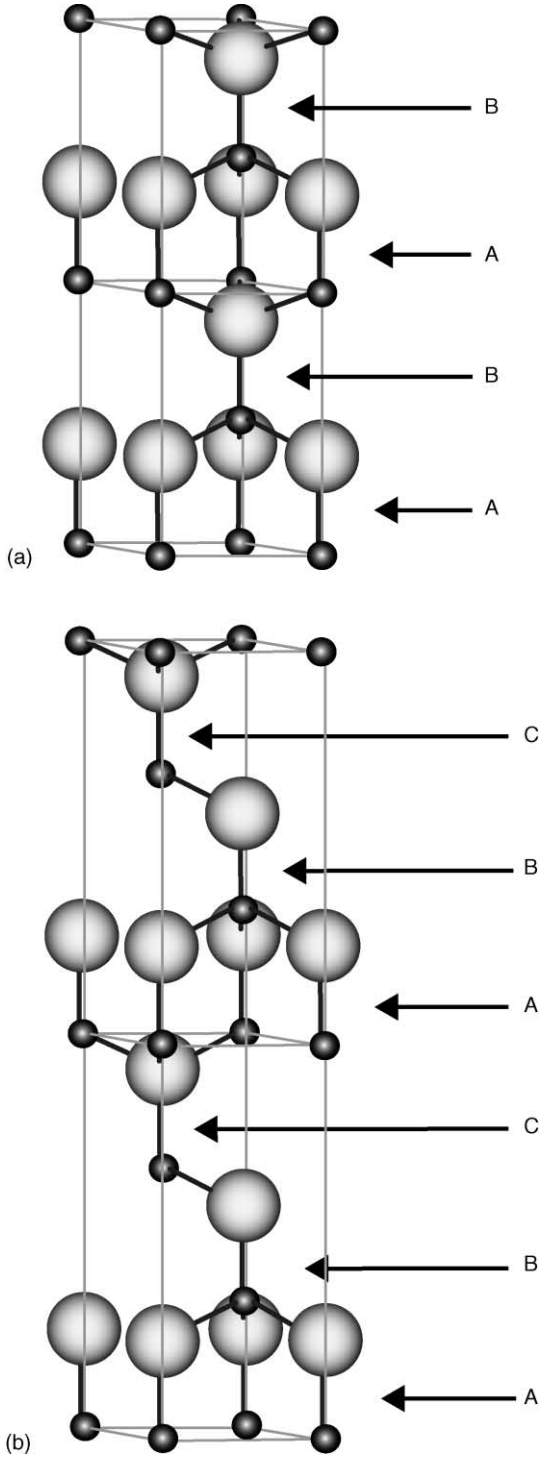

Figure 7 Diagrams of the stacking sequence of layers for two different semiconductor structures. In both cases the metal atoms are small and dark while the larger pale ones are the nonmetal atoms. The structures are: (a). The wurtzite crystal structure. The atoms which occupy the A, B and C sites are marked. Here the vertical direction in which the planes stack is the [0001] direction. (b). The zincblende crystal structure. The atoms which occupy the A and B sites are marked and the vertical direction corresponds to one of the ⟨111⟩ directions in the crystal.

The density of stacking faults in a material is primarily a function of the ease of placing the crystal planes in the wrong order. Under nonequilibrium growth conditions, this can occur easily for many different materials, but for slow growth near equilibrium, the prevalence of stacking faults is governed by the stacking fault energy. This is a measure of the wrong stacking sequence occurring and is also related to the energy of transformation between the zincblende and wurtzite crystal structures. For GaAs, the energy is high and stacking faults are rare, while for II–VI semiconductors the stacking fault energies are low and stacking faults are relatively common.

Typically, stacking faults are observed in TEM planar view micrographs, and on (001) oriented epitaxial samples are clearly visible as triangular regions lying on {111} planes, as described above, nucleated at the interface between the substrate and epitaxial layer.

While stacking faults are accidental introductions in a crystal structure, other 2D defects are introduced deliberately. Heterojunctions between different semiconductor alloys are an obvious example and are responsible for most of the useful properties of advanced semiconductor devices. However, by far the most important 2D crystal defect is the surface of the crystal. This creates a high density of broken bonds, each of which can introduce a defect level in the band structure. Surfaces usually lower their free energy by moving atoms from the bulk equilibrium positions to new sites and forming extra bonds in the plane of the surface. This removes some of the defect levels, but it is still possible to have surface defect densities as large as $10^{18}\,\mathrm{m}^{-2}$ which are associated with enhanced rates of nonradiative recombination of electrons and holes.

Interactions of Defects

Earlier it was assumed that the Burgers vector associated with a dislocation is a lattice vector. The energy of a dislocation per unit length is proportional to the magnitude of the Burgers vector squared:

$$E \propto b^2$$

In some crystals, however, it is possible for the displacement to be composed of two smaller steps, neither of which is a complete lattice vector:

$$\mathbf{b} = \mathbf{b}_1 + \mathbf{b}_2$$

where $\mathbf{b}$ is a lattice vector and $\mathbf{b}_1$ and $\mathbf{b}_2$ are the smaller displacements. In this case, the total energy

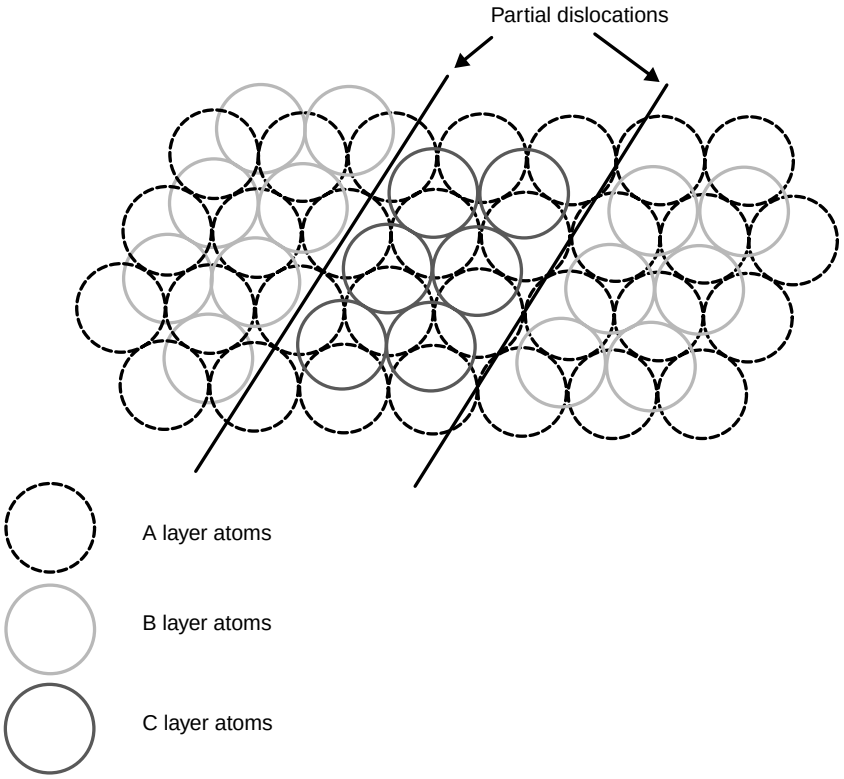

Figure 8 An example of a close packed structure where a region with a stacking fault lies between two partial dislocations.

can be reduced if the dislocation splits into two:

$$E_1 + E_2 \propto b_1^2 + b_2^2 < E$$

These dislocations are known as *partial* dislocations. A normal dislocation splits into two partial dislocations if it is energetically favorable to do so. Figure 8 shows an example in a close packed structure, which illustrates the point without the problem of introducing two different types of atoms. Two partial dislocations run through the top layer. The material lying between them has a different stacking sequence (AC) from the material around it (AB) and must contain a stacking fault. This shows that a 2D defect, such as a stacking fault, is bounded by two 1D defects, in this case partial dislocations.

There also exists an intimate relationship between point defects and dislocations, which may be seen by examining the edge dislocation shown in Figure 5. The edge dislocation may be considered as an extra half-plane of atoms, ABEE′ which terminates along line EE′. The last row of atoms in the plane can be removed from the sheet by one of two processes. Firstly, the atoms at the dislocation core can become interstitials and diffuse away from the dislocation. Alternatively, vacancies can diffuse towards the dislocation. In either case the result is the same; the dislocation line EE′ moves upwards towards AB. The opposite sequence of events (diffusion of interstitials towards the dislocation or vacancies away from it) is also possible and results in a movement of line EE′ downwards. Such processes are known as dislocation climb. Climb is not as common as glide, but it is important as the dislocation acts as a source or sink for point defects. This process contributes to the reduction in radiative efficiency in LEDs and lasers, particularly as the devices age.

Introduction

The vibrations of atoms in solids were first studied theoretically at the beginning of the twentieth century to explain the observed temperature dependence of the heat capacity. Following earlier work by Einstein and Debye, Born and von Karman showed in 1912 that the vibrational properties of a linear chain of alternate light and heavy atoms connected by springs account very well for the observed thermal behavior of solids. It was shown many years later that, if the atoms are alternately positively and negatively charged, the model also gives a good description of the optical properties.

In this article the vibrational properties of a linear diatomic chain of atoms are first described. The model gives a good description of the basic vibrational properties of solids with two atoms per unit cell, such as Si, Ge, and the binary III–V (e.g., GaAs) and II–VI (e.g. CdTe) semiconductors, and explains the origin of optic and acoustic branches of the phonon dispersion curves. This leads naturally to an understanding of the basic far-infrared reflectivity of binary semiconductors. The model is then further developed to account for the effects of impurities and the optical properties of alloys.

The far-infrared properties of semiconductors are then reviewed. We begin with the group IV semiconductors Si and Ge in which there is no first-order interaction with infrared radiation, and explain the origins of second-order interactions, and the effects of disorder and impurities. Examples of the first-order reflection spectra of bulk single crystal binary semiconductors and their alloys are then presented. Localized vibrational modes and phonon combination bands are discussed next. We finish with a brief review of more exotic excitations that occur in layered semiconductors: confined optic modes, surface phonon polaritons, guided waves, and interface modes.

Background Theory of Phonons in Semiconductor Materials

Phonons in a Diatomic Linear Chain Lattice

Consider a line of atoms of alternating type A and B, separated by a distance a, as shown in Figure 1. Suppose that the nth A atom is displaced by a small amount $u_{A,n}$ from its equilibrium position. The forces attempting to return it to its equilibrium position will be proportional to the distance it has moved relative to the neighboring atoms. If we assume that the only significant force involves the nearest neighbor B atoms n and $n+1$, the equation of motion for the nth A atom is

$$M_A \frac{d^2 u_{A,n}}{dt^2} = C(u_{B,n} + u_{B,n+1} - 2u_{A,n}) \qquad [1]$$

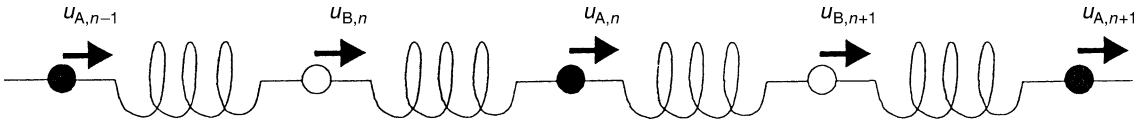

Figure 1 Atomic displacements in a diatomic linear chain.

where M_A is the mass of the atom, and C is the Hooke's law nearest-neighbor force constant. There is a similar equation

$$M_B \frac{d^2 u_{B,n}}{dt^2} = C(u_{A,n-1} + u_{A,n} - 2u_{B,n}) \qquad [2]$$

for the motion of the nth B atom. We assume that the solution of the equations of motion has the wavelike form

$$u_{A,n} = U_A \exp\{i(qan - \omega t\} \qquad u_{B,n} = U_B \exp\{i(qan - \omega t\} \qquad [3]$$

in which U_A and U_B are amplitude factors, ω is the angular frequency, and q is the wavevector, so that qa is the phase factor by which the phase of the wave changes from one site n to the next site $n+1$. The equations of motion are satisfied so long as the angular frequency ω is given by

$$\omega^2 = \frac{C}{M_A M_B}\left[M_A + M_B \pm \sqrt{(M_A + M_B)^2 - 4M_A M_B \sin^2(qa/2)}\right] \qquad [4]$$

There are two possible solutions here because there are two ions in the unit cell. A plot of ω as a function of q is shown in Figure 2a, with q in the range $-\pi/a$ to $+\pi/a$. In the lower branch, the *acoustic* phonon branch, the vibrations at long wavelength (equivalent to small q) are essentially the same as ordinary sound waves. The A and B atoms vibrate in phase, and at long wavelength there is a linear relation between ω and q:

$$\omega \approx v_s q \qquad [5]$$

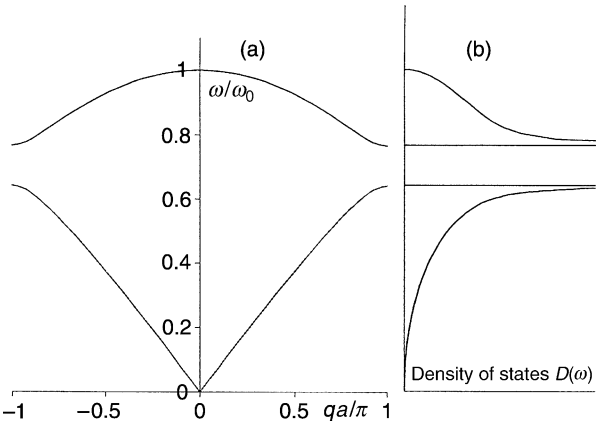

Figure 2 (a) Phonon frequency ω versus wavevector, q, in a one-dimensional diatomic lattice; (b) three-dimensional density of states $D(\omega)$.

where $v_s = \omega_0 a/2$ is the velocity of sound of the acoustic phonons.

The upper branch in Figure 2a, which is of more interest in the present context, is called the *optic* phonon branch. Here the A and B atoms vibrate in antiphase, and because the A and B atoms have equal but opposite charges there is an electric field associated with the vibration. The optic phonon vibrations will consequently affect the propagation of electromagnetic waves through the medium – hence the name – although the vibration frequencies (around 10 THz) are in the far infrared rather than the visible part of the electromagnetic spectrum. At this frequency, the infrared wavelength λ is about 30 μm. The propagation of the infrared will be affected only by phonons whose wavevector q matches the infrared wavevector $k = 2\pi/\lambda$. Since λ is around 10^4 times larger than the typical lattice spacing a in semiconductor materials, it follows that the optical properties of the material may be largely understood merely by considering the long-wavelength phonons with wavevector $q \approx 0$. Thus, in the diatomic case, only the optic phonon of wavevector $q \approx 0$ and frequency

$$\omega_0 = \sqrt{\frac{2C(M_A + M_B)}{M_A M_B}} \qquad [6]$$

is of importance to the propagation of electromagnetic radiation.

Many semiconductor materials are of the diatomic AB type – for example group III–V materials such as GaAs, and II–VI semiconductors such as CdTe. Their phonons are described in detail by three-dimensional versions of the simple linear chain model discussed above. The most basic semiconductor materials, Si and Ge, are clearly monatomic, but their crystal structure is identical to the zincblende structure of GaAs, and they show two phonon bands as in Figure 2a. However, because there is only one type of atom, these materials differ from the diatomic materials in that the optic phonon branch has no electric dipole moment. In Si and Ge, there is no dielectric anomaly around the frequency ω_0 of the type discussed in the following section. In these materials, the only significant optic effects occur when phonons combine in pairs with equal but opposite wavevector q, so that the resultant has very small wavevector that can match the infrared wavevector $k = 2\pi/\lambda$. The significant factor here is the density of states $D(\omega)$, representing the number of phonon states per unit frequency range. In Figure 2b, we show $D(\omega)$ for the diatomic lattice. This is

obtained as

$$D(\omega) = D(q)\frac{\mathrm{d}q}{\mathrm{d}\omega} \qquad [7]$$

where $D(q)$ is the density of states with respect to the wavevector, which is proportional to q^2 for a three-dimensional lattice. Note that $D(\omega)$ has peaks at frequencies corresponding to the zone boundary phonon frequencies because the dispersion curves are flat in these regions. These features are known as critical points, and they have well-defined shapes. Their spectroscopic importance is discussed later.

In bulk three-dimensional crystals, both transverse and longitudinal optic and acoustic phonons occur, each represented by different branches of the phonon dispersion curves, and the transverse branches in cubic materials are doubly degenerate. In three dimensions, more elaborate theoretical models are required, such as the rigid ion model and the shell model, and improved results can sometimes be achieved by including next-nearest-neighbor atoms in the model. As an example, the phonon dispersion curves of GaAs are shown in Figure 3.

It should be noted that the dispersion curves, and hence the associated optical properties, differ for propagation in different crystallographic directions, e.g., [100], [110], and [111].

Born–Huang Optic Phonon Model

The infrared lattice properties of materials at long wavelength are usually described by using the relative permittivity ε (often called the 'dielectric constant'), which is defined through the relation

$$D = \varepsilon\varepsilon_0 E \qquad [8]$$

between the electric field E in a medium and the displacement field D (here, ε_0 is the permittivity of free space). D is the sum of the field E and the polarization P of the medium:

$$D = P + \varepsilon_0 E \qquad [9]$$

P has contributions from lattice displacements (phonons), free electrons (plasmons), and the basic atomic polarizabilities. Since these quantities depend on frequency, ε is also a function $\varepsilon(\omega)$ of angular frequency ω. The charges of the A and B sites are taken as $+Q$ and $-Q$ respectively, and their equations of motion [1] and [2] are extended to include the electric forces $\pm EQ$. As a result of these considerations, the dielectric function can be written in the form

$$\varepsilon(\omega) = \varepsilon_\infty\left[1 + \frac{\omega_\mathrm{L}^2 - \omega_\mathrm{T}^2}{\omega_\mathrm{T}^2 - \omega^2}\right] = \varepsilon_\infty\frac{\omega_\mathrm{L}^2 - \omega^2}{\omega_\mathrm{T}^2 - \omega^2} \qquad [10]$$

Here, ε_∞ is the high-frequency dielectric constant due to the atomic polarizabilities, and ω_L and ω_T are frequencies that are close to the natural vibrational frequency ω_0 that occurs in the absence of electric field effects; the difference $(\omega_\mathrm{L}^2 - \omega_\mathrm{T}^2)$ is of order $\omega_0^2 Q^2/(Ca^3\varepsilon_0)$.

Figure 4 shows a plot of $\varepsilon(\omega)$ as a function of ω. Note that $\varepsilon(\omega)$ diverges at $\omega = \omega_\mathrm{T}$, and that $\omega = 0$ at $\omega = \omega_\mathrm{L}$ ($\omega_\mathrm{L}/\omega_\mathrm{T} = 1.25$ in Figure 4). ω_T is called the transverse optic (TO) phonon frequency: it is the resonance frequency of propagation of transverse

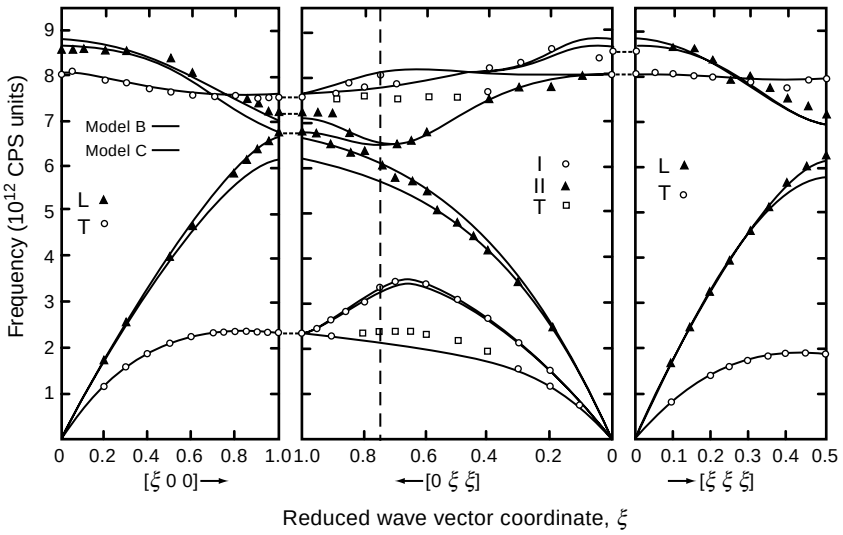

Figure 3 Phonon dispersion curves of GaAs determined by neutron spectrometry (points) compared with calculation (dotted and solid lines). Reproduced with permission from Waugh JLT and Dolling G (1963) Crystal dynamics of gallium arsenide. *Physical Review* 132: 2410.

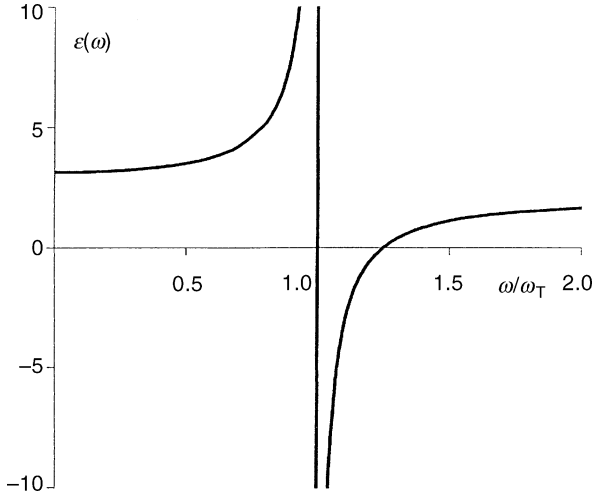

Figure 4 Dielectric function $\varepsilon(\omega)$ as a function of angular frequency, ω.

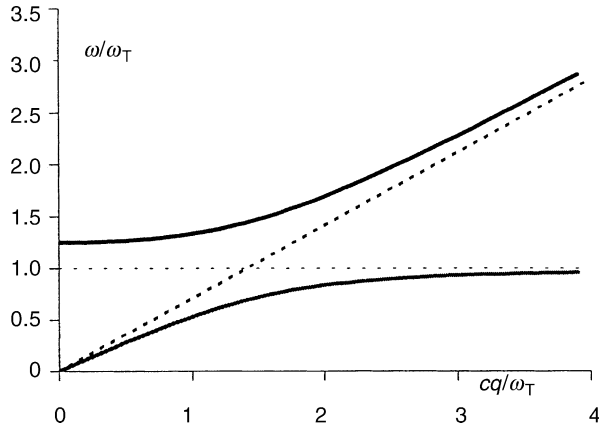

Figure 5 The dispersion curves for phonon polariton modes (solid lines) for a diatomic linear chain of atoms showing the gap in bulk phonon modes between the frequencies ω_T and ω_L.

electromagnetic waves in the material. ω_L is called the longitudinal optic (LO) phonon frequency: it is the frequency of the longitudinal electrostatic wave. Physically, the dielectric constant determines the velocity v of propagation of electromagnetic waves in the material

$$v^2 = \frac{\omega^2}{q^2} = \frac{c^2}{\varepsilon(\omega)} \qquad [11]$$

where c is the velocity of light. Equation [11] has two solutions for ω as a function of wavevector: the two solutions are shown in Figure 5. Note that there is no solution with ω in the range between ω_T and ω_L. The excitations in the region where the graphs are curved are called 'polaritons' – a combination of polar phonon and photon.

The refractive index n of the material is the ratio of v, the velocity of light in the medium, to c, the

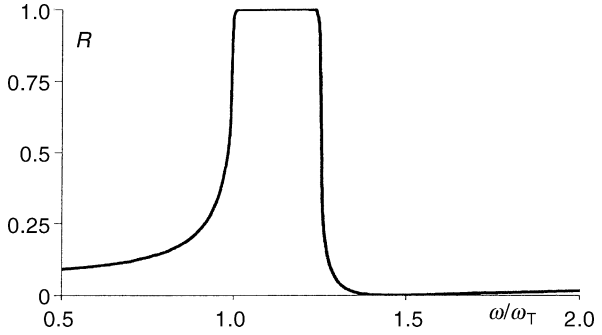

Figure 6 Calculated reflectivity plotted versus angular frequency for a diatomic linear chain of atoms for the case of zero damping.

velocity in free space; thus $n = \sqrt{\varepsilon}$. n is often found from a measurement of the optical reflectivity R. At normal incidence

$$R = \left|\frac{1-n}{1+n}\right|^2 \qquad [12]$$

A graph of R is shown in Figure 6; note that the reflectivity is 100% for ω in the range $\omega_T < \omega < \omega_L$.

Impurity Phonon Modes

Impurity atoms in crystal lattices can significantly affect the infrared properties. The simplest case is when an impurity atom has the same binding but a different mass. Consider the monatomic, one-dimensional case, in which the impurity atom has a mass $M + \delta M$, where M is the normal mass. Let the impurity be at the site $n = 0$. The equations of motion are

$$-M\omega^2 u_n = C(u_{n-1} + u_{n+1} - 2u_n) \quad \text{for } n \neq 0$$

$$-(M+\delta M)\omega^2 u_0 = C(u_{-1} + u_1 - 2u_0) \quad \text{for } n = 0 \qquad [13]$$

These equations have a solution provided that ω satisfies the equation

$$N^{-1}\frac{\delta M}{M}\sum_q \frac{\omega^2}{\omega_q^2 - \omega^2} = 1 \qquad [14]$$

where N is the number of atoms in the linear chain, and ω_q the unperturbed normal mode frequencies. This equation has solutions ω that lie close to the bulk phonon frequencies ω_q. However, if $\delta M < 0$ (i.e. the impurity atom is lighter than the bulk atoms), one additional mode is possible at a frequency ω that is higher than the maximum frequency $\omega_0 = \sqrt{C/M}$ of the bulk phonons. This is the so-called impurity or localized vibrational mode (LVM – see Figure 7).

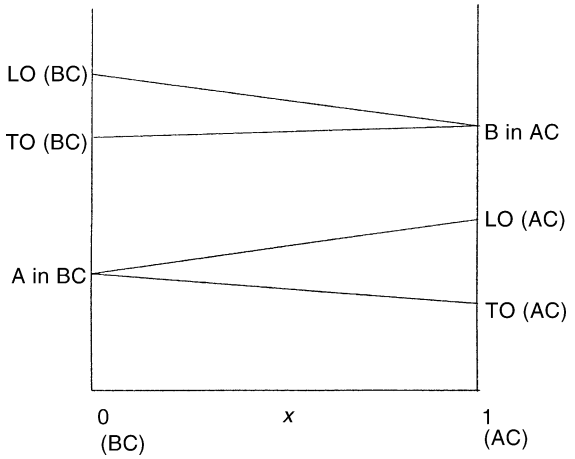

Figure 7 Representation of TO and LO phonon frequencies in a mixed crystal $A_xB_{1-x}C$ plotted versus composition x.

The impurity atom, being lighter than the material atoms, vibrates at a higher frequency than the bulk frequencies; the amplitude of the vibration is greatest at the impurity site, and decreases the further away one goes from the impurity site. If the impurity atom is heavier than the bulk atoms ($\delta M > 0$), there is no distinguishable local mode. In the case of diatomic lattices, an analogous situation pertains: if the impurity is lighter than the bulk atoms, an impurity mode is distinguishable above the top of the optic phonon band; if the impurity is heavier, there is the possibility that a distinct impurity mode may appear in the gap between the acoustic and optic phonon branches.

Mixed Crystals

Mixed compound semiconductor crystals are in widespread use because the bandgap can be adjusted by varying the composition. For example, the ternary material $A_xB_{1-x}C$ is an alloy of a fraction x of the material AC with a fraction $1 - x$ of the material BC. A typical example is $Al_xGa_{1-x}As$. The infrared lattice properties of these materials are classified as 'one-mode' or 'two-mode' depending on how many distinct optic phonon frequencies are observed. The distinction can easily be understood in the context of the discussion above of impurity modes. If an A atom in the bulk material BC has a distinct local impurity optic phonon mode frequency, and similarly for a B impurity in AC, then there will usually be two distinct optic phonon modes throughout the whole composition range $0 < x < 1$: one mode is AC-like, and the other BC-like, as shown in Figure 7. On the other hand, if neither A in BC, nor B in AC, provide distinct optic phonons, there is only one distinguishable optic phonon in the alloy $A_xB_{1-x}C$.

Review of Far-Infrared Properties of Semiconductors

Group IV Semiconductors

We begin with Si and Ge, both of which crystallize in the diamond structure. As mentioned earlier, there is no first-order interaction between far infrared radiation and the TO mode. However, there are several other mechanisms that result in absorption. The dipole moment of the zone center TO phonon in an ionic solid is an example of a symmetry property that, in group theory, is described by a set of selection rules for each different crystal lattice. Other mechanisms that can lead to the creation of a dipole moment are:

Disorder

Disorder destroys the translational symmetry, and hence the selection rules. Consequently, phonon modes that, in a perfect lattice, are not infrared active will become active. The most general case occurs if the crystal becomes completely disordered, in which case all phonon modes become dipole-active and the far-infrared absorption spectrum resembles the phonon density of states. This is illustrated in Figure 8, in

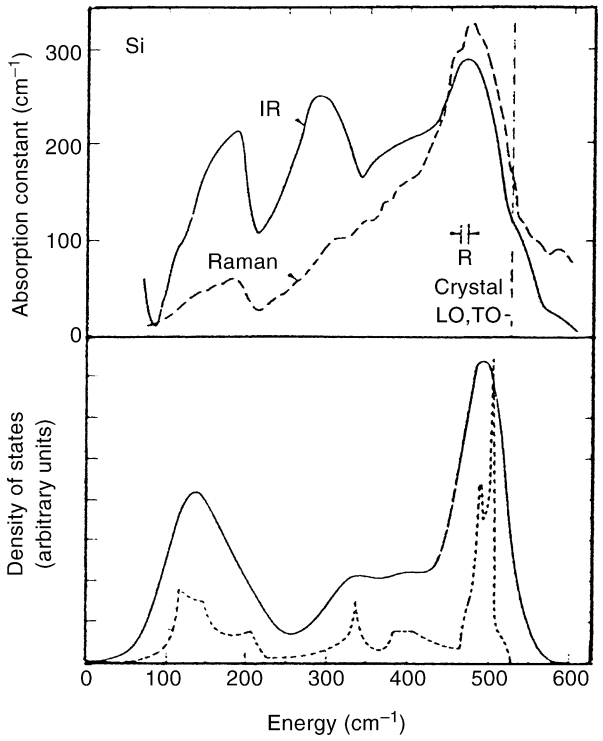

Figure 8 Top: infrared absorption coefficient (solid line) and Raman spectrum (dashed line) of amorphous Si. Bottom: calculated density of states (solid line), and broadened density of states (dashed line). Reproduced with permission from Bradskyn H and Lunio (1974) Infrared vibrational spectra of amorphous Si and Ge. *Physical Review B* 9: 1646, ADS.

which measured infrared and Raman spectra of amorphous Si are compared with the calculated one-phonon density of states.

Phonon combination bands

A combination of the lattice distortions due to two phonons excited simultaneously can produce a resultant displacement of the ions in the lattice with a dipole moment. Such phonon combinations can be excited simultaneously by a far-infrared photon, and they are observed as weak bands in the infrared absorption spectrum. Apart from the dipole moment selection rule, it is also necessary for wavevector conservation to occur. Since $q \sim 0$ for the photon, the two phonons must either be at the zone center, or have equal and opposite wavevectors. An additional consideration is that, if the process is to lead to observable absorption, it should have a high probability as determined by the density of states, so observable absorption features usually arise from critical-point phonon combinations. An example of phonon combination bands in Si is shown in Figure 9. Assignment of the features in the spectrum is usually possible by inspection of the phonon dispersion curves at the zone boundaries, a procedure known as critical-point analysis. Alternatively, the two-phonon density of states can be calculated, taking into account the selection rules, and then compared with the measured spectrum. Similar considerations apply to higher-order phonon combination bands, e.g., three or four phonons, etc., but the strength of the combination bands usually decreases rapidly as the order of interaction increases.

The presence of impurities

As mentioned above, dipole-active localized vibrational modes (LVMs) can occur if the sample is doped with lighter elements as this destroys the local translational symmetry. For instance, an LVM occurs if Si is doped with B, as shown in Figure 10. The LVM frequency is proportional to the ratio $(C/M)^{1/2}$ as seen earlier where C is the force constant and M is the isotopic mass of the substituted atom. As such modes have narrow linewidths, the features in the spectrum due to different isotopes of the same element are easily distinguished, as shown in Figure 10.

Group III–V and II–VI Semiconductors: Bulk Crystals

The group III–V and group II–VI semiconductors crystallize in either the cubic (zincblende) structure, or the hexagonal (wurtzite) structure. Many mixed crystal materials, such as $Al_xGa_{1-x}As$, are grown for

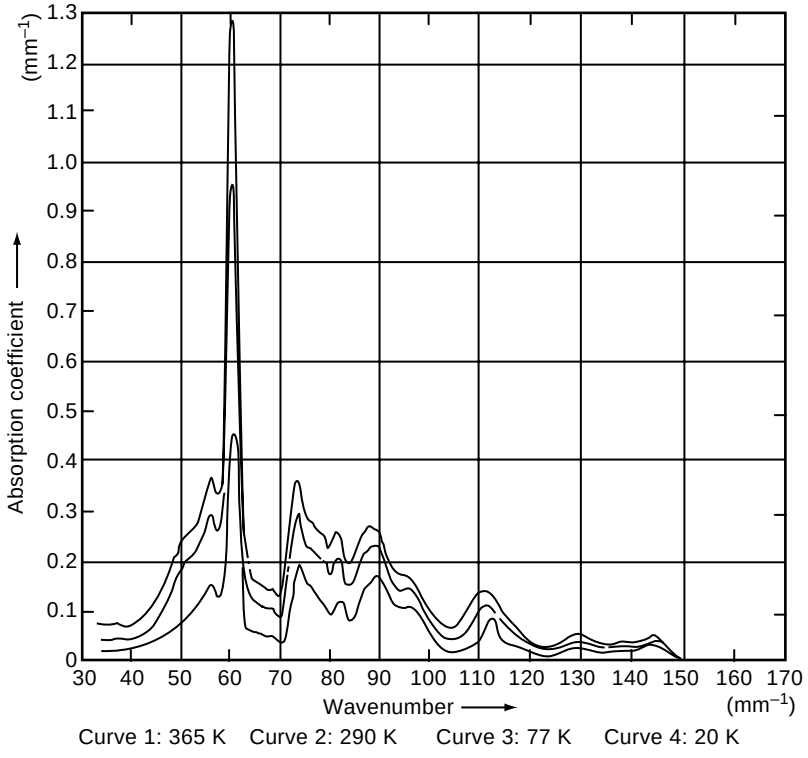

Figure 9 Measured lattice combination bands in a single crystal of silicon at 290 K (top), 77 K (middle), and 20 K (bottom). (Note that 100 mm^{-1} = 1000 cm^{-1}.) Reproduced with permission from Johnson FA (1959) Lattice absorption bands in silicon. *Proceedings of the Physical Society* 73: 265.

electronic applications that require materials with bandgaps not found naturally. Furthermore, a host of low-dimensional structures, such as epilayers, multiple quantum wells (MQWs) and superlattices, are fabricated by molecular beam epitaxy (MBE) or metalorganic vapor phase epitaxy (MOVPE) to create devices that exploit the novel properties which occur when one or more of the physical dimensions are small.

Reflectivity from a bulk single crystal

In the reststrahl frequency range bulk phonon modes cannot propagate and incident radiation is perfectly reflected, i.e., $R = 1$, as shown in the calculated spectrum in Figure 6. Figures 4 and 6 represent the ideal case of a harmonic crystal, in which there is no interaction between the phonon modes, so that all modes have infinite lifetime or, equivalently, spectral features have zero linewidth, corresponding to zero damping. This is close to the behavior of a crystal at absolute zero but, in practice, the phonon modes are coupled, so each mode will decay into combinations of other phonon modes. This leads to finite phonon lifetimes and finite linewidths of all features in the measured spectra. This damping has the effect of

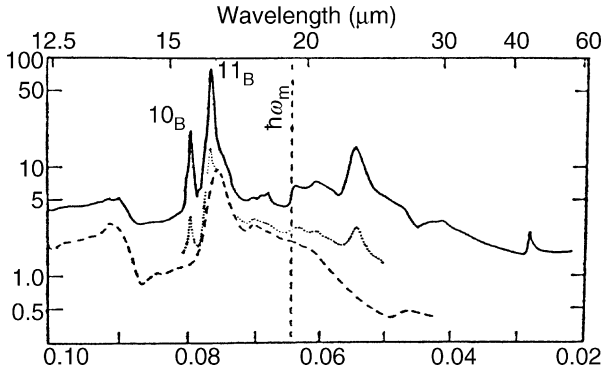

Figure 10 The far-infrared absorption spectrum of Si doped with B ($^{10}B + {}^{11}B$). Reproduced with permission from Angress JF, Goodwin AR and Smith SD (1965) A study of the vibrations of boron and phosphorus in silicon by infrared-red absorption. *Proceedings of the Royal Society A* 287: 64.

rounding off features in the reflectivity compared with Figure 6, and it can be represented analytically by the equation:

$$\varepsilon(\omega) = \varepsilon_\infty + \frac{(\varepsilon(0) - \varepsilon_\infty)\omega_T^2}{\omega_T^2 - \omega^2 - i\gamma\omega} \qquad [15]$$

This differs from eqn [10] only by the addition of the damping coefficient, γ, which takes account in a phenomenological way of the interactions between the phonon modes. Here $\varepsilon(0)$ is the dielectric function at zero frequency, and $\varepsilon(0) - \varepsilon_\infty$ is the oscillator strength (i.e., the dipole strength) of the mode. We shall consider γ again later.

The reflectivity of GaP is shown in Figure 11, and this should be compared with Figure 6. In pure diatomic crystals like the simple ionic solids, e.g., NaCl and KCl, or the binary semiconductors, e.g., GaAs and CdTe, this is the only region of high reflectivity at frequencies below the visible or ultraviolet, and it is often described as the reststrahlen band, from the German term for residual ray.

Reflectivity from mixed crystals of binary semiconductors

The spectra of mixed crystals were discussed above and an example is shown in Figure 12a, which shows the reflection spectra of GaAs, AlAs and five $Ga_{1-x}Al_xAs$ mixed crystals. The TO and LO phonon frequencies were obtained from the spectra using a Kramers–Kronig analysis and classical dispersion theory. Changes in the mode frequencies with composition are interpreted using the so-called random element isodisplacement (REI) model. In Figure 12b, the TO and LO frequencies are plotted versus composition, x, and it can be seen that this system displays typical two-mode behavior, following closely the behavior shown in Figure 7.

Localized vibrational modes due to impurities

LVMs have been widely investigated in binary semiconductors because they offer a useful diagnostic tool for the investigation of impurities. In addition to the identification of isotopic species, high-resolution transmission spectroscopy can be used to determine the sites of the impurity atoms in the lattice. In Figure 13 the LVM absorption band for ^{12}C in GaAs is shown at different resolutions. The ^{12}C atoms are substitutional impurities on the As sites and the different components of the band arise from the different nearest-neighbor isotopic arrangements

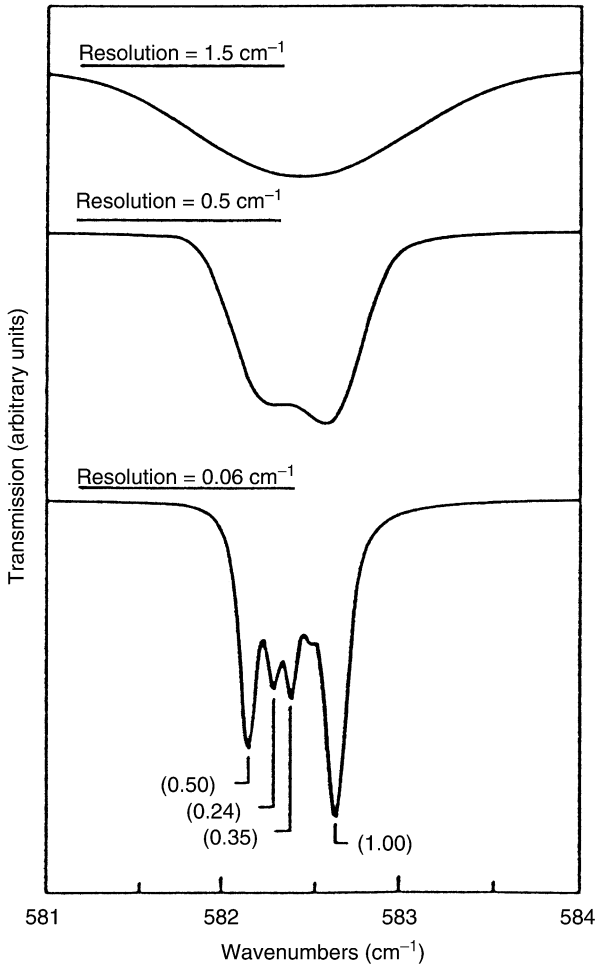

Figure 13 Localized vibrational mode (LVM) absorption band for ^{12}C in GaAs measured at 80 K. The numbers in brackets are estimated band strengths. surrounding the different ^{12}C atoms in the lattice. Note that ^{12}C is much lighter than either of the host lattice atoms, Ga or As, as required theoretically.

Phonon combination bands

Weak features due to the simultaneous excitation of two or more phonons are observed in the spectra of all semiconductors, and there are two excitation mechanisms. The first is direct excitation of two or more phonons by an incident photon via nonlinear terms in the dipole moment. The second process is indirect: the incident photon first excites a zone center TO phonon and the TO phonon then decays into a combination of phonons elsewhere in the Brillouin zone, a process described as anharmonic decay of the TO phonon. Mathematically, it is described by a complex frequency-dependent damping coefficient, $\gamma(\omega)$, in the oscillator equation [15]. Clearly, the latter mechanism is not available in Si and Ge as the TO phonons are not dipole-active. Anharmonicity is very important in strongly ionic crystals like the alkali halides (i.e., group I–VII compounds like NaCl), leading to prominent phonon combination bands, but it becomes progressively less important in semiconductors as the interatomic bonding becomes less ionic and more covalent, which is the case in the sequence through group II–VI (e.g., semiconductors like CdTe or ZnSe), group III–V (e.g., GaAs or InP), and group IV (Ge and Si), which are entirely covalent. Nearly all two-phonon combinations are dipole-active in zinc-blende structure crystals with the result that the transmission spectrum either side of the reststrahlen band is very rich in weak phonon combination bands, as shown in **Figure 14** for GaP and InP.

Layered Semiconductor Structures

Confined optical phonons

Semiconductor superlattices are fabricated for a variety of electronic and optical applications, and the
